## Purpose and Background

Computer engineering is such a vast field that it is difficult and almost impossible to present everything in a single book. This problem is also exaggerated by the fact that the field of computers and computer design has been changing so rapidly that by the time this book is introduced some of the issues may already be obsolete. However, we have tried to capture what is fundamental and therefore will be of lasting value. Also, we tried to capture the trends, new directions, and new developments. This book could easily fill thousands of pages because there are so many issues in computer design and so many new fields that are popping out daily. We hope that in the future CRC Press will come with new editions covering some of the more specialized topics in more details. Given that, and many other limitations, we are aware that some areas were not given sufficient attention and some others were not covered at all. However, we hope that the areas covered are covered very well given that they are written by specialists that are recognized as leading experts in their fields. We are thankful for their valuable time and effort.

## Organization

This book contains a dozen sections. First, we start with the fabrication and technology that has been a driving factor for the electronic industry. No sector of the industry has experienced such tremendous growth. The progress has surpassed what we thought to be possible, and limits that were once thought of as fundamental were broken several times. When the first 256 kbit DRAM chips were introduced the “alpha particle scare” (the problem encountered with alpha particles discharging the memory cell) predicted that radiation effects would limit further scaling in dimensions of memory chips. Twenty years later, we have reached 256 Mbit DRAM chips—a thousand times improvement in density—and we see no limit to further scaling. In fact, the memory capacity has been tripling every two years while the number of transistors on the processor chip has been doubling every two years.

The next section deals with computer architecture and computer system organization, a top-level view. Several architectural concepts and organizations of computer systems are described. The section ends with description of performance evaluation measures, which are the bottom line from the user’s point of view.

Important design techniques are described in two separate sections, one of which deals exclusively with power consumed by the system. Power consumption is becoming the most important issue as computers are starting to penetrate large consumer product markets, and in several cases low-power consumption is more important than the performance that the system can deliver.

Penetration of computer systems into the consumer’s market is described in the sections dealing with signal processing, embedded applications, and future directions in computing.

Finally, reliability and testability of computer systems is described in the last section.

## **Locating Your Topic**

Several avenues are available to access desired information. A complete table of contents is presented at the front of the book. Each of the sections is preceded with an individual table of contents. Finally, each chapter begins with its own table of contents. Each contributed article contains comprehensive references. Some of them contain a “To Probe Further” section where a general discussion of various sources such as books, journals, magazines, and periodicals are discussed. To be in tune with the modern times, some of the authors have also included Web pointers to valuable resources and information. We hope our readers will find this to be appropriate and of much use.

A subject index has been compiled to provide a means of accessing information. It can also be used to locate definitions. The page on which the definition appears for each key defining term is given in the index.

The Computer Engineering Handbook is designed to provide answers to most inquiries and to direct inquirers to further sources and references. We trust that it will meet the needs of our readership.

## **Acknowledgments**

The value of this book is completely based on the work of many experts and their excellent contributions. I am grateful to them. They spent hours of their valuable time without any compensation and with a sole motivation to provide learning material and help enhance the profession. I would like to thank Prof. Saburo Muroga, who provided editorial advice, reviewed the content of the book, made numerous suggestions, and encouraged me to do it. I am indebted to him as well as to other members of the advisory board. I would like to thank my colleague and friend Prof. Richard Dorf for asking me to edit this book and trusting me with this project. Kristen Maus worked tirelessly to put all of this material in a decent shape and so did Nora Konopka of CRC Press. My son, Stanisha, helped me with my English. It is their work that made this book.

**Vojin G. Oklobdzija** is a Fellow of the Institute of Electrical and Electronics Engineers and Distinguished Lecturer of IEEE Solid-State Circuits and IEEE Circuits and Systems Societies. He received his Ph.D. and M.Sc. degrees from the University of California, Los Angeles in 1978 and 1982, as well as a Dipl. Ing. (MScEE) from the Electrical Engineering Department, University of Belgrade, Yugoslavia in 1971.

From 1982 to 1991 he was at the IBM T. J. Watson Research Center in New York where he made contributions to the development of RISC architecture and processors. In the course of this work he obtained a patent on Register-Renaming, which enabled an entire new generation of super-scalar processors.

From 1988–90 he was a visiting faculty at the University of California, Berkeley, while on leave from IBM. Since 1991, Prof. Oklobdzija has held various consulting positions. He was a consultant to Sun Microsystems Laboratories, AT&T Bell Laboratories,

Hitachi Research Laboratories, Silicon Systems/Texas Instruments Inc., and Siemens Corp. where he was principal architect of the Siemens/Infineon's TriCore processor. Currently he serves as an advisor to SONY and Fujitsu Laboratories.

In 1988 he started Integration, which was incorporated in 1996. Integration Corp. delivered several successful processor and encryption processor designs. (see: [www.integration-corp.com](http://www.integration-corp.com))

Prof. Oklobdzija has held various academic appointments, besides the current one at the University of California. In 1991, as a Fulbright professor, he was helping to develop programs at universities in South America. From 1996–98 he taught courses in the Silicon Valley through the University of California, Berkeley Extension, and at Hewlett-Packard.

He holds seven US, four European, one Japanese, and one Taiwanese patents in the area of computer design and seven others currently pending.

Prof. Oklobdzija is a member of the American Association for Advancement of Science, and the American Association of the University Professors. He serves on the editorial boards of the IEEE Transaction of VLSI Systems and the Journal of VLSI Signal Processing. He served on the program committees of the International Conference on Computer Design, the International Symposium on VLSI Technology and Symposium on Computer Arithmetic. In 1997, he was a General Chair of the 13th Symposium on Computer Arithmetic and is serving as a program committee member of the International Solid-State Circuits Conference (ISSCC) since 1996. He has published over 120 papers in the areas of circuits and technology, computer arithmetic and computer architecture, and has given over 100 invited talks and short courses in the USA, Europe, Latin America, Australia, China, and Japan.

### 1.1 Introduction

---

Recently, information technology (IT)—such as Internet, i-mode, cellular phone, and car navigation—has spread very rapidly all over of the world. IT is expected to dramatically raise the efficiency of our society and greatly improve the quality of our life. It should be noted that the progress of IT entirely owes to that of semiconductor technology, especially Silicon LSIs (Large Scale Integrated Circuits). Silicon LSIs provide us high speed/frequency operation of tremendously many functions with low cost, low power, small size, small weight, and high reliability. In these 30 years, the gate length of the metal oxide semiconductor field effect transistors (MOSFETs) has reduced 100 times, the density of DRAM increased 500,000 times, and clock frequency of MPU increased 2,500 times, as shown in [Table 1.1](#). Without such a marvelous progress of LSI technologies, today's great success in information technology would not be realized at all.

The origin of the concept for solid-state circuit can be traced back to the beginning of last century, as shown in [Fig. 1.1](#). It was more than 70 years ago, when J. Lilienfeld using Al/Al<sub>2</sub>O<sub>3</sub>/Cu<sub>2</sub>S as an MOS structure invented a concept of MOSFETs. Then, 54 years ago, first transistor (bipolar) was realized using germanium. In 1960, 2 years after the invention of integrated circuits (IC), the first MOSFET was realized by using the Si substrate and SiO<sub>2</sub> gate insulator [1]. Since then Si and SiO<sub>2</sub> became the key materials for electronic circuits. It takes, however, more than several years until the Silicon MOSFET evolved to Silicon ICs and further grew up to Silicon LSIs. The Silicon LSIs became popular in the market from the beginning of 1970s as a 1 kbit DRAM and a 4 bit MPU (microprocessor). In the early 1970s, LSIs started

by using PMOS technology in which threshold voltage control was easier, but soon the PMOS was replaced by NMOS, which was suitable for high speed operation. It was the middle of 1980s when CMOS became the main stream of Silicon LSI technology because of its capability for low power consumption. Now CMOS technology has realized 512 Mbit DRAMs and 1.7 GHz clock MPUs, and the gate length of MOSFETs in such LSIs becomes as small as 100 nm.

Figure 1.2 shows the cross sections of NMOS LSIs in the early 1970s and those of present CMOS LSIs. The old NMOS LSI technology contains only several film layers made of Si, SiO<sub>2</sub>, and Al, which are basically composed of only five elements: Si, O, Al, B, and P. Now, the structure becomes very complicated, and so many layers and so many elements have been involved.

In the past 30 years, transistors have been miniaturized significantly. Thanks to the miniaturization, the number of components and performance of LSIs have increased significantly. Figures 1.3 and 1.4 show the microphotographs of 1 kbit and 256 Mbit DRAM chips, respectively. Individual tiny rectangle units barely recognized in the 16 large rectangle units of the 256 M DRAM correspond to 64 kbit DRAM. It can be said that the downsizing of the components has driven the tremendous development of LSIs.

Figure 1.5 shows the past and future trends of the downsizing of MOSFET's parameters and LSI chip properties mainly used for high performance MPUs. Future trend was taken from ITRS'99 (International Technology Roadmap for Semiconductors) [2]. In order to maintain the continuous progress of LSIs for future, every parameter has to be shrunk continuously with almost the same rate as before. However, it was anticipated that shrinking the parameters beyond the 0.1  $\mu\text{m}$  generation would face severe difficulties due to various kinds of expected limitations. It was expected that huge effort would be required in research and development level in order to overcome the difficulties.

In this chapter, silicon technology from past to future is reviewed for advanced CMOS LSIs.

# 1.2 Downsizing below 0.1 μm

In digital circuit applications, a MOSFET functions as a switch. Thus, complete cut-off of leakage current in the “off” state, and low resistance or high current drive in the “on” state are required. In addition, small capacitances are required for the switch to rapidly turn on and off. When making the gate length small, even in the “off” state, the space charge region near the drain—the high potential region near the drain—touches the source in a deeper place where the gate bias cannot control the potential, resulting in a leakage current from source to drain via the space charge region, as shown in Fig. 1.6. This is the well-known, short-channel effect of MOSFETs. The short-channel effect is often measured as the threshold voltage reduction of MOSFETs when it is not severe. In order for a MOSFET to work as a component of an LSI, the capability of switching-off or the suppression of the short-channel effects is the first priority in the designing of the MOSFETs. In other words, the suppression of the short-channel effects limits the downsizing of MOSFETs.

In the “on” state, reduction of the gate length is desirable because it decreases the channel resistance of MOSFETs. However, when the channel resistance becomes as small as source and drain resistance, further improvement in the drain current or the MOSFET performance cannot be expected. Moreover, in the short-channel MOSFET design, the source and drain resistance often tends to even increase in order to suppress the short-channel effects. Thus, it is important to consider ways for reducing the total resistance of MOSFETs with keeping the suppression of the short-channel effects. The capacitances of MOSFETs usually decreases with the downsizing, but care should be taken when the fringing portion is dominant or when impurity concentration of the substrate is large in the short-channel transistor design.

Thus, the suppression of the short-channel effects, with the improvement of the total resistance and capacitances, are required for the MOSFET downsizing. In other words, without the improvements of the MOSFET performance, the downsizing becomes almost meaningless even if the short-channel effect is completely suppressed.

To suppress the short-channel effects and thus to secure good switching-off characteristics of MOSFETs, the scaling method was proposed by Dennard et al. [3], where the parameters of MOSFETs are shrunk or increased by the same factor  $K$ , as shown in Figs. 1.7 and 1.8, resulting in the reduction of the space charge region by the same factor  $K$  and suppression of the short-channel effects.

In the scaling method, drain current,  $I_d (= W/L \times V^2/t_{ox})$ , is reduced to  $1/K$ . Even the drain current is reduced to  $1/K$ , the propagation delay time of the circuit reduces to  $1/K$ , because the gate charge reduces to  $1/K^2$ . Thus, scaling is advantageous for high-speed operation of LSI circuits.

If the increase in the number of transistors is kept at  $K^2$ , the power consumption of the LSI—which is calculated as  $1/2fnCV^2$  as shown in Fig. 1.7—stays constant and does not increase with the scaling. Thus, in the ideal scaling, power increase will not occur.

**FIGURE 1.7** Parameters change by ideal scaling.

**FIGURE 1.8** Ideal scaling method.

However, the actual scaling of the parameters has been different from that originally proposed as the ideal scaling, as shown in Table 1.2 and also shown in Fig. 1.5(a). The major difference is the supply voltage reduction. The supply voltage was not reduced in the early phase of LSI generations in order to keep a compatibility with the supply voltage of conventional systems and also in order to obtain higher operation speed under higher electric field. The supply voltage started to decrease from the 0.5  $\mu\text{m}$  generation because the electric field across the gate oxide would have exceeded 4 MV/cm, which had been regarded as the limitation in terms of TDDB (time-dependent break down)—recently the maximum field is going to be raised to high values, and because hot carrier induced degradation for the short-channel MOSFETs would have been above the allowable level; however, now, it is not easy to reduce the

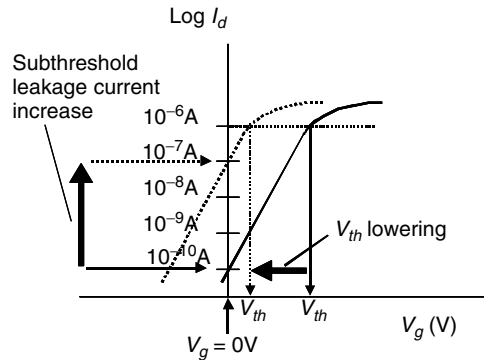

FIGURE 1.9 Subthreshold leakage current at low  $V_{th}$ .

FIGURE 1.10 Scaling limitation factor for Si MOSFET below  $0.1 \mu\text{m}$ .

supply voltage because of difficulties in reducing the threshold voltage of the MOSFETs. Too small threshold voltage leads to significantly large subthreshold leakage current even at the gate voltage of 0 V, as shown in Fig. 1.9. If it had been necessary to reduce the supply voltage of  $0.1 \mu\text{m}$  MOSFETs at the same ratio as the dimension reduction, the supply voltage would have been  $0.08 \text{ V}$  ( $=5 \text{ V}/60$ ) and the threshold voltage would have been  $0.0013 \text{ V}$  ( $=0.8 \text{ V}/60$ ), and thus the scaling method would have been broken down. The voltage higher than that expected from the original scaling is one of the reasons for the increase of the power. Increase of the number of transistors in a chip by more than the factor  $K^2$  is another reason for the power increase. In fact, the transistor size decreases by factor 0.7 and the transistor area decreases by factor 0.5 ( $=0.7 \times 0.7$ ) for every generation, and thus the number of transistors is expected to increase by a factor of 2. In reality, however, the increase cannot wait for the downsizing and the actual increase is by a factor of 4. The insufficient area for obtaining another factor 2 is earned by increasing the chip area by a factor of 1.5 and further by extending the area in the vertical direction introducing multilayer interconnects, double polysilicon, and trench/stack DRAM capacitor cells.

In order to downsizing MOSFETs down to sub- $0.1 \mu\text{m}$ , further modification of the scaling method is required because some of the parameters have already reached their scaling limit in the  $0.1 \mu\text{m}$  generation, as shown in Fig. 1.10. In the  $0.1 \mu\text{m}$  generation, the gate oxide thickness is already below the direct-tunneling leakage limit of 3 nm. The substrate impurity concentration (or the channel impurity concentration) has already reached  $10^{18} \text{ cm}^{-3}$ . If the concentration is further increased, the source-substrate and drain-substrate junctions become highly doped pn junctions and act as tunnel diodes. Thus, the isolation of source and drains with substrate cannot be maintained. The threshold voltage has already

decreased to 0.3–0.25 V and further reduction causes significant increase in subthreshold leakage current. Further reduction of the threshold voltage and thus the further reduction of the supply voltage are difficult.

In 1990s, fortunately, those difficulties were shown to be solved somehow by invention of new techniques, further modification of the scaling, and some new findings for short gate length MOSFET operation. In the following, examples of the solutions for the front end of line are described. In 1993, first successful operation of sub-50 nm n-MOSFETs was reported [4], as shown in Fig. 1.11. In the fabrication of the MOSFETs, 40 nm length gate electrodes were realized by introducing resist-thinning technique using oxygen plasma. In the scaling, substrate (or channel doping) concentration was not increased any more, and the gate oxide thickness was not decreased (because it was not believed that MOSFETs with direct-tunnelling gate leakage operates normally), but instead, decreasing the junction depth more aggressively (in this case) than ordinary scaling was found to be somehow effective to suppress the short-channel effect and thus to obtain good operation of sub-50 nm region. Thus, 10-nm depth S/D junction was realized by introduction of solid-phase diffusion by RTA from PSG gate sidewall. In 1994, it was found that MOSFETs with gate SiO<sub>2</sub> less than 3 nm thick—for example 1.5 nm as shown in Fig. 1.12 [5]—operate quite normally when

the gate length is small. This is because the gate leakage current decreases in proportion with the gate length while the drain current increases in inverse proportion with the gate length. As a result, the gate leakage current can be negligibly small in the normal operation of MOSFETs. The performance of 1.5 nm was record breaking even at low supply voltage.

In 1993, it was proposed that ultrathin-epitaxial layer shown in Fig. 1.13 is very effective to realize super retrograde channel impurity profiles for suppressing the short-channel effects. It was confirmed that 25 nm gate length MOSFETs operate well by using simulation [6]. In 1993 and 1995, epitaxial channel MOSFETs with buried [7] and surface [8] channels, respectively, were fabricated and high drain current drive with excellent suppression of the short-channel effects were experimentally confirmed. In 1995, new raised (or elevated) S/D structure was proposed, as shown in Fig. 1.14 [10]. In the structure, extension portion of the S/D is elevated with self-aligned to the gate electrode by using silicided silicon sidewall. With minimizing the Si<sub>3</sub>N<sub>4</sub> spacer width, the extension S/D resistance was dramatically reduced. In 1991, NiSi silicide was presented for the first time, as shown in Fig. 1.15 [10]. NiSi has several advantages over TiSi<sub>2</sub> and CoSi<sub>2</sub> silicides, especially in use for sub-50 nm regime. Because NiSi is a monosilicide, silicon consumption during the silicidation is small. Silicidation can be accomplished at low temperature. These features are suitable for ultra-shallow junction formation. For NiSi silicide, there

FIGURE 1.15 NiSi Salicide [10].

was no narrow line effect—increase in the sheet resistance in narrow silicide line—and bridging failure by the formation of silicide path on the gate sidewall between the gate and S/D. NiSi-contact resistances to both n<sup>+</sup> and p<sup>+</sup> Si are small. These properties are suitable for reducing the source, drain, and gate resistance for sub-50 nm MOSFETs.

The previous discussion provides examples of possible solutions, which the authors found in the 1990s for sub-50 nm gate length generation. Also, many solutions have been found by others. In any case, with the possible solutions demonstrated for sub-50 nm generation as well as the keen competitions among semiconductor chipmakers for high performance, the downsizing trend or roadmap has been significantly accelerated since late 1990s, as shown in Fig. 1.16. The first roadmap for downsizing was published in 1994 by SIA (Semiconductor Industry Association, USA) as NTRS'94 (National Technology Roadmap for Semiconductors) [11]—at that time, the roadmap was not an international version. On NTRS'94, the clock frequency was expected to stay at 600 MHz in year 2001 and expected to exceed 1 GHz in 2007. However, it has already reached 2.1 GHz for 2001 in ITRS 2000 [12]. In order to realize high clock frequencies, the

gate length reduction was accelerated. In fact, in the NTRS'94, gate length was expected to stay at 180 nm in year 2001 and expected to reach 100 nm only in 2007, but the gate length is 90 nm in 2001 on ITRS 2000, as shown in Fig. 1.16(b).

The real world is much more aggressive. As shown in Fig. 1.16(a), the clock frequency of Intel's MPU already reached 1.7 GHz [12] in April 2001, and its roadmap for gate length reduction is unbelievably aggressive, as shown in Fig. 1.16(b) [13,14]. In the roadmap, 30-nm gate length CMOS MPU with 70-nm node technology is to be sold in the market in year 2005. It is even several years in advance compared with the ITRS 2000 prediction.

With the increase in clock frequency and the decrease in gate length, together with the increase in number of transistors in a chip, the tremendous increase in power consumption becomes the main issue. In order to suppress the power consumption, supply voltage should be reduced aggressively, as shown in Fig. 1.16(c). In order to maintain high performance under the low supply voltage, gate insulator thickness should be reduced very tremendously. On NTRS'94, the gate insulator thickness was not expected to exceed 3 nm throughout the period described in the roadmap, but it is already 1.7 nm in products in 2001 and expected to be 1.0 nm in 2005 on ITRS'99 and 0.8 nm in Intel's roadmap, as shown in Fig. 1.16(d). In terms of total gate leakage current of an entire LSI chip for use for mobile cellular phone, 2 nm is already too thin, in which standby power consumption should be minimized. Thus, high *K* materials, which were assumed to be introduced after year 2010 at the earliest on NTRS'94, are now very seriously investigated in order to replace the SiO<sub>2</sub> and to extend the limitation of gate insulator thinning.

Introduction of new materials is considered not only for the gate insulator, but also almost for every portion of the CMOS structures. More detailed explanations of new technology for future CMOS will be given in the following sections.

### 1.3 Gate Insulator

Figure 1.17 shows gate length ( $L_g$ ) versus gate oxide thickness ( $t_{ox}$ ) published in recent conferences [4,5,14–19]. The *x*-axis in the bottom represents corresponding year of the production to the gate length according to ITRS 2000. The solid curve in the figure is  $L_g$  versus  $t_{ox}$  relation according to the ITRS 2000 [12]. It should be noted that most of the published MOSFETs maintain the scaling relationship between  $L_g$  and  $t_{ox}$  predicted by ITRS 2000. Figures 1.18 and 1.19 are  $V_d$  versus  $L_g$ , and  $I_d$  (or  $I_{on}$ ) versus  $L_g$  curves, respectively obtained from the published data at the conferences. From the data, it can be estimated that MOSFETs will operate quite well with satisfaction of  $I_{on}$  value specified by the roadmap until the generation

FIGURE 1.17 Trend of  $T_{ox}$ .

FIGURE 1.18 Trend of  $V_{dd}$ .

FIGURE 1.19 Trend of drain current.

around  $L_g = 30$  nm. One small concern is that the  $I_{on}$  starts to reduce from  $L_g = 100$  nm and could be smaller than the value specified by the roadmap from  $L_g = 30$  nm. This is due to the increase in the S/D extension resistance in the small gate length MOSFETs. In order to suppress the short-channel effects, the junction depth of S/D extension needs to be reduced aggressively, resulting in high sheet resistance. This should be solved by the raised (or elevated) S/D structures. This effect is more significantly observed in the operation of an 8-nm gate length EJ-MOSFET [20], as shown in Fig. 1.19. In the structure, S/D extension consists of inversion layer created by high positive bias applied on a 2nd gate electrode, which is placed to cover the 8-nm, 1st gate electrode and S/D extension area. Thus, reduction of S/D extension resistance will be another limiting factor of CMOS downsizing, which will come next to the limit in thinning the gate  $\text{SiO}_2$ .

In any case, it seems at this moment that  $\text{SiO}_2$  gate insulator could be used until the sub-1 nm thickness with sufficient MOSFET performance. There was a concern proposed in 1998 that TDDB (Time Dependent Dielectric Breakdown) will limit the  $\text{SiO}_2$  gate insulator reduction at  $t_{ox} = 2.2$  nm [21]; however, recent results suggest that TDDB would be OK until  $t_{ox} = 1.5 - 1.0$  nm [22–25]. Thus,  $\text{SiO}_2$  gate insulator would be used until the 30 nm gate length generation for high-speed MPUs. This is a big change

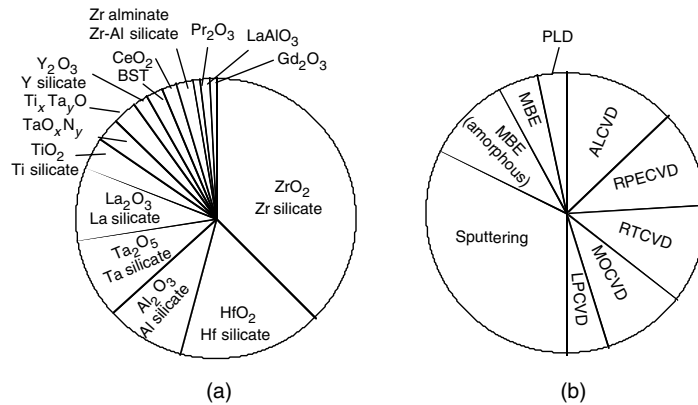

FIGURE 1.21 Recently reported (a) high-k materials and (b) deposition methods.

Among the candidates, ZrO<sub>2</sub> [29–31,34–37] and HfO<sub>2</sub> [28,32,34,36,38–40] become popular because their dielectric constant is relatively high and because ZrO<sub>2</sub> and HfO<sub>2</sub> were believed to be stable at the Si interface. However, in reality, formation and growth of interfacial layer made of silicate (ZrSi<sub>x</sub>O<sub>y</sub>, HfSi<sub>x</sub>O<sub>y</sub>) or SiO<sub>2</sub> at the Si interface during the MOSFET fabrication process has been a serious problem. This interfacial layer acts to reduce the total capacitance and is thought to be undesirable for obtaining high performance of MOSFETs. Ultrathin nitride barrier layer seems to be effective to suppress the interfacial layer formation [37]. There is a report that mobility of MOSFETs with ZrO<sub>2</sub> even with these interfacial layers were significantly degraded by several tens of percent, while with entire Zr silicate gate dielectrics is the same as that of SiO<sub>2</sub> gate film [31]. Thus, there is an argument that the thicker interfacial silicate layer would help the mobility improvement as well as the gate leakage current suppression; however, in other experiment, there is a report that HfO<sub>2</sub> gate oxide MOSFETs mobility was not degraded [38]. For another problem, it was reported that ZrO<sub>2</sub> and HfO<sub>2</sub> easily form micro-crystals during the heat process [31,33].

Comparing with the cases of ZrO<sub>2</sub> and HfO<sub>2</sub>, La<sub>2</sub>O<sub>3</sub> film was reported to have better characteristics at this moment [33]. There was no interfacial silicate layer formed, and mobility was not degraded at all. The dielectric constant was 20–30. Another merit of the La<sub>2</sub>O<sub>3</sub> insulator is that no micro-crystal formation was found in high temperature process of MOSFET fabrication [33]. There is a strong concern for its hygroscopic property, although it was reported that the property was not observed in the paper [33]. However, there is a different paper published [34], in which La<sub>2</sub>O<sub>3</sub> film is reported to very easily form a silicate during the thermal process. Thus, we have to watch the next report of the La<sub>2</sub>O<sub>3</sub> experiments. Crystal Pr<sub>2</sub>O<sub>3</sub> film grown on silicon substrate with epitaxy is reported to have small leakage current [42]. However, it was shown that significant film volume expansion by absorbing the moisture of the air was observed. La and Pr are just two of the 15 elements in lanthanoids series. There might be a possibility that any other lanthanoid oxide has even better characteristics for the gate insulator. Fortunately, the atomic content of the lanthanoids, Zr, and Hf in the earth's crust is much larger than that of Ir, Bi, Sb, In, Hg, Ag, Se, Pt, Te, Ru, Au, as shown in Fig. 1.22.

Al<sub>2</sub>O<sub>3</sub> [41,43] is another candidate, though dielectric constant is around 10. The biggest problem for the Al<sub>2</sub>O<sub>3</sub> is that film thickness dependence of the flatband shift due to the fixed charge is so strong that controllability of the flatband voltage is very difficult. This problem should be solved before it is used for the production. There is a possibility that Zr, Hf, La, and Pr silicates are used for the next generation gate insulator with the sacrifice of the dielectric constant to around 10 [31,35,37]. It was reported that the silicate prevent from the formation of micro-crystals and from the degradation in mobility as described before. Furthermore, there is a possibility that stacked Si<sub>3</sub>N<sub>4</sub> and SiO<sub>2</sub> layers are used for mobile device application. Si<sub>3</sub>N<sub>4</sub> material could be introduced soon even though its dielectric constant is not very high [44–46], because it is relatively mature for use for silicon LSIs.

FIGURE 1.22 Clarke number of elements.

## 1.4 Gate Electrode

Figure 1.23 shows the changes of the gate electrode of MOSFETs. Originally, Al gate was used for the MOSFETs, but soon poly Si gate replaced it because of the adaptability to the high temperature process and to the acid solution cleaning process of MOSFET fabrication. Especially, poly gate formation step can be put before the S/D (source and drain) formation. This enables the easy self-alignment of S/D to the gate electrode as shown in the figure. In the metal gate case, the gate electrode formation should come to the final part of the process to avoid the high temperature and acid processes, and thus self-alignment is difficult. In the case of damascene gate process, the self-alignment is possible, but process becomes complicated as shown in the figure [47]. Refractory metal gate with conventional gate electrode process and structure would be another solution, but RIE (Reactive Ion Etching) of such metals with good selectivity to the gate dielectric film is very difficult at this moment.

As shown in Fig. 1.24, poly Si gate has a big problem of depletion layer formation. This effect would not be ignored when the gate insulator becomes thin. Thus, despite the above difficulties, metal gate is desirable and assumed to be necessary for future CMOS devices. However, there is another difficulty for the introduction of metal gate to CMOS. For advance CMOS, work function of gate electrode should be selected differently for n- and p-MOSFETs to adjust the threshold voltages to the optimum values. Channel doping could shift the threshold voltage, but cannot adjust it to the right value with good control of the short-channel effects. Thus, n<sup>+</sup>-doped poly Si gate is used for NMOS and p<sup>+</sup>-doped poly Si gate is used for PMOS. In the metal gate case, it is assumed that two different metals should be used for N- and PMOS in the same manner as shown in Table 1.3. This makes the process further complicated and makes the device engineer to hesitate to introduce the metal gate. Thus, for the short-range—probably to 70 or 50 nm node, heavily doped poly Si or poly SiGe gate electrode will be used. But in the long range, metal gate should be seriously considered.

# 1.5 Source and Drain

Figure 1.25 shows the changes of S/D (source and drain) formation process and structure. S/D becomes shallower for every new generation in order to suppress the short-channel effects. Before, the extension part of the S/D was called as LDD (Lightly Doped Drain) region and low doping concentration was required in order to suppress electric field at the drain edge and hence to suppress the hot-carrier effect. Structure of the source side becomes symmetrical as the drain side because of process simplicity. Recently, major concern of the S/D formation is how to realize ultra-shallow extension with low resistance. Thus, the doping of the extension should be done as heavily as possible and the activation of the impurity should be as high as possible. Table 1.4 shows the trends of the junction depth and sheet resistance of the extension requested by ITRS 2000. As the generation proceeds, junction depth becomes shallower, but at the same time, the sheet resistance should be reduced. This is extremely difficult. In order to satisfy this request, various doping and activation methods are being investigated. As the doping method, low energy implantation at 2–0.5 keV [48] and plasma doping with low energy [49] are thought to be the most promising at this moment. The problem of the low energy doping is lower retain dose and lower activation rate of the implanted species [48]. As the activation method, high temperature spike lamp anneal [48] is the best way at this moment. In order to suppress the diffusion of the dopant, and to keep the over-saturated activation of the dopant, the spike should be as steep as possible. Laser anneal [50] can realize very high activation, but very high temperature above the melting point at the silicon surface is a concern. Usually laser can anneal only the surface of the doping layer, and thus deeper portion may be necessary to be annealed by the combination of the spike lamp anneal.

**FIGURE 1.26** Elevated source and drain.

In order to further reduce the sheet resistance, elevated S/D structure of the extension is necessary, as shown in Fig. 1.26 [6]. Elevated S/D will be introduced at the latest from the generation of sub-30 nm gate length generation, because sheet resistance of S/D will be the major limiting factor of the device performance in that generation.

Salicide is a very important technique to reduce the resistance of the extrinsic part of S/D—resistance of deep S/D part and contact resistance between S/D and metal. Table 1.5 shows the changes of the salicide/silicide materials. Now CoSi<sub>2</sub> is the material used for the salicide. In future, NiSi is regarded as promising because of its superior nature of smaller silicon consumption at the silicidation reaction [10].

## 1.6 Channel Doping

Channel doping is an important technique not only for adjusting the threshold voltage of MOSFETs but also for suppressing the short-channel effects. As described in the explanation of the scaling method, the doping of the substrate or the doping of the channel region should be increased with the downsizing of the device dimensions; however, too heavily doping into the entire substrate causes several problems, such as too high threshold voltage and too low breakdown voltage of the S/D junctions. Thus, the heavily doping portion should be limited to the place where the suppression of the depletion layer is necessary, as shown in Fig. 1.27. Thus, retrograde doping profile in which only some deep portion is heavily doped is requested. To realize the extremely sharp retrograde profile, undoped-epitaxial-silicon growth on the heavily doped channel region is the most suitable method, as shown in the figure [7–9]. This is called as epitaxial channel technique. The epitaxial channel will be necessary from sub-50 nm gate length generations.

FIGURE 1.28 Interconnect change.

## 1.7 Interconnects

Figure 1.28 shows the changes of interconnect structures and materials. Aluminium has been used for many years as the interconnect metal material, but now it is being replaced by copper with the combination of dual damascene process shown in Fig. 1.29, because of its superior characteristics on the resistivity and electromigration [51,52]. Figure 1.30 shows some problems for the CMP process used for the copper damascene, which is being solved. The major problem for future copper interconnects is the necessity of diffusion barrier layer, as shown in Fig. 1.31. The thickness of the barrier layer will consume major part of the cross-section area of copper interconnects with the reduction of the dimension, because it is very difficult to thin the barrier films less than several nanometers. This leads to significant increase in the resistance of the interconnects. Thus, in 10 years, diffusion-barrier-free copper interconnects process should be developed.

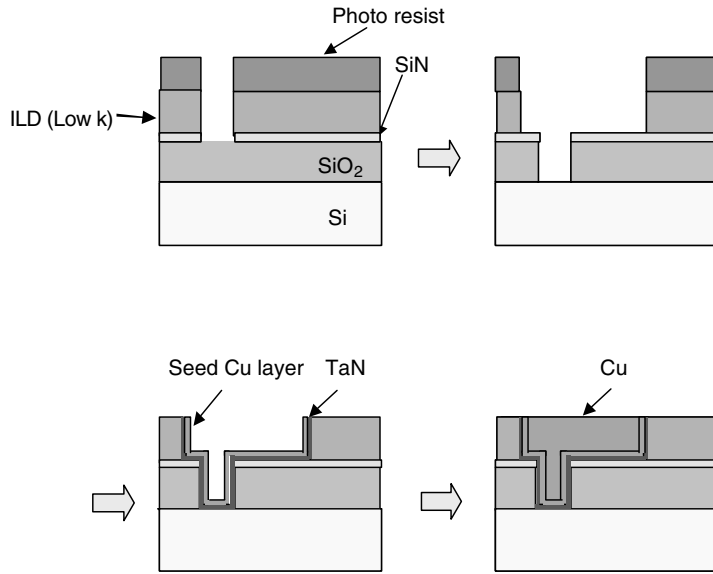

FIGURE 1.29 Dual damascene for Cu.

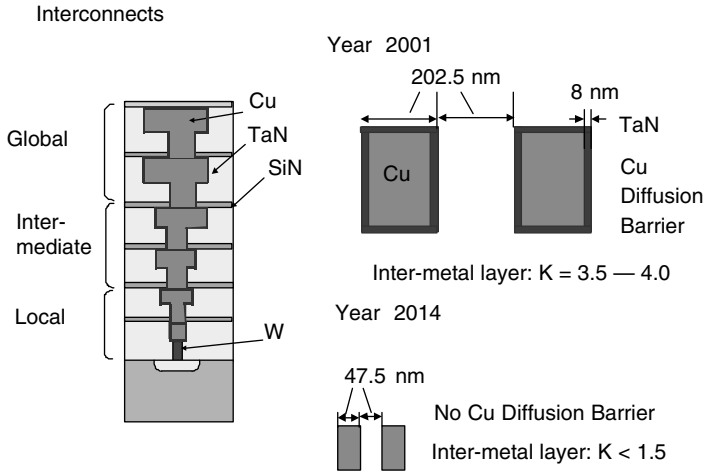

FIGURE 1.30 Dual damascene for Cu.

Reducing the interconnect capacitance is very important for obtaining high-speed circuit operation. Thus, development of low-k inter-deposition layer (IDL) is essential for the future interconnects shown in Table 1.6. Various materials as shown in Table 1.7 are being developed at this moment. Unfortunately, however, only the dielectric constant of 3.2–4.0 has been used for the products. Originally, low-k material with dielectric constant of less than 3.0 was scheduled to be introduced much earlier. However, because of the technological difficulty, the schedule was delayed in ITRS 2000, as shown in Table 1.6.

## 1.8 Memory Technology

Memory device requires some special technologies. Figure 1.32, and Tables 1.8 and 1.9 show the change of DRAM cells. The cell structure becomes too complicated in order to secure the capacitor area in the small dimensions. To solve this problem, new high-k dielectrics and related metal electrode as shown in Table 1.8 have been already developed for production and new materials are also being investigated for future [53]. New dielectric materials are being developed not only for DRAM, but also for other memories such as FERAMs (Ferro-electric RAM) [54].

Although, the structure becomes very complicated, embedded DRAM logic LSIs [55] are attractive and necessary for the SOC (Silicon On a Chip) application. In the future, chip module technology will solve the complexity problem in which different functional chips are made separately and finally assembled on a chip.

## 1.9 Future Prospects

Figures 1.33 and 1.34 show future trends of parameters for 2005 and 2014, respectively, according to the ITRS 2000. Cost of next generation lithography tool is a concern, but it looks that there are solutions for 2005; however, we cannot see obvious solutions for 2014 when gate length becomes 20 nm. Despite the unknown status 10 years from now, the near-term roadmap of high performance LSI makers is too aggressive, as shown in Fig. 1.35. With this tremendously rapid downsizing trend, we might reach the possible downsizing limit in 5 years, as shown in Fig. 1.36. What will happen after that? It should be noted that not all the devices follow the aggressive trends. For example, gate oxide thickness of the mobile devices would not reduce so aggressively. Even using high-k gate insulator, gate leakage current of 1 mA/cm<sup>2</sup> flows through 1 nm (CET) film at  $V_g = 1$  V at this moment, as shown in Fig. 1.37. Thus, rapid pace of the downsizing will not become a merit. According to the device purpose, the pace of the downsizing will

become different and some of the devices will not reach the downsizing limit for a long time. Even if we reach the downsizing limit, we have still many things to do for integration of the devices in multi-chip mode, as shown in Figs. 1.38 and 1.39. For deep twenty-first century, still the device and hardware technology will be important, as shown in Fig. 1.40, and in order to overcome the expected limitations, development of technologies for ultra-small dimensions, for new structures, and for new materials will become important, as shown in Figs. 1.40 and 1.41.

There should be more than several roadmaps  
depending on applications

### Introduction

The term very large scale integration (VLSI) refers to a technology through which it is possible to implement large circuits consisting of up to or more than a million transistors on semiconductor wafers, primarily silicon. Without the help of VLSI technology the advances made in computers and in the Internet would not have been possible. The VLSI technology has been successfully used to build large digital systems such as microprocessors, digital signal processors (DSPs), systolic arrays, large capacity memories, memory controllers, I/O controllers, and interconnection networks. The number of transistors on a chip, depending on the application can range from tens (an op-amp) to hundreds of millions (a large capacity DRAM). The Intel Pentium III microprocessor with 256 kbyte level two cache contains approximately 28 million transistors while the Pentium III microprocessor with a 2 Mbyte level two cache contains 140 million transistors [1]. Circuit designs, where a very large number of transistors are integrated on a single semiconductor die, are termed VLSI designs.

Complementary metal oxide semiconductor (CMOS) VLSI logic circuits can be mainly classified into two main categories: static logic circuits and dynamic logic circuits. Static logic circuits are circuits in which the output of the logic gate is always a logical function of the inputs and always available on the

outputs of the gate regardless of time. A static logic circuit holds its output indefinitely. On the contrary, a dynamic logic circuit produces its output by storing charge in a capacitor. The output thus decays with time unless it is refreshed periodically. Dynamic or clocked logic gates are used to decrease complexity, increase speed, and lower power dissipation. The basic idea behind the dynamic logic is to use the capacitive input of the transistors to store a charge and thus remember a logic level for use later. Logic circuits may also be classified into combinational and sequential logic circuits. Combinational circuits produce outputs which are dependent on inputs only. There is no memory or feedback in the circuit. Circuits with feedback whose outputs depend on the inputs as well as the state of the circuit are called sequential circuits.

The rest of this chapter section is organized as follows. Static CMOS circuits are described, including combinational and sequential circuits in the following subsection. Special circuits, such as Pseudo NMOS logic and pass transistor logic, are also described in the same subsection. Then the next subsection describes dynamic logic circuits. The last subsection describes memory arrays including static RAMs, dynamic RAMs, and ROMs. Section 2.1 concludes with a discussion of VLSI CMOS low power circuits and illustrates a few low power adder circuits. Section 2.1 explains and develops the circuits at the logic level instead of the device level. References [2–10] are excellent sources for detailed analysis.

### The Transistor as a Switch

CMOS logic circuits are made up of n-channel and p-channel metal oxide semiconductor field effect transistors (MOSFETs). The remarkable ability of these transistors to act almost like ideal switches makes CMOS VLSI circuit design practical and interesting. The n-channel MOSFET is often called the NMOS transistor and the p-channel MOSFET is called the PMOS transistor. A PMOS transistor works complementary to an NMOS transistor. Several symbols represent the NMOS and the PMOS transistors. Figure 2.1 shows the simplified circuit symbols of the NMOS and the PMOS transistors. We will assume that a logic 1 (or simply a 1) is a high voltage. In present day VLSI circuit design it could be any value between 1.0 and 5 V. Normally this is equal to the power supply voltage,  $V_{DD}$ , of the circuit. It is also assumed that a logic 0 (or simply a 0) is zero volt or close to zero volt, which is the typical ground potential and often denoted by  $V_{SS}$ . It should be noted that unlike bipolar junction transistors, MOSFETs are symmetrical devices, and the drain and the source terminals can be interchanged. For the NMOS transistor, the terminal where  $V_{DD}$  is connected is the drain, and for the PMOS transistor, the terminal where  $V_{DD}$  is connected is the source. Figure 2.2 illustrates the basic switching action of the NMOS and the PMOS transistors. The NMOS transistor behaves as an open switch when the gate voltage  $S = 0$ , and when the gate voltage  $S = 1$ , the transistor behaves as a closed switch (short circuit). For the PMOS transistor, the complement is true. That is, when  $S = 0$ , the PMOS transistor behaves as a closed switch, and when  $S = 1$ , the transistor behaves as an open switch. The transistor models presented in Fig. 2.2 are a very simplistic approximation, but it is an adequate model to understand the logic level behavior of VLSI circuits. The way the PMOS and NMOS transistors pass the high and low voltages from drain to source or source to drain for the appropriate gate signal is an interesting and peculiar property of these transistors. It has been observed that n-channel passes “0” very well and the p-channel passes “1” very well. Referring to Fig. 2.2, when  $S = 1$ , the NMOS acts like a closed switch, but if we connect  $V_{DD}$  at the node A, at the node B instead of  $V_{DD}$  we will get a voltage slightly less than  $V_{DD}$ , for this reason we call this signal a weak 1. But when  $V_{SS}$  is connected at node A of the NMOS, at node B we get a strong

FIGURE 2.1 Simplified circuit symbols of NMOS and PMOS transistors.

FIGURE 2.2 The basic switching actions of the NMOS and PMOS transistors.

FIGURE 2.3 Series and parallel switch networks using NMOS and PMOS transistors.

ground and we call this signal a strong 0. Again, for the PMOS transistor, the complement is true. For the PMOS, when the gate signal  $S = 0$ , if we connect  $V_{DD}$  at the node  $A$ , we get a strong 1 at node  $B$ , and if we connect  $V_{SS}$  at the node  $A$ , we get a weak 0 at node  $B$ .

The NMOS and PMOS switches can be combined in various ways to produce desired simple and complex logic operations. For example, by connecting  $n$  NMOS or  $n$  PMOS transistors in series, one can realize circuits in which the functionality is true only when all the  $n$  transistors are ON. For instance, in the circuit in Fig. 2.3(a), the nodes  $A$  and  $B$  will get connected only when  $S_1 = S_2 = 1$ . Similarly, in Fig. 2.3(b),  $A$  and  $B$  will get connected only when  $S_1 = S_2 = 0$ . Similarly by connecting  $n$  PMOS or  $n$  NMOS transistors in parallel between two nodes  $A$  and  $B$ , one can realize circuits in which the functionality is true when any one of the  $n$  transistors is ON. For instance, in Fig. 2.3(c), if either  $S_1$  or  $S_2$  is equal to 1, there is a connection between  $A$  and  $B$ . Similarly, in Fig. 2.3(d), if either  $S_1$  or  $S_2$  is equal to 0, there is a connection between  $A$  and  $B$ .

## Static CMOS Circuit Design

### CMOS Combinational Circuits

Any Boolean function, whether simple or complex, depending on the input combinations can have only two possible output values, a logic high or a logic low. Therefore, to construct a logic circuit that realizes a given Boolean function, all that is required is to conditionally connect the output to  $V_{DD}$  for logic high or to  $V_{SS}$  for logic low. Therefore, to construct a logic circuit that realizes a given Boolean function, all that is required is to conditionally connect the output to  $V_{DD}$  for logic high or to  $V_{SS}$  for logic low.

**FIGURE 2.4** The general structure of a CMOS logic circuit.

**FIGURE 2.5** A CMOS inverter: logic symbol, CMOS realization, and the switch level equivalent circuit when the input is equal to 0 and 1.

This is the basic principle behind the realization of CMOS logic circuits. A CMOS logic gate consists of an NMOS pull-down network and a complementary PMOS pull-up network. The NMOS pull-down network is connected between the output and the ground. The PMOS pull-up network is connected between the output and the power supply,  $V_{DD}$ . The inputs go to both the networks. This is schematically illustrated in Fig. 2.4. The number of transistors in each network is equal to the number of inputs. The NMOS pull-down network can be designed using the series and parallel switches illustrated in Fig. 2.3. The PMOS pull-up network is designed as a dual of NMOS pull-down network. That is, parallel components in NMOS network translate into series components in the PMOS network, and series components in NMOS network translate into parallel components in PMOS network. This procedure is elaborated by design examples later in this section.

For a given combination of inputs, when the output is a logic 0, the NMOS network provides a closed path between the output and ground, thereby pulling the output down to ground (logic 0). This is the reason for the name NMOS pull-down network. When the output is a logic 1, for a given combination of inputs, the PMOS network provides a closed path between the output and  $V_{DD}$ , thereby pulling the output up to  $V_{DD}$  (logic 1). This is the reason for the name PMOS pull-up network. For CMOS logic gates for both the outputs (0 and 1), we get strong signals at the output. If the output is a logic high, we get a strong 1 since the output gets connected to  $V_{DD}$  through the PMOS pull-up network, and if the output is a logic low, we get a strong 0 since the output gets connected to  $V_{SS}$  through the NMOS pull-down network. It should be clearly noticed that only one of the networks remains closed at a given time for any combination of the inputs. Therefore, at steady state no dc path exists between  $V_{DD}$  and ground and hence no power dissipation. This is the primary reason for the inherent low power dissipation of CMOS VLSI circuits.

We now illustrate the CMOS realization of inverters, NAND and NOR logic circuits. An inverter is the simplest possible of all the logic gates. An inverter can be constructed by using a PMOS and an NMOS transistor. Figure 2.5 shows the logic symbol, CMOS realization and switch level equivalent circuits of the inverter for both a 0 input and a 1 input. When the input is 0, the NMOS transistor is open (or OFF) and the PMOS transistor is closed (or ON). Since the P switch is closed, the output is pulled high to  $V_{DD}$  (logic 1). When the input is 1, the PMOS transistor is OFF and the NMOS transistor is ON, and the output is pulled down to ground (logic 0), which is the expected result of an inverter circuit.

**FIGURE 2.6** A 2-input CMOS NAND gate and the switch-level equivalent circuits for all the possible input combinations.

**FIGURE 2.7** A 2-input CMOS NOR gate.

A 2-input CMOS NAND gate and the switch level equivalent circuits for all the possible input combinations are shown in Fig. 2.6. This circuit realizes the function  $F = (AB)'$ . The generation of the CMOS circuit has the following steps. For the pull-down network, take the non-inverted expression  $AB$  (called the n-expression) and realize using NMOS transistors. For the pull-up network, find the dual of the n-expression (called the p-expression) and realize using PMOS transistors. In this example the dual is  $A + B$  (p-expression). For the CMOS NAND gate shown in Fig. 2.6, if any of the inputs is a 0, one of the NMOS transistors will be OFF and the pull-down network will be open. At the same time one of the PMOS transistors will be ON and the pull-up network will be closed, and the output will be pulled up to  $V_{DD}$  (logic 1). If all the inputs are high (logic 1), the pull-down network will be closed and the pull-up network will be open and the output will be pulled down to ground (logic 0), which is the desired functionality of a NAND gate.

Figure 2.7 illustrates the CMOS realization of a 2-input NOR gate. In Fig. 2.7, the output value is equal to 0 when either  $A$  or  $B$  is equal to 1 because one of the NMOS transistors will be ON. But if both inputs are equal to 0, the series pair of PMOS transistors between  $V_{DD}$  and the output  $Y$  will be ON, resulting in a 1 at the output, which is the desired functionality of a NOR gate. Figure 2.8 illustrates a 2-input CMOS OR gate realized in two different fashions. In the first method, an inverter is connected to the output of a NOR circuit to obtain an OR circuit. In the second method, we make use of DeMorgan's theorem,  $(A'B) = A + B$ , to realize the OR logic function. It should be noted that the inputs are inverted in the second method. To realize the CMOS AND gate, the same principles can be used.

CMOS compound gates can be realized using a combination of series and parallel switch structures. Figure 2.9 shows the CMOS realization of the logic function  $Y = (ABC + D)'$ . The pull-down network is realized using the n-expression:  $ABC + D$  (the noninverted expression of  $Y$ ). The pull-up network is realized using the dual of the n-expression, which is equal to  $(A + B + C)D$ . In order to further illustrate

FIGURE 2.8 Two different realizations of a 2-input CMOS OR gate.

FIGURE 2.9 CMOS realization of the compound gate  $Y = (ABC + D)'$ .

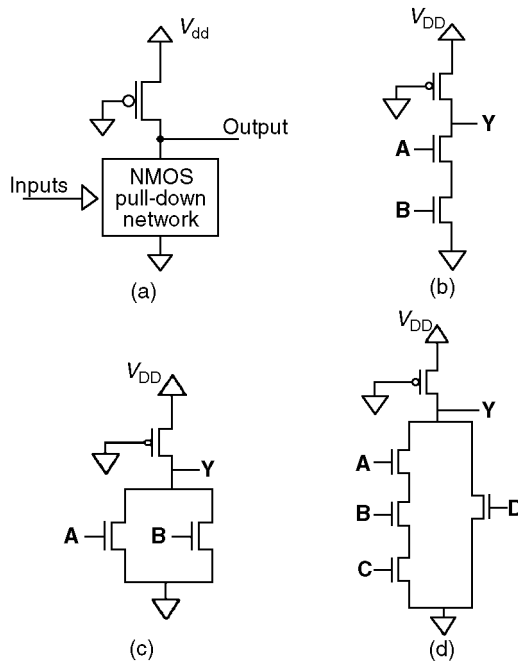

FIGURE 2.10 A CMOS 1-bit full adder.

CMOS designs, we show a full adder design in Fig. 2.10. The two 1-bit inputs are  $A$  and  $B$ , and the carry-in is  $C$ . Two 1-bit outputs are the Sum and the Carry-Out. The outputs can be represented by the equations:  $\text{Sum} = ABC + AB'C' + A'B'C + A'BC'$  and  $\text{Carry-Out} = AB + AC + BC = AB + (A + B)C$  [9]. The implementation of this circuit requires 14 NMOS and 14 PMOS transistors.

### Pseudo-NMOS Logic

Pseudo NMOS is a ratioed logic. That is for the correct operation of the circuit the width-to-length ratios ( $W/L$  s) of the transistors must be carefully chosen. Instead of a combination of active pull-down and pull-up networks, the ratioed logic consists of a pull-down network and a simple load device.

**FIGURE 2.11** (a) The general structure of a Pseudo-NMOS logic; (b) Pseudo-NMOS realization of a 2-input NAND gate; (c) Pseudo-NMOS realization of a 2-input NOR gate; (d) Pseudo-NMOS realization of the logic function  $Y = (ABC + D)'$ .

The pull-down network realizes the logic function and a PMOS with grounded gate presents the load device, as shown in Fig. 2.11(a). The pseudo-NMOS logic style results in a substantial reduction in gate complexity, by reducing the number of transistors required to realize the logic function by almost half. The speed of the pseudo-NMOS circuit is faster than that of static CMOS realization because of smaller parasitic capacitance. One of the main disadvantages of this design style is the increased static power dissipation. This is due to the fact that, at steady state when the output is 0, pseudo-NMOS circuits provide dc current path from  $V_{DD}$  to ground. Figure 2.11(b) shows the realization of a 2-input NAND gate using pseudo-NMOS logic. When the inputs  $A = 0$  and  $B = 0$ , both the transistors in the pull-down network will be OFF and the output will be a logic 1. When  $A = 0$  and  $B = 1$ , or  $A = 1$  and  $B = 0$ , the pull-down network again will be OFF and the output will be logic 1. When  $A = 1$  and  $B = 1$ , both transistors in the pull-down network are ON and the output will be a logic 0, which is the expected result of a NAND gate. Figure 2.11(c) illustrates the pseudo-NMOS realization of a 2-input NOR gate. Another example for the pseudo-NMOS logic realization is given in Fig. 2.11(d). This circuit realizes the function  $Y = (ABC + D)'$ , and the operation of this logic circuitry can also be explained in a manner explained above.

### Pass Transistor/Transmission Gate Logic

In all the circuits we have discussed so far, the outputs are obtained by closing either the pull-up network to  $V_{DD}$  or the pull-down network to ground. The inputs are used essentially to control the condition of the pull-up and the pull-down networks. One may design circuits in which the input signals in addition to  $V_{DD}$  and  $V_{SS}$  are steered to output, depending on the logic function being realized. Pass transistor logic implements a logic gate as a simple switch network. The pass transistor design methodology has the advantage of being simple and fast. Complex CMOS combinational logic functions can be implemented with minimal number of transistors. This results in reduced parasitic capacitance and hence faster circuits. As a pass transistor design example, Fig. 2.12 shows a Boolean function unit realized using

FIGURE 2.12 Multifunction circuitry using pass transistor logic and the function table.

FIGURE 2.14 Transmission gate implementation of XOR gate.

pass transistors [3,7]. In this circuit the output is a function of the inputs  $A$  and  $B$  and the functional inputs  $P_1$ ,  $P_2$ ,  $P_3$ , and  $P_4$ . Depending on the values of  $P_1$ ,  $P_2$ ,  $P_3$ , and  $P_4$ , the  $F$  output is either the NOR, XOR, NAND, AND, or OR of inputs  $A$  and  $B$ . This is summarized in the table in Fig. 2.12.

The simple pass transistor only passes one logic level well, but if we put NMOS and PMOS in parallel we get a simple circuit that passes both logic levels well. This simple circuit is called the transmission gate (TG). The schematic and logic symbol of the transmission gate are shown in Fig. 2.13(a,b). Figure 2.13(c) shows the simplified logic symbol. The CMOS transmission gate operates as a bi-directional switch between nodes  $A$  and  $B$ , which is controlled by  $S$ . The transmission gate requires two control signals. The control signal  $S$  is applied to the NMOS and the complement of the control signal  $S'$  to the PMOS. If the control signal  $S$  is high, both transistors are turned ON providing a low resistance path between  $A$  and  $B$ . If the control signal  $S$  is low, both transistors will be OFF and the path between the nodes  $A$  and  $B$  will be an open circuit.

The transmission gate can be used to realize logic gates and functions. Consider the exclusive-OR (XOR) gate shown in Fig. 2.14 [5]. When both inputs  $A$  and  $B$  are low, the top TG is ON (and the bottom TG is OFF) and its output is connected to  $A$ , which is low (logic 0). If both the inputs are high, the bottom TG is ON (and the top TG is OFF), and its output is connected to  $A'$ , which is also a low (logic 0). If  $A$  is high and  $B$  is low, the top TG is on and the output is connected to  $A$ , which is a high (logic 1). Similarly, if  $A$  is low and  $B$  is high, the bottom TG is on and the output gets connected to  $A'$ , which is a high (logic 1), which is the expected result of a XOR gate. In Fig. 2.14, if we change  $B$  to  $B'$  and  $B'$  to  $B$ , the circuit will realize the exclusive-NOR (XNOR) function. In the next section we will use transmission gates to realize latches and flip-flops.

FIGURE 2.15 A general model of a sequential network.

## Sequential CMOS Logic Circuits

As mentioned earlier, in combinational logic circuits, the outputs are a logic combination of the current input signals. In sequential logic circuits the outputs depend not only on the current values of the inputs, but also on the preceding input values. Therefore, a sequential logic circuit must remember information about its past state. Figure 2.15 shows the schematic of a synchronous sequential logic circuit. The circuit consists of a combinational logic circuit, which accepts inputs  $X$  and  $Y_1$  and produces outputs  $Z$  and  $Y_2$ . The output  $Y_2$  is stored in the memory element as a state variable. The number of bits in the state variable decides the number of available states, and for this reason a sequential circuit is also called a finite state machine. The memory element can be realized using level-triggered latches or edge triggered flip-flops.

For a VLSI circuit designer, a number of different latches and flip-flops are available for the design of the memory element of a sequential circuit. Figure 2.16(a) shows the diagram of a CMOS positive level sensitive  $D$  latch realized using transmission gates and inverters and its switch level equivalent circuits for  $CLK = 0$  and  $CLK = 1$ . It has a data input  $D$  and a clock input  $CLK$ .  $Q$  is the output and the complement of the output  $Q'$  is also available. When  $CLK = 0$ , the transmission gate in the inverter loop will be closed and the transmission gate next to the data input will be open. This establishes a feedback path around the inverter pair and this feedback loop is isolated from the input  $D$  as shown in Fig. 2.16(a). This causes the current value of  $Q$  (and hence  $Q'$ ) to be stored in the inverter loop. When the clock input  $CLK = 1$ , the transmission gate in the inverter loop will be open and the transmission gate close to the input will be closed, as shown in Fig. 2.16(a). Now the output  $Q = D$ , and the data is accepted continuously. That is, any change at the input is reflected at the output after a nominal delay. By inverting the clocking signals to the transmission gates a negative level sensitive latch can be realized.

A negative level sensitive latch and a positive level sensitive latch may be combined to form an edge triggered flip-flop. Figure 2.16(b) shows the circuit diagram of a CMOS positive edge triggered  $D$  flip-flop. The first latch, which is the negative level sensitive latch, is called the master and the second latch (positive level sensitive latch) is called the slave. The electrical equivalent circuits for the CMOS positive edge triggered  $D$  flip-flop for  $CLK = 0$  and for  $CLK = 1$  are also shown in Fig. 2.16(b). When  $CLK = 0$ , both latches will be isolated from each other and the slave latch holds the previous value, and the master latch (negative level sensitive latch) follows the input ( $Q_m = D'$ ). When  $CLK$  changes from 0 to 1, the transmission gate closest to data  $D$  will become open and the master latch forms a closed loop and holds the value of  $D$  at the time of clock transition from 0 to 1. The slave latch feedback loop is now open, and it is now connected to the master latch through a transmission gate. Now the open slave latch passes the value held by the master ( $Q_m = D'$ ) to the output. The output  $Q = Q'_m$ , which is the value of the input  $D$  at the time of the clock transmission from 0 to 1. Since the master is disconnected from the data input  $D$ , the input  $D$  cannot affect the output. When the clock signal changes from 1 to 0, the slave forms a feedback loop, saving the value of the master and the open master starts to sampling and following the input data  $D$  again. But, as is evident from the Fig. 2.16(b), this will not affect the output. Together with RAM and ROM, which are explained in the section on Memory Circuits, these structures form the basis of most CMOS storage elements and are also used as the memory element in the design of sequential circuits. Figure 2.16(c) shows the CMOS realization of the positive edge triggered  $D$  flip-flop, including the transistors required for generating the  $CLK'$  signal—18 transistors are required for its implementation.

## Dynamic Logic Circuits

The basic idea behind the dynamic logic is to use the capacitive input of the MOSFET to store a charge and thus remember a logic level for later use. The output decays with time unless it is refreshed periodically since it is stored in a capacitor. Dynamic logic gates, which are also known as clocked logic gates, are used to decrease complexity, increase speed, and lower power dissipation.

Figure 2.17 shows the basic structure of a dynamic CMOS logic circuit. The dynamic logic design eliminates one of the switch networks from a complementary logic circuit, thus reducing the number of transistors required to realize a logic function by almost 50%. The operation of a dynamic circuit has two phases: a precharge phase and an evaluation phase depending on the state of the clock signal. When clock  $CLK = 0$ , the PMOS transistor in the circuit is turned ON and the NMOS transistor in the circuit is turned OFF, and the load capacitance is charged to  $V_{DD}$ . This is called the precharge phase. The precharge phase should be long enough for the load capacitance to completely charge to  $V_{DD}$ . During the precharge phase, since the NMOS transistor is turned OFF, no conducting path exists between  $V_{DD}$  and ground, thus eliminating static current. The precharging phase ends and the evaluation phase begins when the clock  $CLK$  turns 1. Now the PMOS transistor is turned OFF and the NMOS transistor is turned ON. Depending on the values of the inputs and the composition of the pull-down network, a conditional path may exist between the output and the ground. If such a path exists, the capacitor discharges and logic low output

**FIGURE 2.17** Basic structure of a dynamic CMOS logic circuitry.

**FIGURE 2.18** Dynamic logic implementation of (a) 2-input NAND gate, (b) 2-input NOR gate, and (c) the logic function  $Y = (ABC + D)'$ .

is obtained. If no such path exists between the output and the ground, the capacitor retains its value and a logic high output is obtained. In the evaluate phase, since the PMOS transistor is turned OFF, no path exists between  $V_{DD}$  and ground, thus eliminating the static current during that phase also.

Figure 2.18(a) shows the realization of the 2-input NAND gate using dynamic logic. During the precharge phase ( $CLK = 0$ ), the NMOS transistor is OFF and the PMOS transistor is ON, and the capacitor is precharged to logic 1. During the evaluate phase, if the inputs  $A$  and  $B$  are both equal to 0, both the

transistors in the pull-down network will be OFF, and the output goes into high impedance state and holds the precharged value of logic 1. When  $A = 0$  and  $B = 1$ , or  $A = 1$  and  $B = 0$ , the pull-down network again will be OFF and the output holds the precharged value of logic 1. When  $A = 1$  and  $B = 1$ , both transistors in the pull-down network are ON, and the load capacitor discharges through the low resistance path provided by the NMOS pull-down network, and the output will be a logic 0, which is the expected result of a NAND gate. It should be noted that once the capacitor discharges, it cannot be charged until the next precharge phase. Figure 2.18(b) illustrates the dynamic logic implementation of a 2-input NOR gate. Another example for the dynamic logic realization is given in Fig. 2.18(c). This circuit realizes the function  $Y = (ABC + D)'$ , and the operation of this dynamic logic circuitry can also be explained in a manner explained earlier.

### Memory Circuits

Semiconductor memory arrays are widely used in many VLSI subsystems, including microprocessors and other digital systems. More than half of the real estate in many state-of-the-art microprocessors is devoted to cache memories, which are essentially memory arrays. Memory circuits belong to different categories; some memories are volatile, i.e., they lose their information when power is switched off, whereas some memories are nonvolatile. Similarly, some memory circuits allow modification of information, whereas some only allow reading of prewritten information. As shown in Fig. 2.19, memories may be classified into two main categories, Read/Write Memories (RWMs) or Read Only Memories (ROMs). Read/Write Memories or memory circuits that allow reading (retrieving) and writing (modification) of information are more popularly referred to as Random Access Memories or RAMs. (Historically, RAMs were referred to by that name to contrast with non-semiconductor memories such as disks which allow only sequential access. Actually, ROMs also allow random access in the way RAMs do; however, they should not be called RAMs. The advent of new RAM chips such as page mode DRAMs and cached DRAMs have rendered RAMs to be strictly not random access memories because latency for random access to any location is not uniform any more.)

In contrast to RAMs, ROMs are nonvolatile, i.e., the data stored in them is not lost when power supply is turned off. The contents of the simple ROM cannot be modified. Some ROMs allow erasing and rewriting of the information (typically, the entire information in the whole chip is erased). The ROMs, which are programmed in the factory and are not reprogrammable anymore, are called mask-programmed ROMs, whereas programmable ROMs (PROMs) allow limited reprogramming, and erasable PROMs (EPROMs), electrically erasable PROMs (EEPROMs), and FLASH memories allow erasing and rewriting of the information in the chip. EPROMs allow erasure of the information using ultraviolet light, whereas EEPROMs and FLASH memories allow erasure by electrical means.

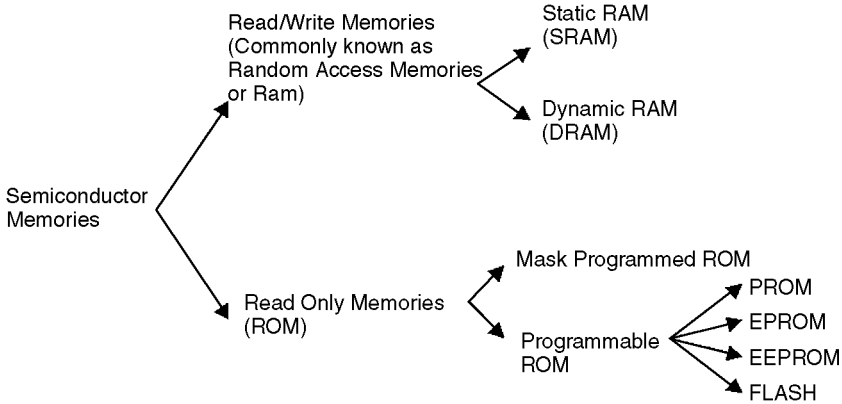

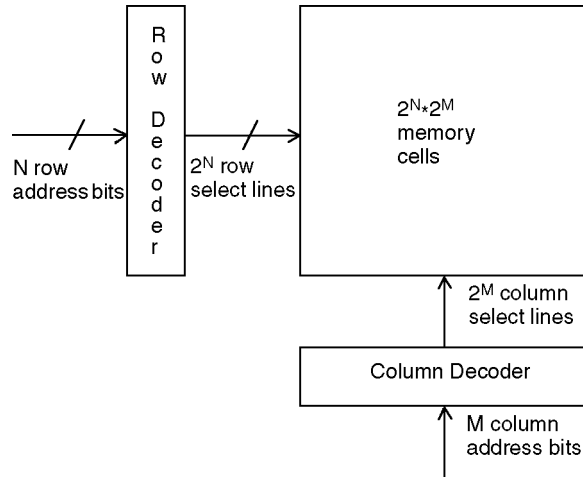

FIGURE 2.19 Different types of semiconductor memories.

**FIGURE 2.20** Typical memory array organization.

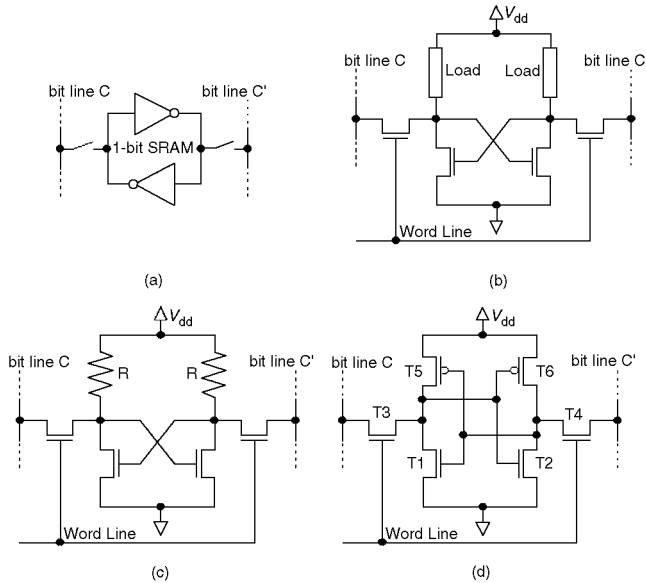

Memory chips are typically organized in the form of a matrix of memory cells. For instance, a 32-kbit memory chip can be organized as 256 rows of 128 cells each. Each cell is capable of storing one bit of binary information, a 0 or a 1. Each cell needs two connections to be selected, a row select signal and a column select signal. All the cells in a row are connected to the same row select signal (also called word-line) and all the cells in a column are connected to the same column select signal (also called bit-line). Only cells that get both the row and column selects activated will get selected. [Figure 2.20](#) shows the structure of a typical memory cell array. A 32-kbit memory chip will have 15 address lines, and if the chip is organized as 256 rows or 128 cells, 8 address lines will be connected to the row address decoder and 7 address lines will be connected to the column address decoder.

### Static RAM Circuits

Static RAMs are static memory circuits in the sense that information can be held indefinitely as long as power supply is on, which is in contrast to DRAMs which need periodic refreshing. A static RAM cell basically consists of a pair of cross-coupled inverters, as shown in [Fig. 2.21\(a\)](#). The cross-coupled latch has two possible stable states, which will be interpreted as the two possible values one wants to store in the cell, the “0” and the “1”. To read and write the data contained in the cell, some switches are required. Because the two inverters are cross-coupled, the outputs of the two transistors are complementary to each other. Both outputs are brought out as bit line and complementary bit line. Hence, a pair of switches are provided between the 1-bit cell and the complementary bit lines. [Figure 2.21\(b\)](#) illustrates the structure of a generic MOS static RAM cell, with the two cross-coupled transistors storing the actual data, the two transistors connected to the word line and bit-lines acting as the access switches and two generic loads, which may be active or passive. [Figure 2.21\(c\)](#) illustrates a case where the loads are resistive, whereas [Fig. 2.21\(d\)](#) illustrates the case where the loads are PMOS transistors. A resistive load can be realized using undoped polysilicon. Such a resistive load yields compact cell size and is suitable for high density memory arrays; however, one cannot obtain good noise rejection properties and good energy dissipation properties for passive loads. Low values of the load resistor results in better noise margins and output pull-up times; however, high values of the resistor is better to reduce the amount of standby current drawn by each memory cell. The load can also be realized using an active device, which is the approach in the 6-transistor cell in [Fig. 2.21\(d\)](#). This 6-transistor configuration, often called the full CMOS SRAM, has desirable properties of low power dissipation, high switching speed, and good noise margins. The only disadvantage is that it consumes more area than the cell with the resistive load.

**TABLE 2.1**

Desired Action	WB	WB'	Operation
WRITE 1	0	1	WT1 OFF, WT2 ON, forcing $C'$ low
WRITE 0	1	0	WT1 ON, WT2 OFF, forcing $C$ low
Do not write	0	0	WT1 and WT2 OFF, forcing $C$ and $C'$ to be high

**FIGURE 2.21** Different configurations of the SRAM cell: (a) basic two-inverter latch, (b) generic SRAM cell topology, (c) SRAM cell with resistive load, (d) the 6-transistor CMOS SRAM cell.

In Fig. 2.21(d), the cross-coupled latch formed by transistors T1 and T2 forms the core of the SRAM cell. This transistor pair can be in one of two stable states, with either T1 in the ON state or T2 in the ON state. These two stable states form the one-bit information that one can store in this transistor pair. When T1 is ON (conducting), and T2 is OFF, a “0” is considered to be stored in the cell. When a “1” is stored, T2 will be conducting and T1 will be OFF. The transistors T3 and T4 are used to perform the read and write operations. These transistors are turned ON only when the word line is activated (selected). When the word line is not selected, the two pass transistors T3 and T4 are OFF and the latch formed by T1 and T2 simply “holds” the bit it contains. Once the memory cell is selected by using the word line, one can perform read and write operations on the cell. In order to write a “1” into the cell, the bit line  $C'$  must be forced to logic low, which will turn off transistor T1, which leads to a high voltage level at T1’s drain, which turns T2 ON and the voltage level at T2’s drain goes low. In order to write a “0”, voltage level at bit line  $C$  is forced low, forcing T2 to turn off and T1 to turn ON. To accomplish forcing the bit-lines to logic low, a write circuitry has to be used. Figure 2.22 illustrates a static RAM cell complete with read and write circuitry [6]. The write circuitry consists of transistors WT1 and WT2 that are used to force  $C$  or  $C'$  to low-voltage appropriately (Table 2.1). Typically, two NOR gates are used to generate the appropriate gate signals for the transistors WT1 and WT2 (not shown in Fig. 2.22).

The read circuitry is also illustrated in Fig. 2.22. In order to read values contained in a cell, the cell is selected using the word select line. Both transistors T3 and T4 are ON, and one of either T1 or T2 is ON. If T1 is ON, as soon as the row select signal is applied, the voltage level on bit line  $C$  drops slightly because it is pulled down by T1 and T3. The data read circuitry detects the small voltage difference between the  $C$  and  $C'$  lines ( $C'$  is higher) and amplifies it as a logic “0” output. If T2 is ON, as soon as

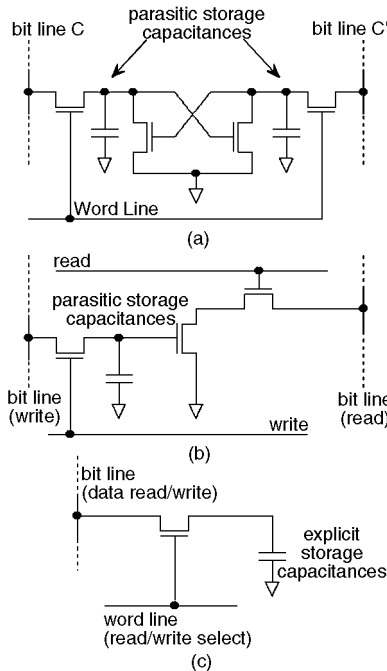

FIGURE 2.22 CMOS SRAM cell with read amplifier and data write circuitry [6].

the row select signal is applied, the voltage level on complementary bit line  $C'$  drops slightly because it is pulled down by T2 and T4. The data read circuitry detects the small voltage difference between  $C$  and  $C'$  lines ( $C$  is higher) and amplifies it as logic “1” output. The data read circuitry can be constructed as a simple source-coupled differential amplifier or as a differential current-mirror sense amplifier circuit (as indicated in Fig. 2.22). The current-mirror sense amplifier achieves a faster read time than the simple source-coupled read amplifier. The read access speed can be further improved by two- or three-stage current mirror differential sense amplifiers [6].

### Dynamic RAM Circuits

All RAMs lose their contents when power supply is turned off. However, some RAMs gradually lose the information even if power is not turned off, because the information is held in a capacitor. Those RAMs need periodic refreshing of information in order to retain the data. They are called dynamic RAMs or DRAMs.

Static RAM cells require 4–6 transistors per cell and need 4–5 lines connecting to each cell including power, ground, bit lines, and word lines. It is desirable to realize memory cells with fewer transistors and less area, in order to construct high density RAM arrays. The early steps in this direction were to create a 4-transistor cell as in Fig. 2.23(a) by removing the load devices of the 6-transistor SRAM cell. The data is stored in a cross-coupled transistor pair as in the SRAM cells we discussed earlier. But it should be noted that voltage from the storage node is continuously being lost due to parasitic capacitance, and there is no current path from a power supply to the storage node to restore the charge lost due to leakage. Hence, the cell must be refreshed periodically. This 4-transistor cell has some marginal area advantage over the 6-transistor SRAM cell, but not any significant advantage. An improvement over the 4-transistor DRAM cell is the 3-transistor DRAM cell shown in Fig. 2.23(b). Instead of using a cross-coupled transistor pair, this cell uses a single transistor as the storage device. The transistor is turned ON or OFF depending

**FIGURE 2.23** Different configurations of a DRAM cell: (a) 4-transistor DRAM cell, (b) 3-transistor DRAM cell, (c) 1-transistor DRAM cell.

on the charge stored on its gate capacitance. Two more transistors are contained in each cell, one used as read access switch and the other used as write access switch. This cell is faster than the 4-transistor DRAM cell; however, every cell needs two control and two I/O (bit) lines making the area advantage insignificant.

The widely popular DRAM cell is the single transistor DRAM cell shown in Fig. 2.23(c). It stores data as charge in an explicit capacitor. There is also one transistor which is used as the access switch. This structure consumes significantly less area than a static RAM cell. The cell has one control line (word line) and one data line (bit line). The cells can be selected using the word line, and the charge in the capacitor can be modified using the bit line.

### Read Only Memories (ROMs)

ROM arrays are simple memory circuits, significantly simpler than the RAMs, which we discussed in the preceding section. A ROM can be viewed as a simple combinational circuit, which produces a specified output value for each input combination. Each input combination corresponds to a unique address or location. Storing binary information at a particular address can be achieved by the presence or absence of a connection from the selected row to the selected column. The presence or absence of the connection can be implemented by a transistor. Figure 2.24 illustrates a  $4 \times 4$  memory array. At any time, only one word line among A1, A2, A3, and A4 is selected by the ROM decoder. If an active transistor exists at the cross point of the selected row and a data line (D1, D2, D3, and D4), the data line is pulled low by that transistor. If no active transistor exists at the cross point, the data line stays high because of the PMOS load device. Thus, absence of an active transistor indicates a “1” whereas the presence of an active transistor indicates a “0”.

ROMs are most effectively used in devices, which need a set of fixed values for operation. The set of values are predetermined before fabrication and a transistor is made only at those cross-points where one is desired. If the information that is to be stored in the ROM is not known prior to fabrication, a transistor is made at every cross-point. The resulting chip is a write-once ROM. The ROM is programmed

FIGURE 2.24 Read only memory (ROM) circuit.

by cutting the connection between the drain of the MOSFET and the column (bit) line. ROMs are effective in applications where large volumes are required.

### Low-Power CMOS Circuit Design

The increasing importance and growing popularity of mobile computing and communications systems have made power consumption a critical design parameter in VLSI circuits and systems. The design of portable devices requires consideration of the peak power for reliability and proper circuit operation, but more critical is the time-averaged power consumption to operate the circuits for a given amount of time to perform a certain task [11,12]. There are four sources of power dissipation in digital CMOS VLSI circuits, which are summarized in the following equation:

$$\begin{aligned}
 P_{\text{avg}} &= P_{\text{switching}} + P_{\text{short-circuit}} + P_{\text{leakage}} + P_{\text{static}} \\
 &= C_L V V_{\text{DD}} f + I_{\text{sc}} V_{\text{DD}} + I_{\text{leakage}} V_{\text{DD}} + I_{\text{static}} V_{\text{DD}} \\
 &= C_L V^2 f + I_{\text{sc}} V_{\text{DD}} + I_{\text{leakage}} V_{\text{DD}} + I_{\text{static}} V_{\text{DD}}
 \end{aligned}$$

where

- $P_{\text{avg}}$  = time-averaged power
- $P_{\text{switching}}$  = switching component of power
- $P_{\text{short-circuit}}$  = short circuit power dissipation
- $P_{\text{leakage}}$  = leakage power
- $P_{\text{static}}$  = static power
- $C_L$  = load capacitance
- $V$  = voltage swing (and in most cases this will be the same as the supply voltage  $V_{\text{DD}}$ )
- $f$  = clock frequency
- $I_{\text{sc}}$  = short-circuit current
- $I_{\text{leakage}}$  = leakage current
- $I_{\text{static}}$  = static current

In some literature, the authors like to group  $P_{\text{leakage}}$  and  $P_{\text{static}}$  together and call it as the static component of power.

The switching component of the power occurs when energy is drawn from the power supply to charge parasitic capacitors made up of gate, diffusion, and interconnect capacitance. For properly designed circuits, the switching component will contribute more than 90% of the power consumption, making it the primary target for power reduction [12]. A system level approach, which involves optimizing algorithms, architectures, logic design, circuit design, and physical design, can be used to minimize power. The physical capacitance can be minimized through choice of substrate, layout optimization, device sizing, and choice of logic styles. The choice of supply voltage has the greatest impact on the power-delay product, which is the amount of energy required to perform a given function. From the expression for the switching component of power ( $P_{\text{switching}} = C_L V^2 f$ ), it is clear that if the supply voltage is reduced, the power delay-product will improve quadratically. Unfortunately, a reduction in supply voltage is associated with a reduction in circuit speed. However, if the goal is to increase the MIPS/Watt in general purpose computing for a fixed level, then various architectural schemes can be used for voltage reduction.

The short-circuit power dissipation,  $P_{\text{short-circuit}}$ , is due to short-circuit current,  $I_{\text{sc}}$ . Finite rise and fall time of the input waveforms result in a direct current path between supply voltage  $V_{\text{DD}}$  and ground, which exists for a short period of time during switching. Such a path never exists in dynamic circuits, as precharge and evaluate transistors should never be ON simultaneously, as this would lead to incorrect evaluation. Short-circuit currents are, therefore, a problem encountered only in static designs. Through proper choices of transistor sizes, the short-circuit component of power dissipation can be kept to less than 10%.

Leakage power,  $P_{\text{leakage}}$ , is due to the leakage current,  $I_{\text{leakage}}$ . Two types of leakage currents seen through in CMOS VLSI circuits: reverse biased diode leakage current at the transistor drain, and the subthreshold leakage current through the channel of an “OFF” device. The magnitude of these leakage currents is set predominantly by the processing technology. The sub-threshold leakage occurs due to carrier diffusion between the source and the drain when the gate-source voltage,  $V_{\text{gs}}$ , has exceeded the weak inversion point, but still below the threshold voltage  $V_t$ . In this regime, the MOSFET behaves almost like a bipolar transistor, and the subthreshold current is exponentially dependent on  $V_{\text{gs}}$ . At present  $P_{\text{leakage}}$  is a small percentage of total power dissipation, but as the transistor size becomes smaller and smaller and the number of transistors that can be integrated into a single silicon die increases, this component of power dissipation is expected to become more significant.

Static power,  $P_{\text{static}}$ , is due to constant static current,  $I_{\text{static}}$ , from  $V_{\text{DD}}$  to ground when the circuit is not switching. As we have seen earlier, complementary CMOS combines pull-up and pull-down networks and only one of them is ON at any given time. Therefore, in true complementary CMOS design, there is no static power dissipation. There are times when deviations from the CMOS design style are necessary. For example in special circuits such as ROMs or register files, it may be useful to use pseudo NMOS logic circuit due to its area efficiency. In such a circuit under certain output conditions there is a constant static current flow,  $I_{\text{static}}$ , from  $V_{\text{DD}}$  to ground, which dissipates power.

The power reduction techniques at the circuit level are quite limited when compared with the other techniques at higher abstraction levels. At the circuit level, percentage power reduction in the teens is considered good [11]; however, low-power circuit techniques can have major impact because some circuits are repeated several times to complete the design. For example, adders are one of the most often used arithmetic circuits in digital systems. Adders are used to perform subtraction, multiplication, and division operations. Reducing power consumption in adders will result in reduced power consumption of many digital systems. Various different types of adders have different speeds, areas, power dissipations, and configurations available for the VLSI circuit designer. Adders or subsystems consisting of adder circuits are often in the critical path of microcomputers and digital signal processing circuit; thus a lot of effort has been spent on optimizing them. As shown in Fig. 2.10, the straight forward realization of a CMOS full adder will require 28 transistors. This adder is not optimized for power dissipation. Recently, there has been tremendous research effort in the design and characterization of low-power adders. The 14-transistor (14T) full adder proposed by Abu Shama et al. [13], dual value

logic (DVL) full adder techniques outlined by Oklobdzija et al. [14], and the static energy recovery full (SERF) adder proposed by Shalem et al. [15,16] are examples of power optimized full adder circuits. More often optimization of one parameter involves the sacrificing of some other parameters. The 14T adder shown in Fig. 2.25, DVL adder shown in Fig. 2.26, and SERF adder shown in Fig. 2.27 are power efficient adders, which also have good delay characteristics [15,16]. Power, area, and delay characteristics of various different low power adder topologies are compared and presented by Shalem et al. [15,16].

## Concluding Remarks

The feature size in the Intel Pentium III microprocessor is  $0.18\ \mu\text{m}$ . Chips with feature size  $0.13\ \mu\text{m}$  are emerging as this chapter section is published. Several hundreds of millions of transistors are being integrated into the same chip. Excellent design automation tools are required in order to handle these large-scale designs. Although automatic synthesis of circuits has improved significantly in the past few years, careful custom hand-designs are done in many high-performance and low-power integrated circuits. Gallium Arsenide (GaAs) and other compound semiconductor-based circuits have been used for very high-speed systems, but the bulk of the circuits will continue to be in silicon, until efficient and high-yield integration techniques can be developed for such technologies.

## 2.2 Pass-Transistor CMOS Circuits

### Introduction

Complementary metal oxide semiconductor (CMOS) logic circuits are widely used in today's very large scale integration (VLSI) chips. The CMOS circuit performs logic functions through complementary switching of nMOS and pMOS transistors according to their gate voltage, which is controlled by the input signal values "1" or "0". Here, "1" corresponds to a high voltage, namely  $V_{\text{dd}}$  in the circuit, and "0" corresponds to a low voltage, Gnd. For example, in the case of the inverter shown in [Fig. 2.28\(a\)](#), when input is set to "0", the pMOS transistor becomes conductive and the nMOS transistor becomes nonconductive, so the capacitance  $C_{\text{out}}$  is charged and the output is pulled up to  $V_{\text{dd}}$ , resulting in a logic value of "1". Here,  $C_{\text{out}}$  is the input capacitance of the circuit in the next stage, the wiring capacitance, or the parasitic

FIGURE 2.28 Comparison of CMOS logic with PTL.

FIGURE 2.29 Comparison for 2-input XOR logic.

capacitance, and so on. On the other hand, when “1” is input, the nMOS transistor becomes conductive and the pMOS transistor becomes nonconductive in turn.  $C_{out}$  is then discharged, and the output is pulled down to Gnd. Thus, “0” is output, and inverter operation is achieved. As shown here, in the CMOS circuit nMOS and pMOS transistors complementarily perform the pull-up and pull-down operations, respectively. This complementary operation allows the logic signal to swing fully from  $V_{dd}$  to Gnd, resulting in a high noise margin. As a result, CMOS circuits are widely used in VLSI chips, such as microprocessors.

As an alternative to CMOS logic, pass-transistor logic (PTL) has recently been getting much attention. This is because well-constructed PTL can provide a logic circuit with fewer transistors than the corresponding CMOS logic circuit. In the PTL circuit, one nMOS transistor can perform both the pull-up and pull-down operations by utilizing not only the gate but also the drain/source as signal terminals, as shown in Fig. 2.28(b) [1]. Here, the signal connected to the gate of the transistor ( $B$  in this figure) is called the control signal, and the signal connected to the drain/source ( $A$  in this figure) is called the pass signal. In PTL, logic operation is performed by connecting and disconnecting the input signal to the output. For example, in this figure, when the control signal is set to “0”, the nMOS transistor becomes nonconductive. However, when the control signal is set to “1”, the transistor becomes conductive, pulling the output up or down according to the input voltage, and the input signal is then transmitted to the output. Thus, PTL is also called a transmission gate.

PTL is often used to simplify logic functions. For example, Fig. 2.29 shows a comparison of PTL and CMOS circuits for 2-input XOR logic,  $Out = A\bar{B} + \bar{A}B$ . PTL provides this XOR logic circuit with only two transistors, while the CMOS circuit requires six transistors. (To generate complementary signals for  $A$  and  $B$ , an additional four transistors in two inverters are required for both circuits.) This simplification ability of PTL is effective not only for reducing chip size, but also for enhancing operating speed and reducing power consumption. This is because the decrease in the number of transistors reduces the total capacitance in the circuit, which must be charged and discharged for the logic operation, thus wasting power and causing delay. In addition, the pMOS-free structure of the PTL is also advantageous in terms of operating speed and power consumption. This is because the capacitance of a pMOS transistor is twice as large as that of an nMOS transistor due to the wider size required by its inferior current characteristics. The lack of a pMOS transistor thus enables lower capacitance, resulting in both faster speed and lower power.

Because of these advantages, PTL is preferably used in arithmetic units in microprocessors, in which complex logic functions such as XOR are needed to implement adders and multipliers with high-performance [2–8]. PTL is also used to implement  $D$ -type latches and DRAM memory cell to reduce chip size or the number of transistors, as shown in Fig. 2.30.

## Problems of PTL

In the 1990s, so-called top-down design, in which logic circuits are automatically synthesized, has been widely applied for random logic such as the control block of a microprocessor, rather than bottom-up design. This is mainly because the size of VLSI chip has been increasing dramatically, and manual design can no longer be used in terms of design period and cost. In top-down design, as shown in Fig. 2.31, logic circuits are designed using a hardware description language (HDL), such as Verilog-HDL or VHDL (Very High Speed Integrated Circuit Hardware Description Language). These HDLs are used to describe the register-transfer-level functionality of logic circuits. The conversion from the HDL to a circuit is performed automatically by a logic synthesis tool, a so-called CAD tool. The logic synthesis tool generates a netlist of the target circuit through the combinations of fundamental circuit elements called cells, which are prepared in a cell library. The netlist represents the logic circuit in the form of connections between cells. Finally, an automatic layout tool generates a mask pattern for fabricating the VLSI chip. Top-down design of LSI is similar to today's software compilation process, so it is often called silicon compilation.

Despite many advantages, however, PTL has not been adapted for such synthesized logic blocks in top-down design. This is mainly because adequate CAD tools that can synthesize PTL have not yet been developed. One of the main reasons for this is the great difference between CMOS and PTL circuits. For example, PTL designed inadequately may contain a sneak path that provides an unintended short-circuit path from  $V_{dd}$  to Gnd, causing the circuit not to work correctly. CMOS circuits, on the other hand, have never such paths. For example, the PTL circuit shown in Fig. 2.32(a) seems to work correctly for the logic function:  $Out = AB + CD$ . Here,  $AB$  represents logic AND of two variables,  $A$  and  $B$ , and this boolean equation represents that  $Out$  is given by logic OR of  $AB$  and  $CD$ . However, when  $A = 1$ ,  $B = 1$ ,  $C = 0$ , and  $D = 1$ , the output is connected to both  $V_{dd}$  and Gnd at the same time, resulting in a short-circuit current from  $V_{dd}$  to Gnd.

The complex electrical behavior of PTL also makes automatic synthesis of PTL difficult. The  $V_{th}$  drop shown in Fig. 2.32(b) is a typical problem [1]. As described before, in PTL, the pull-up and pull-down

FIGURE 2.32 Problem of PTL.

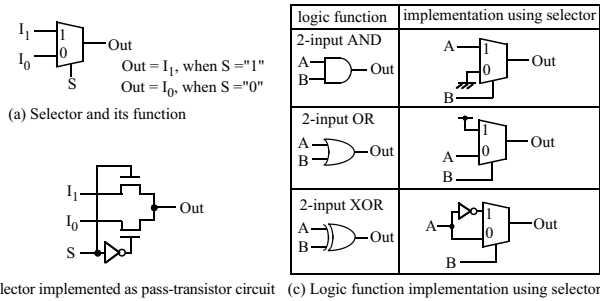

FIGURE 2.33 Selector and pass-transistor circuit.

operations are performed by the same nMOS transistor; that is, the pull-up operation is accomplished by a source-follower nMOS transistor. Thus, the maximum pulled-up voltage is limited to  $V_{dd} - V_{th}$ , where  $V_{th}$  is a threshold voltage of the nMOS transistor, and the nMOS transistor does not become conductive when the gate-source voltage is less than  $V_{th}$ . Such a dropped signal may cause serious problems, such as a short-circuit current from  $V_{dd}$  to Gnd, when it drives other CMOS circuits, such as inverter. Moreover, the decreased signal swing due to the  $V_{th}$  drop degrades the noise margin. This problem is effectively solved by using a structure combining nMOS and pMOS transistors, as shown in Fig. 2.32(c). However, such a structure loses the advantages of pMOS-free structure of PTL. In addition, in a PTL circuit, the number of serially connected pass-transistors must be carefully considered, because a PTL circuit has quadratic delay characteristics with respect to the number of the stages of pass-transistors [1].

## Top-Down Design of Pass-Transistor Logic Based on BDD

As described in the previous section, PTL has not generally been applied for random logic circuits because of the lack of adequate synthesis techniques. However, the recent increasing demand for LSI chips with enhanced performance, reduced power, and lower cost has been changing this situation, and now many methods for automatically synthesizing PTL circuits for random logic have been proposed [9–20]. Most of them use selector logic and binary decision diagrams (BDDs). This is because BDDs and selector logic are suitable for generating pass-transistor logic circuits, and PTL synthesized from a BDD has many advantages, as described below. BDDs are thus widely used in PTL synthesis [17].

The selector, also called multiplexer, has good correspondence with the pass-transistor circuit. The function of the selector is shown in Fig. 2.33(a). Here, two inputs,  $I_0$  and  $I_1$ , are called data inputs, and input  $S$ , which selects one of the two data inputs, is called the control input. The selector is easily implemented as a wired OR structure of two pass-transistors with one inverter, as shown in Fig. 2.33(b). The selector is thus suitable for pass-transistor circuits. In addition, it has an advantage in that by changing the connections of the two data inputs  $I_0$  and  $I_1$ , any kind of logic function can be implemented, as shown in Fig. 2.33(c).

However, the selector shown in Fig. 2.33(b) requires an inverter to generate the selection signal for input  $I_0$ . Consequently, the delay of the circuit is increased by the delay of the inverter. To overcome this, dual-rail, pass-transistor circuits such as CPL (complementary pass-transistor logic) and SRPL (swing

FIGURE 2.34 Dual-rail, pass-transistor logic circuits.

FIGURE 2.35 BDD and other logic representations for 2-input XOR logic.

restored pass-transistor logic) shown in Fig. 2.34(a,c) [2,3,6] are effective solutions. These circuits have both positive and negative polarities for all signals complementarily, so there is no need for an inverter to generate complementary signals. Thus, high-speed operation becomes possible. Moreover, the differential operation in these dual-rail pass-transistor circuits is also effective in improving the noise-margin characteristics of the pass-transistor circuit. In addition, dual-rail PTL can still provide logic circuits with fewer transistors than their CMOS counterparts [1,2], although it requires twice as many transistors as a single-rail pass-transistor circuit. In this chapter, a method for synthesizing single-rail PTL is described below, because same method can be applied to dual-rail PTL by just changing pass-transistor selector from single-rail to dual-rail PTL.

BDD is one type of logic representation and expresses a logic function in a binary tree [21–23]. For example, Fig. 2.35(a–c) shows three typical logic representations for 2-input XOR logic: (a) boolean equation, (b) truth table, and (c) BDD. As shown in Fig. 2.35(c), the BDD consists of nodes and edges. The nodes are categorized into two types: variable nodes and constant nodes of “0” or “1”. A variable node represents a variable of the logic function. For example, node A in the BDD corresponds to the variable A in the logic function shown in Fig. 2.35(a,b). A variable node has one outgoing edge and two incoming edges, a 0-edge and a 1-edge. In this figure, a 0-edge is denoted by a dotted line and a 1-edge by a straight line, although there are other representations used in BDDs. These two incoming edges show the logic functions when the variable of the node is set to “0” and “1”, respectively. The logic functions are represented by the connections of these elements. For example, when (A, B) is (0, 0), Out becomes 0 in the truth table. This corresponds to selecting the 0-edge at the nodes A and B. The path to node “0” can be traced from the root in the BDD in Fig. 2.35(c). Furthermore, the fact that there are two cases, (A, B) = (0, 1) and (1, 0), for Out = 1 in the truth table corresponds to the fact that in the BDD there are two paths from the root to “1”; that is, A = 0 → B = 1 and A = 1 → B = 0.

A BDD can be simplified by using complementary edges. The complementary edges are used to represent the inverted logic of a node, as shown in Fig. 2.36(a). By using complementary edges, two nodes, B and B-bar, can be combined as one node and the BDD can be simplified. For example, Fig. 2.36(b) shows a simplified BDD with complementary edges for the BDD shown in Fig. 2.35(c).

BDDs have a good correspondence with selector logic and pass-transistor circuits, as shown in Fig. 2.37, because the BDD represents logic functions in a binary tree structure. Thus, it is possible to generate a pass-transistor circuit for a target logic function by replacing the nodes in the BDD with pass-transistor selectors and connecting their control inputs with the input variables related to the nodes [10].

A detailed example how to synthesize PTL from a BDD is shown in Fig. 2.38(a–i). BDD is first constructed for the logic functions shown in Fig. 2.38(a). The BDD can be built by recursively applying

FIGURE 2.36 BDD with complementary edges for function in Fig. 2.35.

BDD	Selector	Pass-transistor circuit

FIGURE 2.37 Correspondence among BDD, selector, and pass-transistor circuit.

FIGURE 2.38 Example of PTL synthesis using BDD.

Shannon expansion, as shown below, to the logic function [22]:

$$f = \bar{a} \cdot f(a = 0) + a \cdot f(a = 1)$$

In this example, Shannon expansion is first applied to input variable  $A$  (Fig. 2.38(b)), then to input variable  $B$  (Fig. 2.38(c)). In Fig. 2.38(c), both the 1-edge of node  $B$  of Out1 and the 0-edge of node  $A$  of Out2 are equivalent to the logic function  $CD + \bar{C}\bar{D}$ , so these two edges are shared, as shown in Fig. 2.38(d). Such a BDD that shares two or more isomorphic sub-graphs among different outputs is called a shared BDD. By applying Shannon expansion to variables  $C$  and  $D$ , as shown in Fig. 2.38(e), the final BDD shown in Fig. 2.38(f) is obtained.

Although a PTL circuit can be obtained by simply replacing all the nodes in a BDD with pass-transistor selectors, such a PTL may not work correctly, or it may have a very long delay because of electrical problems in the pass-transistor circuit, as described in the section on “Problems of PTL”. To overcome these problems, buffers like that shown in Fig. 2.38(g) are inserted [1,10]. This buffer consists of an inverter and a pull-up pMOS transistor. It can restore the signal swing with little short-circuit current, because the gate of the pMOS transistor has feedback connection from the output, so the pull-up pMOS transistor forcedly pulls up the inverter input to  $V_{dd}$  even if a  $V_{th}$ -dropped signal is input. The gate width of the pull-up pMOS transistor is set small enough for pull-up operation, because a wide-gate pMOS transistor makes it difficult for the nMOS pass-transistors to pull down the input node of the inverter and can degrade the speed of the pull-down operation.

Level restoration buffers are inserted in the following three types of nodes in a BDD. First, for the primary output node, buffers are inserted to prevent  $V_{th}$ -dropped signals of the pass-transistor selectors from driving other CMOS circuits. Second, buffers are inserted for nodes with two or more fanouts for current amplification. Finally, for nodes that belong to a series of long-chained nodes, buffers are needed to prevent the relatively long delay due to the quadratic delay characteristics of the pass-transistor circuit. However, using too many buffers adversely increases the overall delay of the circuit because of their intrinsic delay. Thus, buffers are inserted every three stages, in general [10]. In addition, for a node in which a buffer is inserted, inverters should also be inserted in the two incoming edges of the node to adjust the polarity. Inverter propagation is thus performed to remove extra inverters by adjusting the polarity between adjacent nodes. Figure 2.38(h) shows the result of buffer insertion and inverter propagation. In this example, three buffers are inserted without additional inverters, due to inverter propagation.

Finally, by replacing the nodes in the BDD with 2-input pass-transistor selectors and mapping groups of several selectors and a buffer into cells, the target pass-transistor circuit shown in Fig. 2.38(i) is obtained. Here, for the leaf nodes—that is, the two nodes  $D$  in Fig. 2.38(h)—selectors whose two inputs  $I0$  and  $I1$  are connected to  $V_{dd}$  or Gnd are generated, so these selectors can be removed or simplified into an inverter, as shown in Fig. 2.37.

These speed-up buffers are not required for all paths. This is because in an actual circuit, a few bottleneck paths called critical paths limit its maximum operating speed, and these buffers are not necessary for other paths, unless their delay do not exceed those of the critical paths. Reducing the total number of the buffers in this way is effective for power and area reduction [16].

The synthesized PTL completely corresponds to the BDD except for the inserted buffers and inverters, as shown in Fig. 2.38. Thus, in PTL synthesis, reducing the size and depth of the BDD is important. This is the greatest difference from CMOS logic synthesis, in which reducing the literal count of boolean equation is essential.

PTL synthesized from a BDD has various advantages. One of the most important advantages is that the synthesized PTL is guaranteed to be sneak-path free [9]. This is because in a BDD, all paths terminate in “1” or “0” and only one of them is activated at a time. Therefore, the synthesized PTL includes no paths that can be connected to both  $V_{dd}$  and Gnd at the same time.

Another superior characteristic of PTL synthesized from a BDD is that the synthesized result is independent of the quality of the input HDL description. In other words, even if the input HDL contains some redundancy, the synthesized PTL is free from any redundancy. This excellent characteristic derives

FIGURE 2.39 Reduce operation and reduced BDD.

FIGURE 2.40 BDD size dependency on variable ordering for  $\text{Out} = AB + CD + EF$ .

from the property of a BDD called canonicity [21]. Canonicity means that after reduce operation that removes isomorphic sub-graphs, as shown in Fig. 2.39(a-c), the final BDD is always identical for the same logic function and the same variable ordering, even if the initial BDDs are different. Here, variable ordering means the order of the input variables in the BDD construction. A BDD for which the redundant sub-graphs have been removed by the reduce operation is called a reduced BDD (RBDD) or reduced ordered BDD (ROBDD). In this chapter, a BDD is assumed to be a ROBDD, unless otherwise stated. Because of this canonicity property of BDDs, the synthesized PTL is independent of the input HDL quality and redundancy free. This is one of the most important advantages of PTL synthesized from a BDD, compared with CMOS logic synthesis, in which the result depends on the quality of the input HDL description. The canonicity of BDDs also plays an important role in other fields in logic synthesis such as formal verification of logic functions [21].

### Variable Ordering of BDDs

As described in the previous section, the BDD has various superior characteristics for PTL synthesis. However, it has a drawback in that its size strongly depends on the input variable ordering. In PTL synthesis, the size of the BDD is directly reflected by the synthesized result. Therefore, finding the variable ordering that generates the minimum-size BDD is important. For example, Fig. 2.40 compares the BDDs for the logic function  $\text{Out} = AB + CD + EF$  for two different variable orders: (a)  $A \rightarrow B \rightarrow C \rightarrow D \rightarrow E \rightarrow F$ , and (b)  $A \rightarrow C \rightarrow E \rightarrow B \rightarrow D \rightarrow F$ . As shown in the figure, for case (a), the node count of the BDD is 6. On the other hand, 14 nodes are required for the same logic function in case (b). In general, an inefficient variable order can increase the size of a BDD by an order of magnitude.

However, the problem of finding appropriate variable ordering for arbitrary logic functions is well known to be an NP-complete problem [23]. For a logic function with a small number of inputs, it is possible to examine all combinations of variable ordering with a practical time. However, such a method

FIGURE 2.41 Logic circuit for  $Out = AB + CD + EF$  and variable ordering.

FIGURE 2.42 Variable ordering by sifting.

cannot be applied to an actual logic function whose inputs exceed 100, because the number of combinations becomes too huge ( $100! \approx 10^{157}$ ). Therefore, heuristic methods for finding an approximate optimal ordering have been developed [24–27]. These methods can be roughly categorized into two types: static methods and the dynamic methods.

One example of a static method is to determine the variable ordering based on information obtained from the circuit structure for the logic function. For example, in the case of the logic function in Fig. 2.40, the corresponding circuit is as shown in Fig. 2.41. Thus, the input pairs  $A$  and  $B$ ,  $C$  and  $D$ , and  $E$  and  $F$  should be adjacent in the variable ordering as in Fig. 2.41(a), not as in Fig. 2.41(b). An adequate ordering can be searched for under these constraints.

On the other hand, in a dynamic method, the optimal order is searched for by changing the order of the variables in the BDD. Figure 2.42(a) shows a representative method of this type, called sifting [26]. In sifting, by applying a swap operation, in which the orders of two adjacent variables are swapped as shown in Fig. 2.42(b), and by applying the reduce operation iteratively, an appropriate order for each variable is determined and the size of BDD is minimized. Variations of this method have also been proposed [27].

In practice, these methods can be combined. For example, the initial variable ordering is determined by a static method and the BDD is constructed, then the BDD is minimized using a dynamic method. Another approach that reduces the size of the BDD by changing the local ordering in the BDD has also been proposed [28].

## Multilevel Pass-Transistor Logic

A PTL circuit synthesized by the method described in the section on “Top-Down Design of Pass-Transistor Logic Based on BDD” may not be acceptable in terms of delay. This is because that type of PTL has a flat structure and the selectors are serially connected over  $n$  stages for a logic function with  $n$  inputs, since the control input of each selector is connected only to the primary input, as shown in Fig. 2.43(a). To solve this problem, multilevel pass-transistor circuits like that shown in Fig. 2.43(b) are expected to be as effective as multilevel logic in CMOS logic circuits. In this section, the synthesis method for such multilevel pass-transistor logic (MPL) is described. To distinguish it from MPL, the pass-transistor logic described in the previous section is called monolithic PTL.

MPL has a hierarchical structure, in which the control inputs of the pass-transistor selectors are connected not only to the primary inputs but also to the outputs of other pass-transistor selectors, as

FIGURE 2.43 Monolithic PTL and multilevel PTL.

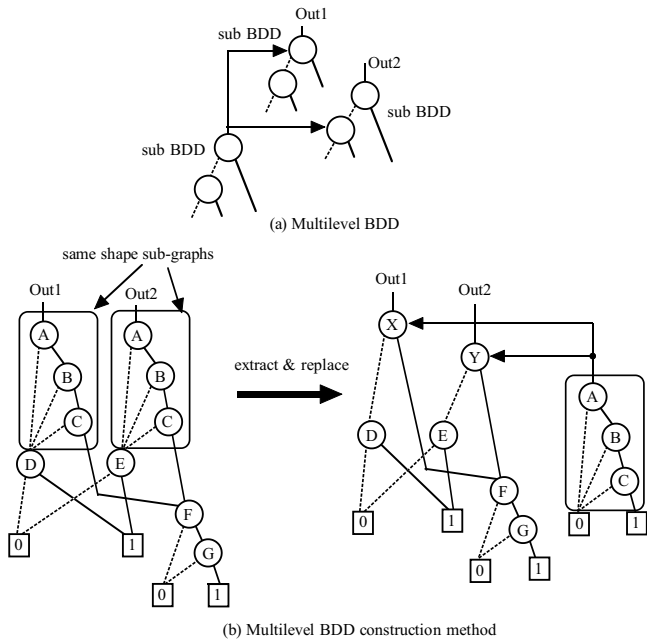

FIGURE 2.44 Example of multilevel BDD and its construction method.

shown in Fig. 2.43(b). MPL can be synthesized from a multilevel BDD shown in Fig. 2.44(a). The methods for building a multilevel BDD can be categorized into two types. One is based on conversion from a monolithic BDD described in the section on “Top-Down Design of Pass-Transistor Logic Based on BDD”. Figure 2.44(b) shows a representative method in this category [11]. In this method, sub-graphs that cannot be shared because at least one of their edges is not equivalent are searched for. Then, the detected sub-graphs are extracted and replaced with new nodes. For these new nodes, new introduced variables are assigned. In Fig. 2.44(b), X and Y are the new introduced variables. These variables are connected to the output of a new BDD, which has the same diagram as the extracted sub-graph except that its 0-edge and 1-edge are terminated to “0” and “1” nodes, respectively. By this extraction, it is possible to convert the monolithic BDD into two or more sub-BDDs, which are multiply connected with one another and have the same logic function as the original. Finally, by replacing the nodes with pass-transistor selectors, as described in the section on “Top-Down Design of Pass-Transistor Logic Based on BDD,” the MPL is obtained. Here, in the MPL the outputs of the pass-transistor selectors can be connected to the control inputs of other pass-transistor selectors, so level-restoration buffers are required for these places.

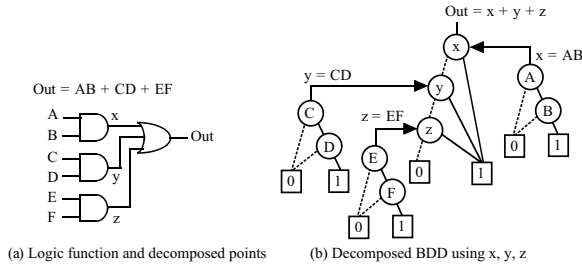

FIGURE 2.45 Example decomposed BDD.

FIGURE 2.46 Elimination by composition.

MPL has superior characteristics compared to monolithic PTL, especially in terms of delay, because the depth of sub-BDDs in a multilevel BDD is much less than that of a monolithic BDD. Empirically, the delay can be reduced by a factor of 2 compared to the monolithic PTL [11]. In addition, MPL is effective in simplifying the circuit, because more sub-graphs than in the monolithic BDD can be shared by extraction.

The other method is to directly build hierarchical BDDs simultaneously, without constructing a monolithic BDD [9]. Such a BDD is also called a decomposed BDD. Figure 2.45 shows an example. The decomposed BDD is constructed from input to output according to the structure of the circuit corresponding to the logic function. During the construction, the size and depth of the BDD is monitored and if either value is over a limit, BDD construction is stopped and a new intermediate variable that points to the output of the BDD is introduced. In this example,  $x$ ,  $y$ , and  $z$  are the intermediate variables. BDD construction is then restarted and the decomposed BDD is obtained by repeating this process. Here, a point where a new intermediate variable is introduced is called a decomposed point.

The decomposed BDD has a superior characteristic in that for certain logic functions, such as a multiplier, which cannot be constructed in a practical size from a monolithic BDD [23], it is possible to build a decomposed BDD and synthesize a pass-transistor circuit. Therefore, the decomposed BDD is essential for a practical PTL synthesis, and many methods based on the decomposed BDD have been proposed [12,13,34]. Another merit of the decomposed BDD is that by changing the decomposed points, the characteristics of the synthesized MPL can be flexibly controlled [9,12,13]. However, the decomposed BDD has a drawback, in that canonicity is not guaranteed because of the freedom in selecting decomposed points. This means that the synthesized result depends on the quality of the input logic description, or in other words, it may contain some redundancy. For this reason, in a decomposed BDD, sub-BDDs are simplified by several methods [9,12] such as elimination, shown in Fig. 2.46. Elimination removes the redundancy by composition of two or more sub-BDDs. Moreover, as with multilevel CMOS logic synthesis, BDD simplification based on “don’t care” conditions, such as satisfiability don’t care (SDC) and observability don’t care (ODC), can be applied, as shown in Fig. 2.47 [12,29,30].

## PTL Cell

In practical PTL synthesis several cells, each of which packs one or more selectors, inverters, and a pull-up pMOS transistor, are used, although PTL circuits can be synthesized with only two cells, namely a selector and an inverter. These packed cells of one or more selectors are effective not only

FIGURE 2.47 BDD simplification with “don’t care” conditions.

FIGURE 2.48 Example of pass-transistor cells.

FIGURE 2.49 PTL cell configuration.

for reducing the chip size but also for reducing the power and delay, because parasitic capacitance can be reduced.

Figure 2.48 shows an example of a PTL cell-set [31]. In this example, each PTL cell contains an inverter to generate complementary signals for the control input of the selector, although other cell configurations without inverters can also be considered, as shown in Fig. 2.49. This seems wasteful in terms of cell area, but in fact, external inverters adversely increase the final chip size because a large area is required for the wire connecting the external inverters and PTL cells [32].

The structure of a PTL cell is quite different from that of a CMOS cell [31]. This is because the symmetrical layout of pMOS and nMOS transistors as in a CMOS cell results in a large cell size in a PTL cell, where the number of nMOS transistors is much greater than that of pMOS transistors, and at least three sizes of transistors (small for inverters and a pull-up pMOS transistor, mid-size for the nMOS transistors of the selectors, and large for the output buffers) are required. In addition, sharing the diffusion area of the nMOS transistors in a selector is also important, not only to reduce the chip size but also to reduce the parasitic capacitance in the PTL cell. For this purpose, a method based on the Eulerian path is used, as shown in Fig. 2.50 [31].

### PTL and CMOS Mixed Circuit

Although in many cases PTL can provide a superior circuit with fewer transistors than conventional CMOS logic, it is not always superior. For example, as shown in Fig. 2.51 for simple 2-input NAND and 2-input NOR logic, PTL circuits require six transistors, while CMOS circuits only require four. For these cases, a

CMOS circuit provides better performance in terms of area and delay. However, a PTL circuit still provides lower power consumption because of its pMOS-free structure, which enables small capacitance.

Pass-transistor circuits are more suitable for implementing logic functions in which some signals are selected by other signals. In contrast, CMOS circuits are more suitable for implementing NAND/NOR logic (or AND/OR logic). Thus, PTL and CMOS mixed structures, in which logic corresponding to a selector is implemented with PTL circuits and other logic is implemented with CMOS circuits, are attractive [33,34]. In this section, such mixed-logic circuits called pass-transistor and CMOS collaborated logic (PCCL) are described.

The key to PCCL is finding CMOS-beneficial parts and selector-beneficial parts in the logic functions. To accomplish this, the BDD-based method shown in Fig. 2.52(a) is used, in which first an entire PTL circuit is constructed from a multilevel BDD or decomposed BDD, and then some parts are replaced with CMOS circuits. The key to this procedure is to find CMOS-beneficial functions based on the BDD. This is accomplished as follows: those selectors with one of two inputs fixed to  $V_{dd}$  or Gnd operate as AND or OR logic (NAND or NOR logic) rather than as a selector, so they are good candidates to be replaced with CMOS circuits, as shown in Fig. 2.52(b). Using this method, logic functions can be categorized into pro-selector functions and pro-AND/OR functions.

Figure 2.53 shows a detailed example of the PCCL synthesis flow. For the logic function shown in Fig. 2.53(a), the multilevel BDD shown in Fig. 2.53(b) is constructed. The PTL shown in Fig. 2.53(c) is then obtained from the BDD. Then, in the synthesized PTL, selectors in which one of the two data inputs is fixed to  $V_{dd}$  or Gnd are searched for. As described before, however, because of the low-power characteristics of the pass-transistor circuits, the power consumption will increase if all these pass-transistor

FIGURE 2.52 PCCL synthesis flow.

FIGURE 2.53 Example of PCCL synthesis.

**FIGURE 2.54** Relationship between cost parameter and area, power, and pass-transistor ratio.

selectors are re-mapped to CMOS circuits. Therefore, it is necessary to choose which circuits are suitable for the purpose, rather than simply replacing selectors with CMOS circuits automatically. To accomplish this, a cost function is used, such as this example:

$$\text{cost} = \text{area}^{\alpha} \times \text{delay}^{\beta} \times \text{power}^{\gamma}$$

where  $\alpha$ ,  $\beta$ , and  $\gamma$  are the weights for the area, delay, and power, respectively.

By changing the parameters of the cost function, the characteristics of the synthesized PCCL can flexibly be controlled for the purpose. Figure 2.53(d–f) shows area-oriented, delay-oriented, and power-oriented PCCLs derived from the PTL in Fig. 2.53(c), by changing the cost parameters. In this figure, there are three pass-transistor selectors (1), (2), and (3) that correspond to the selectors in Fig. 2.52(b). However, in the case of the area-oriented PCCL, only selectors (1) and (3) are converted (to CMOS 2-input NAND and 2-input NOR circuits, respectively), because for pass-transistor selector (2), the inverter needed to adjust the polarity in CMOS implementation resulting in a larger area. In the case of delay-oriented PCCL, all three selectors are converted to CMOS circuits, because the delay can be reduced by replacing selector (2), containing a slow inverter, with a CMOS circuit. On the other hand, in the case of the power-oriented PCCL, CMOS circuits are not adopted because the pass-transistor selectors use less power, as described before. Figure 2.53(g) shows the comparison of the results of these three PCCLs with CMOS counterpart. PCCL is superior to CMOS for all these cases.

This flexible control of the characteristic of the synthesized circuit by changing the cost parameters is possible for large logic function. Figure 2.54 shows an example, in which the cost parameters are continuously changed from area-oriented to power-oriented. The size of the logic function is about 10 k gate in CMOS configuration. By changing the pass-transistor ratio from 10% to 60%, the power is reduced by over 40%, but at the expense of area by 10%. The optimum pass-transistor ratio is usually 10–60%, although it strongly depends of the kind of the logic functions.

### 2.3 Synthesis of CMOS Pass-Transistor Logic

*Dejan Marković*

#### Introduction

Pass-transistor logic (PTL) circuits are often superior to standard complementary metal oxide semiconductor (CMOS) circuits in terms of layout density, circuit delay, and power consumption. Lack of sophisticated design automation tools for synthesis of random logic functions limits the usage of PTL networks to the implementation of Boolean functions, comparators, and arithmetic macros—full-adder cells and multipliers. The research over the last 10–15 years [1] has been mainly focused on the development of more efficient circuit techniques and the formalization of synthesis methodologies. Newly introduced PTL circuit techniques were compared to the existing PTL and standard CMOS techniques, but comparison results were not always consistent [2].

The basic element of pass networks is the MOS transistor, in which gate is driven by a control signal, often termed “gate variable.” The source of this transistor is connected to a signal, called “pass variable,” that can have constant or variable voltage potential which is passed to the output when the transistor is “on.” In a case of NMOS, when the gate signal is “high,” input is passed to the output, and when the gate is “low,” the output is floating (high impedance), [Fig. 2.55](#).

Section 2.3 surveys the existing pass-transistor logic families, including their main characteristics and associated challenges. The main focus is placed on the discussion of different methods for synthesis of PTL circuits. Emphasis is given to a unified method for mapping logic functions into circuit realizations using different pass-transistor logic styles. The method is based on Karnaugh map representation of a logic function, and it is convenient for library-based synthesis, since it can easily generate optimized basic logic gates—the main building blocks in library-based designs.

**FIGURE 2.55** NMOS pass-transistor [21].

## Pass-Transistor Logic Styles

Various PTL circuits, static or dynamic, can be implemented using two fundamental design styles: the style that uses NMOS pass-transistors only and the style that uses both NMOS and PMOS pass-transistors. Within each of these two styles, there is a further differentiation based on realization of the output stage.

### NMOS Pass-Transistor Logic

Complementary pass-transistor logic (CPL), introduced in [3], consists of an NMOS pass-transistor network, and CMOS output inverters. The circuit function is implemented as a tree consisting of pull-down and pull-up branches. Since the “high” level at the pass-transistor outputs experiences degradation by the threshold voltage drop of NMOS transistors, the outputs are restored to full-swing by CMOS inverters, Fig. 2.56. Conventional CPL [3] uses restoration option (a). It is suitable for driving large output loads because the output load is decoupled from the internal nodes of the PTL network. Subfamily based on restoration option (b) is called differential cascode voltage switch with the pass-gate (DCVSPG), and it is good in driving smaller loads. Restoration option (c) is associated with the logic family called swing-restored pass-transistor logic (SRPL) [4]. Another variation of (b), which employs level restoring circuit shown in Fig. 2.56(d), was introduced in [5] in a logic family called power saved pass-transistor logic (PSPL). Compared to conventional CPL, this technique compromises circuit speed for smaller power consumption, resulting in worse energy-delay product.

Sizing of pass-transistors is an important issue. As discussed in [5], the NMOS transistors closer to the output have smaller size than the transistors farther away from the output because the transistors closer to the output pass smaller swing “high” signals due to the voltage drop across the transistors away from the output. However, this technique has to be carefully applied because small output transistors might not be able to provide sufficient driving strength at the output if the output load is large.

The LEAP pass-transistor library [6], uses two level restoring circuits, one for driving small loads, Fig. 2.57(a), and another for driving very large loads, Fig. 2.58(b). This level restoring technique decouples the true and complementary outputs in conventional CPL (dashed PMOS transistors in Fig. 2.56(a)).

CPL has traditionally been applied to the implementation of arithmetic building blocks [3,6–9], and it has been shown to result in high-speed operation due to its low input capacitance and reduced transistor count. Also, this logic family has smaller noise margins compared to the conventional CMOS.

**FIGURE 2.58** DTMOS devices: (a) standard DTMOS, (b) with limiter device, (c) with augmenting device.

### **Technology Scaling of NMOS Pass-Transistor Logic**

Technology scaling rules, given by the SIA roadmap, do not work in favor of NMOS-based PTL networks because the threshold voltage is predicted to scale at a slower rate than the supply voltage. This not only incurs speed degradation of the pass-transistor networks, but also slows down the pull-down of the output buffers, causing excessive leakage currents. To overcome this barrier, dynamic threshold MOS (DTMOS) is used. Various DTMOS devices that can be used in PTL networks are analyzed in [10]. Standard DTMOS device shown in Fig. 2.58(a) is suitable for supply voltages below 0.5 V, while for higher supplies the source-to-body junction could become forward-biased, causing excessive gate current. The use of auxiliary minimum-sized devices allows devices shown in Fig. 2.58(b,c), to operate at higher supplies. These two schemes are advantageous especially for driving larger loads when the area penalty for minimum-sized auxiliary devices is smaller, because the driver transistors are large. It is therefore expected that the supply voltage scaling does not impose barrier to the use of NMOS pass-transistor networks.

### **CMOS Pass-Transistor Logic**

#### **Double Pass-Transistor Logic (DPL)**

To avoid signal swing degradation along the NMOS pass-transistor network, twin PMOS transistor branches are added to N-tree in double pass-transistor logic (DPL) for full-swing operation [9]. DPL logic family was introduced with the idea of overcoming swing degradation problem of CPL, resulting in improved circuit performance and improved noise margins at reduced supply voltages. Additional PMOS transistors in DPL result in increased input capacitance, but the symmetrically arranged and balanced input signals as well as the double-transmission characteristics compensate for the speed degradation arising from increased input loading. As introduced in [9], basic DPL logic gates have the same overall area as CPL gates—the widths of the PMOS transistors in DPL are two-thirds and the width of the NMOS transistors in DPL are one-third of the width of the NMOS transistor in CPL gates, respectively.

Newly introduced DPL was compared to CPL and standard CMOS on the example of a full-adder in 0.25  $\mu\text{m}$ , loaded with 0.2 pF. It has been shown in [9] that for this load both pass-transistor designs, CPL and DPL, have higher power consumption than CMOS due to their dual-rail structure. When the load capacitance is smaller, then PTL architectures actually dissipate less power. Speed improvement of DPL gates has been demonstrated by AND/NAND and OR/NOR ring oscillators that have shown performance improvement of 15–30% relative to CMOS counterparts [9].

#### **Dual Value Logic (DVL)**

Another logic family that uses both NMOS and PMOS pass-transistors is dual value logic (DVL), introduced in [11,12]. DVL is derived from DPL with the idea to eliminate redundant branches in DPL. This is performed in the following three steps: (1) elimination of redundant branches, (2) signal rearrangement, and (3) the selection of faster halves, as illustrated in Fig. 2.59. DVL preserves the full swing operation of DPL with reduced transistor count.

Elimination of redundant branches can be performed by direct elimination (faster NAND half), or it can be performed by merging functionality of two branches into one (faster AND half), Fig. 2.59.

FIGURE 2.59 DVL: Elimination of redundant branches from DPL.

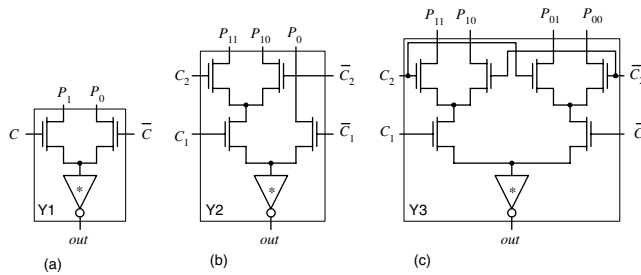

FIGURE 2.60 Pass-transistor function cells in LEAP library [6].

The final step in synthesizing a DVL gate is the selection of the faster halves obtained in previous two steps. Main benefit of DVL is reduced transistor count relative to DPL. Since DVL gates have inherent asymmetry and imbalance of their inputs, circuit resizing is often required for balanced performance. Original work [11] reported about 20% improvement in speed of AND/NAND gate in DVL compared to equal area gate in DPL. The idea of DVL, extended to synthesis of random logic functions [11] will be discussed in more detail in the section on “Synthesis of Complex Logic Networks.”

## Synthesis of Pass-Transistor Networks

The PTL synthesis methodologies can be classified into two categories: (1) binary decision diagram (BDD)-based and (2) other, which are not based on BDDs. Direct synthesis of large pass-transistor networks is difficult because of speed degradation when the signal propagates through long pass-transistor chains. The delay in PTL networks is a quadratic function of the number of PTL cells, while the delay in standard CMOS logic networks is a linear function of the number of cells. Therefore, large PTL networks need to be decomposed into smaller cells to overcome the significant delay degradation. When new pass-transistor families were introduced, the emphasis was usually given on their suitability for block design, and less attention was paid to the tradeoffs in the design of basic logic gates, which are essential blocks in the design of large PTL circuits.

### Binary Decision Diagram-Based Synthesis

Synthesis using pass-transistor cell library was introduced in [6]. The library consists of only seven cells—three function cells (Y1, Y2, and Y3) shown in Fig. 2.60 and four inverters with various drive capability shown in Fig. 2.57. The idea is to partition the BDD into smaller trees that can be mapped to the library cells. Logic design is carried out by a logic/circuit synthesis tool called “circuit inventor,” which first converts

the design into a BDD representation, then maps it into netlists of library cells. The netlist is then passed to an automatic place-and-route tool which generates the layout. This synthesis method generates PTL layouts superior to automatically generated static CMOS layouts in terms of area, delay, and power consumption, but this was true only for relatively small designs. In larger designs, unnecessary cascading of output inverters proves to be inefficient in terms of area. The reason for this, as pointed out in [13], is the use of primitive BDD approach with static variable ordering and without decomposition, which has been shown to result in bigger BDDs than the BDDs constructed with the approach of dynamic variable ordering and decomposition. A summary of the different types of BDD decompositions can be found in [14].

Pass-transistor mapper (PTM) was presented in [15] as an improvement of the “circuit inventor” tool. PTM technique was based on the same pass-transistor library cells, with the main improvement being the use of optimized reduced-order BDDs (ROBDDs) [16] that allowed for synthesis of large logic functions. Efficiency of PTM was verified in comparison with CMOS-based synthesis algorithms presented in [17]. Although PTM typically generated more compact layout with smaller overall active capacitance, speed of larger blocks was in favor of CMOS implementations. For example, cordic block synthesized by PTM had 30% smaller area, but three times longer delay than the same block in standard CMOS. Smaller blocks averaged a factor of 1.4 reduction in delay and marginal increase in area.

BDD-based optimization of pass-transistor networks guarantees the avoidance of sneak current paths. However, it has been shown that BDDs are not suitable for synthesizing area-efficient pass-transistor networks [18]. As an alternative, 123 decision diagrams (123-DD)—layout driven synthesis—were proposed in [18]. Main feature of this method is that the designs can be directly mapped into layout because the synthesis is driven from layout, including the consideration of interconnect. This synthesis technique utilizes two metal layers, with a set of rules that define geometrical placement and connectivity between transistors. Tested on single output functions, 123-DD synthesis method resulted in about 30% area improvement compared to standard synthesis techniques [19]. More details about these comparisons and the method can be found in [20].

### **Synthesis Based on Karnaugh Maps**

The method of Karnaugh maps can be effectively applied to the optimization of logic gates. Random logic functions with up to six inputs can be efficiently synthesized from the Karnaugh maps. Synthesis of pass-transistor networks using Karnaugh maps was presented in [21] and demonstrable area savings have been shown for small PTL cells. Approach to synthesis of PTL circuits based on incomplete transmission gates without degrading circuit performance, the idea similar to DVL, was presented in [20]. The focus of this section is on a unified approach to synthesis of basic logic gates in both NMOS and CMOS PTL circuits, developed in [22]. The synthesis method is further enhanced to the generation of circuits with balanced input loads, suitable for library-based designs. The versatility of these circuits is increased by application of complementarity and duality principles.

#### ***Synthesis of NMOS PTL Networks***

A general method for translation of Karnaugh maps into circuit realizations is applied to design logic AND/NAND, OR/NOR, and XOR/XNOR gates. The use of complementarity and duality principles simplifies the generation of the entire set of 2-input and 3-input logic gates.

The rules for synthesis of NMOS pass-transistor network in CPL are given below:

1. Cover Karnaugh map with largest possible cubes (overlapping allowed).
2. Derive the value of a function in each cube in terms of input signals.
3. Assign one branch of transistor(s) to each of the cubes and connect all branches to one common node, which is the output of NMOS pass-transistor network.

The generation of complementary and dual functions is simple, by observing the basic properties of these gates as given below.

*Complementarity principle:* The same circuit topology with inverted pass signals produces the complementary logic function.

**FIGURE 2.61** Illustration of duality principle in NMOS pass-transistor networks [22].

**FIGURE 2.62** Synthesis of 2-input functions: (a) Karnaugh map of AND function, (b) circuit diagram of AND/NAND function, (c) circuit diagram of OR/NOR function [22].

*Duality principle:* The same circuit topology with inverted gate signals gives the dual logic function. The dual logic functions are: AND-OR and NAND-NOR. XOR and XNOR are self-dual.

The duality principle follows from DeMorgan’s rules, and it is illustrated by the example of AND to OR transformation, Fig. 2.61. The procedure of a logic gate synthesis is shown using an example of 2-input AND function, Fig. 2.62. The value covered by cube  $C_1$  is equal to  $B$ , which becomes pass signal of the transistor branch driven with  $\bar{B}$ . Similarly the transistor representing cube  $C_2$  passes input signal  $A$  when the gate signal  $B$  is “high.” The NMOS transistor branches corresponding to  $C_1$  and  $C_2$  implement 2-input AND gate. Complementarity principle applied to AND circuit results in the transistor realization of NAND circuit shown in Fig. 2.62(b). By applying duality principle on AND, two-input OR function is synthesized. NOR gate is then generated from OR (complementarity) or from NAND (duality), Fig. 2.62(c).

### CPL Gates with Balanced Input Loads

The aforementioned synthesis procedure does not guarantee balanced loading of input signals. In AND/NAND circuit of Fig. 2.62(b) loads on input signals  $A$ ,  $\bar{A}$ ,  $B$ , and  $\bar{B}$  are not equal. The gates shown in Fig. 2.62 are commutative with respect to their inputs, and when signals  $A$  and  $B$  are swapped in the NAND circuit of Fig. 2.62(a), resulting AND/NAND circuit has the balanced input loading, Fig. 2.63,

FIGURE 2.63 Circuit diagram of 2-input functions with balanced input load [22].

FIGURE 2.64 Synthesis of 2-input XOR/XNOR function: (a) Karnaugh map of XOR function, (b) circuit diagram of XOR/XNOR function [22].

FIGURE 2.65 Synthesis of 3-input AND/NAND function: (a) Karnaugh map of AND function, (b) circuit diagram of AND/NAND function [22].

where each input “sees” the load given by Eq. (2.1).

$$C_{in} = C_{drain} + C_{gate} \quad (2.1)$$

Balanced loading does not come without cost—circuits in Fig. 2.63 would require more layout area due to increased wiring complexity. Balancing also does not guarantee balanced propagation of true and complementary signals because logical transitions of input signals do not experience similar paths in true and complementary circuits. For instance, when  $B$  changes from “high” to “low,” and  $A$  is “high,” the output of AND circuit transitions “low”-to-“high” because *gate* signals ( $B, \bar{B}$ ) have switched. Complementary signal—the output of the NAND gate—on the other hand, undergoes the “high”-to-“low” transition, affected by the switching of *source* signal  $\bar{B}$ . The two different paths, gate-to-output and source-to-output, cause different rising/falling delays of true and complementary output signals.

Realization of 2-input XOR/XNOR circuit, with balanced input loads, is shown in Fig. 2.64. The XNOR function is obtained from XOR by applying the complementarity principle and swapping input variables for balanced input loading.

Input loads cannot be balanced for any circuit topology and any number of inputs. To illustrate this, a single-stage 3-input AND/NAND circuit shown in Fig. 2.65 is analyzed. Eight input signals (including complementary signals) are connected to the total of 14 terminals, resulting in imbalanced inputs. If the

FIGURE 2.66 Circuit diagram of 3-input OR/NOR function [22].

3-input AND/NAND gates were implemented as cascade of 2-input gates with balanced loads, the loading would remain balanced.

The example in Fig. 2.65 also illustrates the reduction in transistor count by overlapping cubes  $C_1$  and  $C_3$ . The consequence of the overlapping is that both of the corresponding branches are simultaneously pulling down for those input vectors under which the cubes overlap. Direct realization of 3-input OR/NOR circuit, Fig. 2.66, is straightforward if complementarity and duality are applied to circuit in Fig. 2.65. A three-input XOR/XNOR circuit in CPL is typically composed of 2-input XOR/XNOR modules [3].

### Synthesis of CMOS PTL Networks (DPL and DVL)

#### Synthesis of DPL

DPL has twice as many transistors as CPL for the same logic function. Consequently, the synthesis of double pass-transistor logic is based on covering every input vector in the Karnaugh map twice. The idea is to assure all logic “0”s in the map are passed to the output through at least one NMOS branch and all logic “1”s through at least one PMOS branch.

The rules to synthesize random logic function in DPL from its Karnaugh map are:

1. Two NMOS branches cannot be overlapped on logic “1”s. Similarly, two PMOS branches cannot be overlapped on logic “0”s.
2. Pass signals are expressed in terms of input signals or supply. Every input vector has to be covered with exactly two branches.

*Complementarity principle:* The complementary logic function in DPL is generated after the following modifications of the true function: (1) swap PMOS and NMOS transistors, and (2) invert all pass and gate signals. Unlike purely NMOS pass-transistor networks, in CMOS networks both pass and gate signals need to be inverted because the PMOS and NMOS transistors are swapped in step (1).

*Duality principle:* The dual logic function in DPL is generated when PMOS and NMOS transistors are swapped, and  $V_{dd}$  and GND are swapped.

The procedure to synthesize DPL circuits is illustrated on the example of 2-input AND circuit shown in Fig. 2.67. Cube  $C_1$ , Fig. 2.67(a), is mapped to an NMOS transistor, with the source connected to ground and the gate connected to  $\bar{B}$ . Cube  $C_2$  is mapped to a PMOS transistor, which passes  $A$ , when gate signal  $\bar{B}$  is “low.” The NMOS transistor of  $C_3$  pulls down to ground, when  $A$  is “low,” and the PMOS transistor of  $C_4$  passes  $B$ , when  $A$  is “high.” Complementary circuit (NAND), Fig. 2.67(b), is generated from AND, by applying the complementarity principle. Following the duality principle, OR circuit is formed from AND circuit, Fig. 2.68.

Different 2-input XOR/XNOR circuit arrangements are possible, depending on mapping strategy. Fig. 2.69 shows a realization with balanced load on both true and complementary input signals. Three-input functions in DPL are implemented as cascaded combinations of 2-input DPL modules.

**FIGURE 2.67** Synthesis of 2-input AND/NAND function: (a) Karnaugh map of AND function, (b) circuit diagram AND/NAND function [22].

**FIGURE 2.69** Synthesis of 2-input XOR/XNOR function: (a) Karnaugh map of XOR function, (b) circuit diagram XOR/XNOR function [22].

### Synthesis of DVL

The rules to synthesize random logic function in DVL from Karnaugh map are outlined below:

1. Cover all input vectors that produce “0” at the output with largest possible cubes (overlapping allowed) and represent those cubes with NMOS devices, in which sources are connected to GND.
2. Repeat step 1 for input vectors that produce “1” at the output and represent those cubes with PMOS devices, in which sources are connected to  $V_{dd}$ .
3. Finish with mapping of input vectors that are not mapped in steps 1 and 2 (overlapping with cubes from steps 1 and 2 allowed) that produce “0” or “1” at the output. Represent those cubes with parallel NMOS (good pull-down) and PMOS (good pull-up) branches, in which sources are connected to the corresponding input signals.

The complementarity and duality principles are identical as in DPL. Generation of 2-input AND/NAND function is shown in Fig. 2.70. Circuit realizations with balanced loads are not possible in this case. Signals in brackets of Fig. 2.70(b) denote alternative signal arrangement in NAND circuit. The optimal signal arrangement depends on circuit environment and switching probabilities of input signals.

Efficient realization of 2-input OR/NOR circuits is shown in Fig. 2.71. Realization of 2-input XOR/XNOR circuit is identical to DPL, Fig. 2.69. Direct circuit implementation of 3-input DVL gates is shown in Fig. 2.72.

**FIGURE 2.70** Synthesis of 2-input AND/NAND function: (a) Karnaugh map of AND function, (b) circuit diagram of AND/NAND function [22].

**FIGURE 2.72** Karnaugh map and circuit diagram of 3-input AND function [22].

**FIGURE 2.73** Circuit diagram of 3-input OR/NOR function [22].

Overlapping cubes  $C_1$  and  $C_2$ , Fig. 2.72, saves area, which allows for wider transistors for cube  $C_3$ . The OR/NOR circuit, directly generated from the AND circuit, is shown in Fig. 2.73.

### Synthesis of Complex Logic Networks

Synthesis of large pass-transistor networks is a challenging problem. The method presented in the “Synthesis of Pass-Transistor Networks” section can be extended to synthesize larger functions, as well as to synthesize complementary CMOS circuits. Complementary CMOS logic is essentially a special case of

**TABLE 2.2** Comparison of Different Realizations of 3-Input Function  $F = B'C + ABC'$  [22]

Realization	No. of Input Signals	Signal Termination	Transistor Count	Output Load
CMOS	9	10G	10	4S
DVL (e)	9	8G + 6S	8	6S
DVL (f)	9	7G + 3S	7	4S

**FIGURE 2.74** Karnaugh map coverage of 3-input function in (a) complementary CMOS, (b) DVL, (c) DVL and corresponding circuit realizations in (d) complementary CMOS, (e) DVL, and (f) DVL [22].

pass-transistor logic, constrained that all source signals must terminate to  $V_{dd}$  or GND. This unnecessary constraint is removed in PTL, but at the same time complexity of designing large PTL circuits is increased. The most area-efficient method to synthesis of large PTL networks is decomposition into fundamental units with small number of inputs, typically two or three. To illustrate this, the synthesis of random logic function using three different mapping techniques is analyzed.

Consider the function

$$F = \bar{B} \cdot C + A \cdot B \cdot \bar{C} \quad (2.2)$$

and its three different realizations shown in Fig. 2.74. All three circuits implement the same function, but have different total active switching capacitance and different energy consumption. This example is extension of the analysis provided in [11] towards generalization of random logic function synthesis. Realization in complementary CMOS, Fig. 2.74(d), has smaller load on input signals and internal output load than the DVL realization in Fig. 2.74(e). Two realizations of DVL show different mapping strategies: the first strategy is to cover the map with largest possible cubes, Fig. 2.74(b), while the second strategy, Fig. 2.74(c), is based on map decomposition and reduction to implementation of basic 2-input functions. The DVL realization in Fig. 2.74(f) has smallest total load on input signals and similar internal output load as complementary CMOS realization, as shown in Table 2.2.

This example illustrates the importance of strategy used to cover Karnaugh map and leads to a conclusion that functional decomposition is the most efficient method in PTL circuit optimization. Straightforward coverage of Karnaugh map with largest cubes, as shown in Fig. 2.74(b) results in a circuit with lower performance, Fig. 2.74(e), while more careful coverage with decomposition of inputs, Fig. 2.74(c), results in a circuit with both smaller transistor stack and smaller transistor count, Fig. 2.74(f).

## Summary

Pass-transistor logic circuits are often more efficient than conventional CMOS circuits in terms of area, speed, and power consumption. This has been particularly the case when PTL is applied to the implementation of adders and multipliers. There are two main PTL design styles: NMOS-only pass-transistor networks, and CMOS pass-transistor networks. The use of DTMOS pass-transistors would allow an NMOS-based pass-transistor networks to operate at scaled supply voltages without significant speed degradation. The CMOS-based pass-transistor networks present the generalization of complementary CMOS where the pass variables could terminate to a variable voltage potential instead of  $V_{dd}$  or GND in standard CMOS. This added flexibility of PTL circuits increases complexity of synthesis of large pass-transistor networks. Decomposition of a complex function into its fundamental units, typically gates with two or three inputs, seems to be optimal solution. Finding a correspondence between logic function and these fundamental units can be performed in a systematic way using BDD-based synthesis algorithms or other non-BDD methods. Among the other non-BDD methods, synthesis and optimization based on Karnaugh maps presents systematic approach to synthesis of logic gates with balanced input loads. Further optimization of PTL circuits under multiple and/or variable transistor thresholds or supply voltage is a challenging problem for future research.

### Background for the Introduction of SOI CMOS

As the popularity of broadband access networks in the home continues to expand and multimedia data such as video and sound are received over high-speed Internet connections, the introduction of electronic commerce is expected to reach a serious stage. For the implementation of such services, there is an urgent need for the development of high-performance terminals and network information processing systems. The key devices for realizing that hardware are high-end microprocessors and digital signal processors that have high performance and low power consumption. The predicted trend for high-performance LSI clock frequencies taken from the 1994 NTRS (National Technology Roadmap for Semiconductors) [1] and the 1999 ITRS (International Technology Roadmap for Semiconductors) [2] is shown in Fig. 2.75.

FIGURE 2.75 On-chip local clock frequency.

FIGURE 2.76 Trend in microprocessor power.

The increases in LSI speed that we have seen so far are expected to continue at least until the year 2010, when the clock frequency should reach 10 GHz. Power consumption, on the other hand, is increasing along with processor speed, as we see in the trend in microprocessor power consumption reported by the International Solid-State Circuits Conference (ISSCC) (Fig. 2.76). Recently, high-performance MPUs that operate at gigahertz speeds and consume over 100 W of power have been reported. The calculated power density of these devices is nearly  $100 \text{ W/cm}^2$ , and with further increases in speed, the energy densities may approach those of a nuclear reactor [3]. This situation is recognized as a power crisis for LSI devices, and there is a need for lower power consumption and higher speed than is being obtained through the scaling of bulk Si devices. Furthermore, the market for portable information devices has experienced large growth, especially cell phones. To be conveniently useful, these information devices must be small, light, and have a sufficiently long use time under battery operation. Thus, there is a strong demand for lowering the power consumption of microprocessors, which account for nearly half of the power consumed by these information devices. This situation paves the way for the introduction of SOI (silicon on insulator) CMOS (complementary metal oxide semiconductor) devices, which are suited to low parasitic capacitance and operation on low supply voltage, as well as for the introduction of copper lines in the LSI wiring and a low-permittivity layer between wiring layers. The history of the development of the current SOI devices that employ a thin-film SOI substrate is shown in Table 2.3. The stream of development, which leads to the current SOI CMOS devices that employ an SOI substrate, originated with the forming of CMOS circuits on a SIMOX substrate for the first time in 1978 and the demonstration of the operation of those circuits [4].

## Distinctive Features of SOI CMOS Structures

A cross-section of an SOI CMOS structure is shown in Fig. 2.77. In an SOI CMOS structure, a metal oxide semiconductor field effect transistor (MOSFET) is formed on a thin SOI layer over a buried oxide layer, and the entire MOSFET is enclosed in a silicon oxide layer; the n-MOSFETs and p-MOSFETs are completely separated by an insulator. Furthermore, the process technology that is required for the fabrication of the CMOS devices is similar to the conventional bulk Si-CMOS process technology, and device structures are also simpler than for bulk CMOS. For that reason, compared to CMOS using ordinary bulk Si substrate, the CMOS that employ an SOI substrate have various distinctive features that result from those structures, as shown in Fig. 2.78. Here, in particular, the features of small junction capacitance, no substrate bias effects, and reduced cross-talk are described. These are powerful features for attaining higher LSI performance, lower power consumption, and multifunctionality.

**FIGURE 2.77** SOI CMOS structure.

As shown in Fig. 2.79, the MOSFET drain junction capacitance consists mainly of the capacitance between the drain and the substrate. In SOI structures, the capacitance between the drain and the substrate comprises a series connection of the buried oxide layer capacitance created by the silicon oxide layer, which has a dielectric constant 1/3 smaller than Si, and the capacitance of the extended depletion layer that is below the buried oxide layer. In SOI structures, the concentration of dopant in the substrate can be  $10^{14} \text{ cm}^{-3}$  or less, and by using the capacitance of the depletion layer that is below the buried oxide layer, the drain contact capacitance can be reduced to about 1/10 that of a MOSFET that employs a bulk Si substrate even if the buried oxide layer is about 100 nm thick. This is true even if we consider that the drain voltage changes in the range between 0 V and the supply voltage in CMOS circuit operation. Furthermore, reduction of the drain voltage  $V_d$  decreases the depletion layer width of the drain n<sup>+</sup>-p junction in proportion to  $(V_{bi} + V_d)^{1/2}$  (where  $V_d$  is the drain voltage and  $V_{bi}$  is the built-in potential), so the drain capacitance is increased. Thus, the fact that lower supply voltages in SOI structures result

FIGURE 2.78 Features of a fully depleted SOI transistor.

FIGURE 2.79 Small junction capacitance.

in lower junction capacitance due to the SOI structure is a remarkable advantage considering the trend of reducing the LSI supply voltage in order to reduce power consumption.

In SOI structures, there is no MOS reverse body effect, because the body is electrically floating due to the presence of the buried oxide layer, as shown in Fig. 2.80. In MOSFETs on a bulk Si substrate, the body, which is to say the p-well, is connected to ground, so when the circuit is operating, the body potential,  $V_{BS}$ , is always negative. Thus, if threshold voltage of MOSFETs ( $V_{th}$ ) rises, the drain current decreases. When the supply voltage is 1 V or more in n-MOSFETs on an SOI substrate, holes generated in the high electric field drain region accumulate in the body region and create a positive body bias. Thus the  $V_{BS}$  becomes positive,  $V_{th}$  is reduced, and the drain current increases. This feature results in better performance than is obtained with MOSFETs on bulk Si substrate in the case of logic gates that consist of stacked MOSFETs and pass transistor logic gates.

For the development of multifunction LSI chips, the implementation of a mixed analog/digital (mixed-signal LSI) chip, which is a single chip on which reside RF circuits and analog-digital conversion circuits rather than just a digital signal processing block, is desired as a step toward realizing the system-on-a-chip.

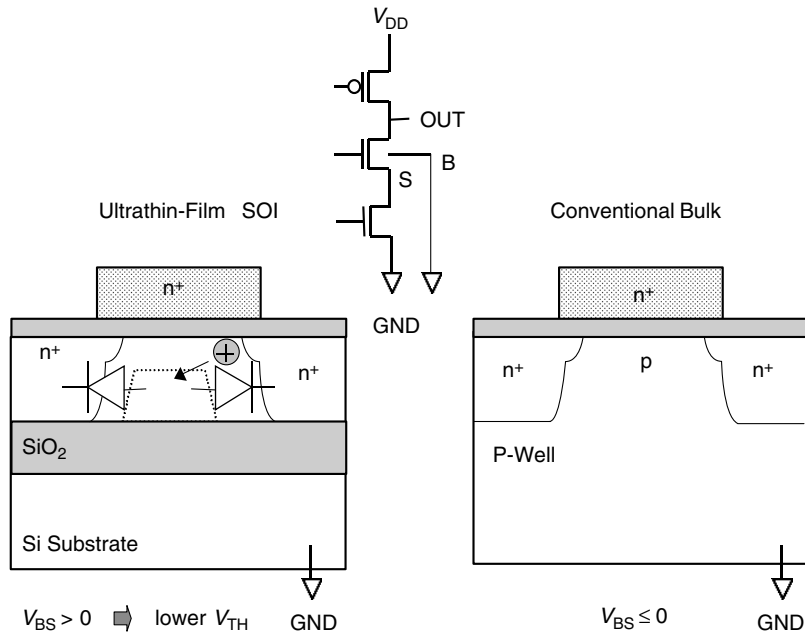

FIGURE 2.80 No reverse body effects.

FIGURE 2.81 Cross talk suppression.

A problem in such development is cross talk, which is the effect that the switching noise generated by the digital circuit block has on the high precision analog circuit via the substrate. With SOI structures, as shown in Fig. 2.81, it is possible to reduce the effect of this cross talk by using a high-resistance SOI substrate (having a resistivity of  $1000 \Omega\text{ cm}$  or more, for example) to create a high impedance in the noise propagation path [5]. Furthermore, even with an ordinary SOI substrate, by surrounding the analog circuit with N+ active SOI layer and applying a positive bias to it to form a depletion layer below the buried oxide layer, it is possible to suppress the propagation of the noise [6]. Although guard ring structures and

FIGURE 2.82 Cross section TEM image of fully depleted SOI CMOS.

FIGURE 2.83 Comparison of a 48-b multiplier performance between SOI and bulk-Si using 0.25- $\mu\text{m}$  CMOS technology.

double-well structures are employed as measures against cross-talk for CMOS circuits on bulk Si substrates, too, SOI structures are simpler, as described previously, and inexpensive countermeasures are possible.

Here, an example of a trial fabrication of an LSI of the SOI CMOS structures that have the features described above on a SIMOX substrate (described later) and the performance of a multiplier on that LSI are described. A cross-section TEM photograph of a CMOS logic LSI of 0.25  $\mu\text{m}$  gates formed on a 50-nm SOI layer is shown in Fig. 2.82. In order to reduce the parasitic resistance of the thin Si layer, a tungsten thin-film was formed by selective CVD. A four-layer wiring structure is used. The dependence of the performance of a 48-bit multiplier formed with that structure on the supply voltage is shown in Fig. 2.83. For comparison, the performance of a multiplier fabricated from the same 0.25  $\mu\text{m}$  gate CMOS form on a bulk Si substrate is also shown. For a proper comparison, the standby leak current levels of the multipliers that were compared were made the same [7]. Clearly, the lower the supply voltage, the more striking is the superiority of the performance of the SOI CMOS multiplier. From 32% higher performance at 1.5 V, the performance advantage increases to 46% at 1.0 V. Thus, the SOI CMOS

structures are a powerful solution in the quest for higher LSI performance, lower operating voltage, and lower power consumption.

### Higher Quality and Lower Cost for the SOI Substrate

Against the backdrop of the recognition of SOI CMOS as a key technology for logic LSI of higher performance and lower power consumption, the fact that SOI substrates based on Si substrates have higher quality and lower cost are extremely important. A thin-film SOI substrate that has a surface layer of Si that is less than 0.1  $\mu\text{m}$  thick serves as the substrate for forming the fine CMOS devices of a logic LSI chip. In addition, various factors of substrate quality, including the quality of the SOI layer, which affects the reliability of the gate oxide layer and the standby leak current, the uniformity of thickness of the SOI layer and the buried oxide layer and controllability in the production process, roughness of the SOI surface, the characteristics of the boundary between the buried oxide layer and the SOI layer, whether or not there are pinholes in the buried oxide layer, and the breakdown voltage, must be cleared [8,9]. Furthermore, for the production of SOI CMOS with the same production line, as is used for CMOS on bulk Si substrate, the absence of metal contamination and a metal contamination gettering capability are needed. Also, adaptability for mass production, cost reduction, and larger wafer diameters must be considered. From this point of view, remarkable progress has been achieved in thin-film SOI substrates for fine CMOS over these past several years. In particular, the SOI substrates that have attracted attention are broadly classified into SIMOX (separation by implanted oxygen) substrates and wafer bonding (WB) substrates, as shown in Fig. 2.84. A SIMOX substrate is formed by oxygen ion implantation and high-temperature annealing. Wafer bonding substrates, on the other hand, are made by bonding together a Si substrate on which an oxide layer is formed, which is called a device wafer (DW) because the devices are formed on it, and another substrate, called the handle wafer (HW), and then thinning down the DW from the surface so as to create an SOI layer of the desired thickness. For fine CMOS, a thin SOI layer of less than 0.1  $\mu\text{m}$  must be fabricated to a layer thickness accuracy of within  $\pm 5\text{--}10\%$ . Because that accuracy is difficult to achieve with simple grinding or polishing technology, various methods are being studied. Of those, two methods that are attracting attention are ELTRAN (epitaxial layer transfer) [10] and UNIBOND [11]. ELTRAN involves the use of a porous Si layer formed by anodizing and a Si epitaxial layer to form the separation layer of the DW and HW; the UNIBOND substrate uses hydrogen ion implantation in the formation of the peel-off layer. It has already been demonstrated that the application of these SOI substrates to 300 mm wafers and mass production is technologically feasible, and because this is also considered to be important from the viewpoint of application to logic LSI chips, which are a typical representative of MPUs, an overview of the technology and issues is presented in the next section.

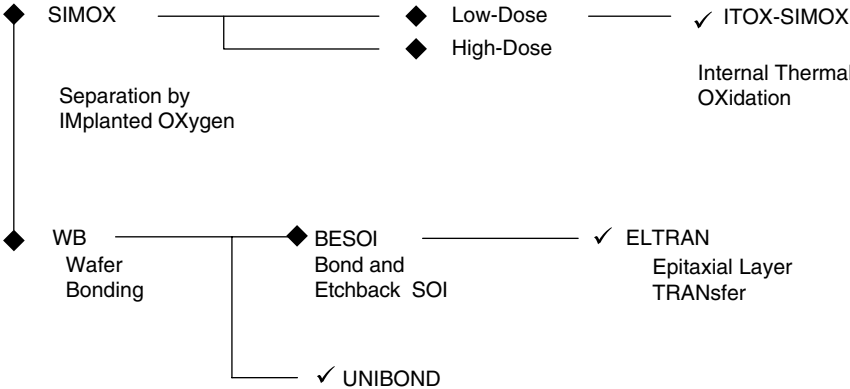

FIGURE 2.84 SOI material technologies for production.

FIGURE 2.85 Main process steps of ITOX-SIMOX.

### SIMOX Substrates

For SIMOX substrates, the buried oxide (BOX) layer is formed by the implantation of a large quantity of oxygen ions at energies of about 200 keV followed by annealing at high temperatures above 1300°C, as shown in Fig. 2.85 [4]. Because the amount of oxygen implanted and the implantation energy are controlled electronically with high accuracy, there is excellent control of the uniformity of the thickness of the SOI layer and the BOX layer. A substrate obtained by high-dose oxygen implantation in the order of  $10^{18} \text{ cm}^{-2}$  is called a high-dose SIMOX substrate and has a BOX layer thickness of about 400–500 nm. The presence of  $10^8 \text{ cm}^{-2}$  or more dislocation density in the SOI layer and the long period of time required for the high-dose oxygen ion implantation create problems with respect to the quality of the SOI layer and the cost and mass producibility of the substrate. On the other hand, it has been discovered that if the oxygen ion implantation dose is lowered to about  $4 \times 10^{17} \text{ cm}^{-2}$ , there are dose regions in which the dislocation density is reduced to below  $300 \text{ cm}^{-2}$ , resulting in high quality of the SOI layer and lower substrate cost [12]. Such a substrate is referred to as a low-dose SIMOX substrate. However, the BOX layer of this substrate is thin (about 90 nm), making it necessary to reduce the number of pinholes and other defects in the BOX layer. In later studies, it was found that a further high-temperature oxidation at over 1300°C after high-temperature annealing results in the formation of a thermal oxide layer at the interface between the SOI layer and BOX layer at the same time as the oxidation of the SOI layer surface [13]. Typically, the BOX layer thickness is increased by about 40 nm. A substrate produced with this internal oxidation processing is referred to as an ITOX-SIMOX substrate. In this way, an SOI layer can be formed over an oxide layer of high quality, even on SIMOX substrates formed by oxygen ion implantation.

### ELTRAN Substrates

Although thin-film SOI substrates for fine CMOS devices are categorized as either SIMOX substrates or wafer bonded substrates, as shown in Fig. 2.84. ELTRAN substrates are classified as BESOI (Bond and Etch-back SOI) substrates, a subdivision of the bonded substrate category. The BESOI substrate is produced by the growth of a two-layer structure that consists of the final layer that remains on the DW as the SOI layer and a layer that has a high etching speed by epitaxial growth followed by the formation of a thermal oxide layer on the surface and subsequent bonding to the HW. After that, most of the substrate is removed from the backside of the DW by grinding and polishing. Finally, the difference in etching speed is used to leave an SOI layer of good uniformity. The fabrication process for an SOI substrate produced by the ELTRAN method is shown in Fig. 2.86 [14]. First, a porous Si layer that comprises two layers of different porosities is formed by anodization near the surface of the Si substrate on which the devices are formed (DW). After smoothing of the wafer surface by annealing in hydrogen to move the surface Si atoms, the layer that is to remain as the SOI layer is formed by epitaxial growth. After forming the layer that is to become the buried oxide layer by oxidation, the DW is bonded to the HW. Next, a water jet is used to separate the DW and HW at the boundary of the two-layer porous Si layer structure. Finally, the porous Si layer is removed by selective chemical etching of the Si layer, hydrogen annealing

FIGURE 2.86 Main process steps of ELTRAN.

FIGURE 2.87 Main process steps of UNIBOND.

is performed, and then the surface of the SOI layer is flattened to the atomic level. The ELTRAN method also uses epitaxial layer forming technology, so layer thickness controllability and uniformity of the layer that will become the SOI layer are obtained.

### UNIBOND Substrates

The UNIBOND method features the introduction of the high controllability of ion implantation technology to wafer-bonded substrate fabrication technology [11]. The process of UNIBOND SOI substrate fabrication is shown in Fig. 2.87. Hydrogen ions are implanted to a concentration of about  $10^{16} \text{ cm}^{-2}$  in a DW on which a thermal oxide layer has previously been formed and then the DW is bonded to the HW. Then, after an additional annealing at low temperatures of about 400–600°C, separation from the hydrogen ion implanted layer occurs. The surface of the SOI layer is smoothed by light polishing to obtain the SOI substrate. By using ion implantation to determine the thickness of the SOI layer, controllability and uniformity are improved.

Here, three types of SOI substrates that have attracted particular attention have been introduced, but it is highly possible that in future, the SOI substrates will undergo further selection on the basis of productivity, cost, LSI yield, adaptability to large wafer diameters, and other such factors.

### SOI MOSFET Operating Modes

SOI MOSFETs have two operating modes: the fully depleted (FD) mode and the partially depleted (PD) mode. The differences between those modes are explained using Fig. 2.88. For each operating mode, the cross-sectional structure of the device and the energy band diagram for the region near the bottom of the body in the source–body–drain direction are shown. For the FD device, the entire body region is depleted, regardless of the gate voltage. Accordingly, FD devices generally have a thinner body region

FIGURE 2.88 SOI device operation modes.

FIGURE 2.89 Id-Vd characteristics in FD and PD modes.

than PD devices. For example, the thickness of the body region of a PD device is about 100 nm, but that of an FD device is about 50 nm. In the PD device, on the other hand, the body region is only partly depleted and electrically neutral region exists. The presence of the region, focusing attention on the change in potential in the depth direction of the body region from the gate oxide layer, limits the gate field effect to within the body region, and the neutral region in which there is no potential gradient exists in the lower part of the body. Accordingly, the difference in potential between the surface of the body region and the bottom of the region is greater in a PD device than in an FD device, and the potential barrier corresponding to the holes between the source and body near the bottom of the body region is higher in the PD structure than in the FD structure. This difference in potential barrier height corresponding to the holes creates a difference in the number of holes that can exist within the body region, as shown in Fig. 2.88. These holes are created by impact ionization when the channel electrons pass through the high electric field region near the drain during n-MOSFET operation. The holes flow to the source via the body region. At that time, more holes accumulate in the body region of the PD structure, which has a higher potential barrier than the FD structure. This fact brings about a large difference in the floating body effect of the FD device and the PD device, determines whether or not a kink appears in the drain current-voltage characteristic and creates a difference in the subthreshold characteristic, as shown in Fig. 2.89.

## PD-SOI Application to High-Performance MPU

An example of a prototype LSI that employs PD-SOI technology and which was presented at the latest ISSCC is shown in Table 2.4. The year 1999 will be remembered as far as application of SOI to a high-performance MPUs is concerned. In an independently organized session at ISSCC that focused on SOI technology, IBM reported a 32-bit Power PC (chip size of 49 mm<sup>2</sup>) that employs 0.25  $\mu\text{m}$  PD-SOI technology [15] and a 64-bit Power PC (chip size of 139 mm<sup>2</sup>) that employs 0.2  $\mu\text{m}$  PD-SOI technology [16]. Samsung reported a 64-bit ALPHA microprocessor (chip size of 209 mm<sup>2</sup>) that employs 0.25  $\mu\text{m}$  FD-SOI technology [17]. According to IBM, the SOI-MPU attained performance that was 20–35% higher than an MPU fabricated using an ordinary bulk Si substrate. Furthermore, in the year 2000, IBM reported the performance of a 64-bit Power PC microprocessor that was scaled down from 0.22  $\mu\text{m}$  to 0.18  $\mu\text{m}$ , confirming a 20% increase in performance [18]. In this way, the scenario that increased performance could be attained for SOI technology through finer design scales in the same way it can be done for bulk Si devices was first established. IBM is attracting attention by applying these high-performance SOI-MPUs to middle-range commercial products, such as servers for e-business etc. and shipping them to market as examples of the commercialization of SOI technology [19]. Also, many manufacturers that are developing high-performance MPUs have recently begun programs for developing SOI-MPU. Currently, PD-SOI technology is becoming the mainstream in the high-performance MPU. The characteristics of PD-SOI and FD-SOI are compared in Table 2.5. In the high-performance MPU, improvement of transistor performance through aggressive increase in integration scale is an essential requirement, and PD-SOI devices have the merit that the extremely fine device design scenario and process technology that have been developed for bulk Si devices can be used without modification. Also, as described previously, because the PD-SOI can have a thicker body region than the FD-SOI (about 100 nm), those devices have the advantage of a greater fabrication margin in the contact forming process and the process for lowering the parasitic resistance of the SOI layer. On the other hand, the PD-SOI devices exhibit a striking floating

FIGURE 2.90 Pass gate leakage.

body effect, so it is necessary to take that characteristic into consideration in the circuit design of a practical MPU.

### Floating Body Effect

PD-SOI structures exhibit the kinking phenomenon, as shown in Fig. 2.89, but IBM has reported that the most important factor in the improvement of MPU performance, in addition to reduction of the junction capacitance and reduction of the back gate effect, is increasing the drain current due to impact ionization. This makes use of the phenomenon in which, if the drain voltage exceeds 1.1 V, the holes that are created by impact ionization (in the case of an n-MOSFET) accumulate in the body region, giving the body a positive potential and thus lowering the  $V_{th}$  of the n-MOSFET, and thus increasing the drain current. The increase in drain current due to this effect is taken to be 10–15%. On the other hand, from the viewpoint of devices for application to large-scale LSI, it is necessary to consider the relation between the MOSFET  $V_{th}$  and standby leak current. According to IBM, even if there is a drop in  $V_{th}$  due to the floating body effect, there is no need to preset the device  $V_{th}$  setting for the operating voltage to a higher value than is set for bulk Si devices in the worst case for the increase in the standby leak current, which is to say, transistors that have the shortest gate lengths at high temperatures [15].

Next, consider the pass gate leak problem [15,20], which is shown in Fig. 2.90. In the case of an n-MOSFET on SOI, consider the state in which the source and drain terminals are at the high level and the gate terminal is at the low level. If this state continues longer than 1  $\mu$ s, for example, the body potential becomes roughly  $V_s - V_{bi}$  (where  $V_s$  is the source terminal voltage and  $V_{bi}$  is the built-in potential). In this kind of state, the gate voltage is negative in relation to the n-MOSFET source and drain, and holes accumulate on the MOS surface. If, in this state, the source is put into the low level, the holes that have accumulated on the MOS surface become surplus holes, and the body region–source pn junction is biased in the forward direction so that a pulsed current flows, even if the gate is off. Because this phenomenon affects the normal operation of the access transistors of DRAM and SRAM and the dynamic circuits in logic LSIs, circuit design measures such as providing a margin for maintenance of the signal level in SRAM and dynamic logic circuits are required. For DRAM, it is necessary to consider shorter refresh frequencies than are used for bulk Si devices.

Finally, we will describe the dependence of the gate delay time on the operating frequency, which is called the history effect [15,21]. As previously described, the body potential is determined by the balance between charging due to impact ionization and discharging through the body–source pn junction diode, and a change in that produces a change in the MOSFET  $V_{th}$  as well. For example, consider the pulse width relationship of the period of a pulse that is input to an inverter chain and the pulse width after passing through the chain, which is shown in Fig. 2.91. The n-MOSFETs of the odd-numbered

FIGURE 2.91 History effects.

stages have lower  $V_{th}$  than do the n-MOSFETs of the even-numbered stages. The reason for this characteristic is that the odd-stage n-MOSFETs have a high body potential due to impact ionization. This imbalance in  $V_{th}$  in the inverter chain results in the longer pulse width after passing through the chain. The time constant for the charging and discharging is relatively long (1 ms or longer, for example), so the shorter the pulse period becomes, the smaller the extension of the pulse width becomes. IBM investigated the effect of changes in the dynamic body potential during the operation of this kind of circuit on various logic gate circuit delay times and found that the maximum change in the delay time was about 8%. Although this variation in delay times is increased by the use of PD-SOI devices, various factors also produce variation when bulk Si devices are used. For example, there is a variation in delay time of 15–20% due to changes in line width within the chip that result from the fabrication process, a variation of 10–20% due to a 10% fluctuation in the on-chip supply voltage, and a variation of between 15% and 20% from the effect of temperature changes (25–85°C). Compared with these, the 8% change due to the floating body is small and permissible in the design [15].

## FD-SOI Application to Low-Power, Mixed-Signal LSI

### Features of FD-SOI Device

As we have already seen in the comparisons of Fig. 2.78 and Table 2.5, in addition to the SOI device features, the special features of the FD-SOI device include a steep subthreshold characteristic and small dynamic instabilities such as changes in  $V_{th}$  during circuit operation due to the floating body effect. In particular, the former is an important characteristic with respect to low-voltage applications. The subthreshold characteristics of FD-SOI devices and bulk Si devices are compared in Fig. 2.92. Taking the subthreshold characteristic to be the drain current–gate voltage characteristic in the region of gate voltages below the  $V_{th}$ , the drain current increases exponentially with respect to the gate voltage ( $V_g$ ). The steeper this characteristic is, the smaller can be made the drain leak current when  $V_g = 0$ , which is to say the standby leak at the time the LSI was made even if  $V_{th}$  is set to a small value. An effective way to realize low-power LSI chips is to lower the voltage. In order to obtain circuit speed performance at low-voltages, it is necessary to set  $V_{th}$  to a low value. On the other hand, because there is a trade-off between reduction of the  $V_{th}$  and the standby leak current, we can see that the characteristic described above is important [7,22]. As a criterion for steepness, the subthreshold coefficient ( $S$ ) is defined as the change in the gate voltage that is required to change the drain current in the subthreshold region by a factor of 10. This coefficient corresponds to the proportion of the change in channel surface potential with respect to the change in gate voltage. For the FD type structure, the body region is fully depleted, so the channel

FIGURE 2.92 Steep subthreshold slope in FD device.

FIGURE 2.93 No need for body contacts in FD device.

depletion layer capacitance in the bulk Si device,  $C_{dep}$ , is a series connection of the body depletion layer capacitance,  $C_{Si}$ , and the buried oxide layer capacitance,  $C_{BOX}$ , and the controllability of the gate voltage with respect to the channel surface potential is improved.

Furthermore, from the viewpoint of circuit design, the superiority of the FD-SOI device relative to the PD-SOI device is that the kink phenomenon does not appear in the drain voltage current characteristic (Fig. 2.89), and, further, that dynamic instabilities such as changes in  $V_{th}$  caused by the floating body effect during circuit operation are small [23]. As a result, there is an advantage in terms of the layout area, because there is no need for body contacts including for analog circuits, and it is also possible for the layouts and other such design assets that have been used for bulk Si to be used as they are (Fig. 2.93). An example of a prototype FD-SOI device LSI that takes advantage of the features described above that was newly announced at the ISSCC is shown in Table 2.6.

### Low-Power, Mixed-Signal LSI Application

Further advancement of portable systems in the form of wearable information equipment with a wireless interface will enable us to enjoy various multimedia applications anywhere and anytime. The realization of wearable communication devices requires lower power consumption, ultra-compactness, reduced

weight, lower cost, a wireless interface function, and a barrier-free human interface function. The key to satisfying those requirements is an analog-digital, mixed-signal LSI that integrates analog-digital conversion circuits, RF circuits, etc., and digital signal processing circuits on a single chip and also operates on ultra-low power supplies of 1 V or less (Fig. 2.94).

However, in the development of mixed-signal system LSI chips, problems arise that need not be considered in efforts to achieve finer design rules and increased integration scales for conventional digital LSIs. Examples include the improvement of analog circuit performance under low supply voltages and the reduction of the effects of cross talk noise from digital circuits on analog circuits. A promising solution for those problems is the use of FD-SOI device technology, which offers the promise of low-voltage, low-power operation.

Considering the digital circuit first, a method of reducing energy consumption by lowering the voltage and employing adiabatic charging is described. The problems associated with lower voltage operation for analog circuits and circuit technology for overcoming those problems is then discussed.

### Digital Circuits

The low-voltage, low-power trend for digital circuits is shown in Fig. 2.95. That figure is based on the supply voltage trend described in the 1999 SIA International Technology Roadmap for Semiconductors [2]

FIGURE 2.95 Low-voltage trends in digital circuits.

and shows the trend in power consumption per basic gate, normalized to the power consumption for 5 V operation. The supply voltage for 0.05  $\mu\text{m}$  generation LSI circuits is predicted to be 0.5 V in the year 2011, a reduction of two orders of magnitude from the 5 V operation of the 0.5  $\mu\text{m}$  generation. However, it is possible to realize wearable information equipment that requires ultra-low-power-consumption ahead of that low-voltage, low-power consumption time trend, even without waiting for the finer processes of 2011, by using a combination of FD-SOI devices and MTCMOS circuits [24] or adiabatic charging circuits [25]. NTT is proceeding along a low-voltage research roadmap that shows 1 V operation in the year 2000 and 0.5 V operation sometime between 2003 and 2005.

MTCMOS (Multi-Threshold CMOS) circuits [24] are an effective means to achieve lower operating voltages in digital circuits (Fig. 2.96). These circuits are constructed of MOSFETs that have two different

threshold voltages—some have a high  $V_{th}$  and others a low one. High-speed operation at low supply voltages can be achieved by using low  $V_{th}$  MOSFETs to construct the logic circuits and blocking the standby leak current that arises in these logic circuits because of the low  $V_{th}$  with power switch transistors constructed of high  $V_{th}$  MOSFETs, making it possible to apply these circuits to battery-driven devices such as wearable information equipment. A DSP (1.2 V, 20 MHz operation) that employs this technology has already been introduced in a wristwatch personal handy-phone system terminal, contributing to lower power consumption in audio signal processing [26].

Using FD SOI devices to construct the MTCMOS circuits even further improves the operation speed under low-voltage conditions [27]. By combining 0.25–0.18  $\mu\text{m}$  gate FD SOI devices and MTCMOS circuit technology, it is fully possible to implement a digital signal processing chip for a wearable terminal that operates at high speeds (100 MHz or higher) at 1 V. The performance levels of various prototype MTCMOS/SIMOX chips are listed in Table 2.7.

### Analog Circuits

#### Problems associated with low-voltage operations

We will begin with the problems concerning the low-voltage driving of amplifiers and analog switches, which are the basic circuits of analog circuits. The trends in supply voltage ( $V_{dd}$ ), cut-off frequency ( $fT$ ), and analog signal frequency ( $f_{sig}$ ) that accompany the increasingly finer scale of bulk-Si CMOS devices are shown in Fig. 2.97. These parameters are drawn from the trends related to mixed-signal LSI circuits predicted in the 1999 SIA Roadmap [2]. The supply voltage exhibits a trend toward portable devices. The reduction in signal amplitude that comes with a lower supply voltage is a critical concern for analog circuits. The lower signal amplitude causes a degradation of the signal-to-noise (S/N) ratio. Because the linear output range of the basic amplifier used in analog circuits extends from ground to  $V_{dd}$  minus about twice the  $V_{th}$  of the transistor. So, lowering of the  $V_{th}$  is essential to realizing a 1-V, operation-mixed signal LSI circuit.

On the other hand, lowering the  $V_{th}$  increases the leak current of the analog switch, reduces the accuracy of the A/D converter, generates an offset voltage in the sample-hold circuit, creates high-frequency distortion in switch-type mixer circuits, etc. The relation between the transistor  $V_{th}$  and the voltage variation caused by the analog switch leak current and the relation between the transistor  $V_{th}$  and the analog signal amplitude, when  $V_{dd}$  is 1 V, are shown in Fig. 2.98. The voltage variation values in that figure are the values calculated for an SC integrator (10 MHz sampling frequency and 1 pF integral capacitance) that uses analog switches. For a  $V_{th}$  of 200 mV, the voltage variation in the subthreshold characteristics ( $S = 85\text{--}90$  mV/dec) of bulk Si devices and PD SOI devices is 3 mV or more, and 8-bit accuracy in an A/D converter cannot be guaranteed with a 1-V amplitude input signal. FD SOI devices, on the other hand, have a steep subthreshold characteristic and the leak current can be suppressed, so the voltage variation is 1 mV or less. This feature can improve the relations among the S/N ratio, signal band, voltage variation due to leak current, etc., which are trade-offs in analog circuit design.

FIGURE 2.97 Trends in A-D, mixed signal LSI technology.

FIGURE 2.98 Relation between analog signal amplitude, accuracy, and  $V_{th}$ .

#### 1V A/D-D/A conversion circuit

To solve the analog switch leak current problem described earlier, NTT has developed a 1-V operation noise shaping A/D-D/A converter with an RC integrator that does not employ analog switches. We have also proposed a configuration in which the integrator output is either the input signal only or the quantization noise only (swing-suppression circuit Fig. 2.99) as opposed to the conventional secondary  $\Delta\Sigma$  circuit, in which the output of the two-stage integrator is the large-amplitude sum of the input signal and quantization noise [28]. In that way, it is possible to compensate the reduced dynamic range of the

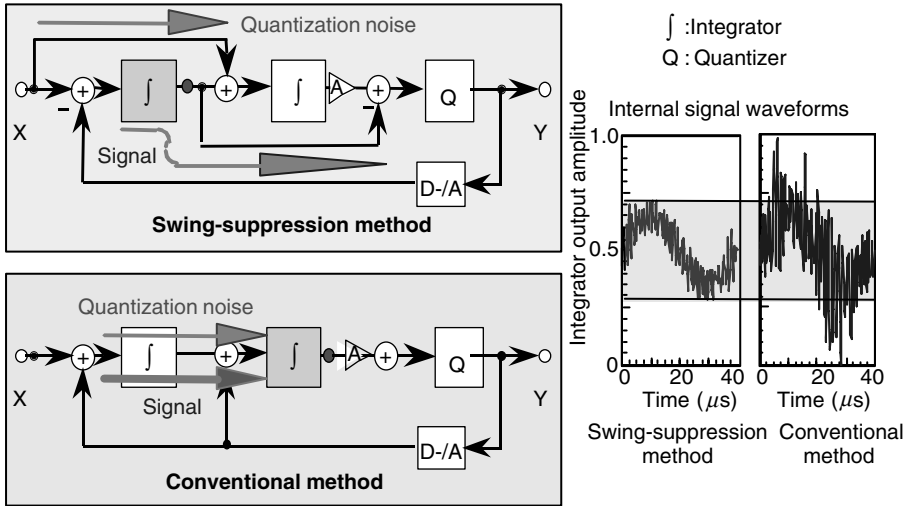

FIGURE 2.99 1 V A/D converter using the swing-suppression circuit.

FIGURE 2.100 Performance of an SOI-A/D conversion circuit.

amplifier used in the integrator that results from the reduced voltage. Using a prototype that employs 0.5–0.35  $\mu\text{m}$  gate bulk Si devices, we have already confirmed 16-bit precision conversion operation in the voice band (20 kHz) on a 1-V supply voltage with a power consumption of 3 mW or less.

To handle multimedia data such as audio, still pictures and video, it is necessary to increase the conversion speed and increase the bandwidth of the signal that can be handled. The performance of the A/D converter and an application example are shown in Fig. 2.100, along with the actual performance range for a circuit configured with 0.25–0.18  $\mu\text{m}$  gate FD-SOI devices. We expect that a broadband A/D converter, which operates on a 1-V supply voltage and can be applied to wireless communication, can be realized.

### RF circuit

Concerning the wireless interface, standardization for the next-generation mobile communications is proceeding, beginning with IMT-2000, which aims for commercial implementation in 2001 (Fig. 2.101). Among those standards, what is attracting attention with respect to the application of CMOS circuits are the wireless communication technology standards for short-range communication in the 2.4 GHz ISM band (Bluetooth and HomeRF).

A prototype 2 GHz band, 1 V, low-noise amplifier that employs 0.25  $\mu\text{m}$  FD CMOS/SIMOX devices has already been reported [29]. Moreover, RF circuit technology that allows reduction of the voltage to the limit of the elemental transistor by using tank current sourcing (TCS) technology to reduce the number of vertical stages of the transistor to 1 has recently been developed. That has made it possible to realize a 2 GHz band RF front-end circuit that operates on a mere 0.5 V [30] (Fig. 2.102).

When the communication range is 10 m or less and the transmission output is several milliwatts or less, as in the Bluetooth Class 3 standard, the entire 2.4 GHz band RF circuit that is required for the wireless interface can be configured with 0.25–0.18  $\mu\text{m}$  gate FD-SOI devices. Doing so makes it possible to implement a low-voltage, low-power consumption wireless interface circuit that operates on from 1 V to 0.5 V, thus providing a powerful wireless interface for implementing future fingertip-size communication devices.

**Cross Talk Immunity**

In a mixed-signal LSI circuit (see Fig. 2.94), it is necessary to protect the analog circuit from the effects of the noise generated by the high-speed switching of the digital circuit in order to prevent degradation of the S/N and accuracy of the analog circuit that is formed on the same chip as the digital circuit. This is a particularly important point in the implementation of the RF amplifier and high-precision A/D converter. When SOI structures are used, the insulation separation is effective for suppressing substrate cross talk noise. Furthermore, if a high-resistance SOI substrate is used, the performance of the on-chip inductor that is used in the RF circuit can be improved [31].

The effect of cross talk was evaluated experimentally by designing a circuit in which a TEG is placed near an RF low-noise amplifier and inverter chain [5]. The circuit was test-fabricated by a 0.25  $\mu\text{m}$  FD CMOS/SIMOX process with an ordinary SIMOX substrate (30–40  $\Omega\text{ cm}$ ) and with a high-resistance SIMOX substrate (1 k $\Omega\text{ cm}$  or more). The placement of the TEG is shown in Fig. 2.103. The circuit was operated by inputting a 5 MHz rectangular wave to the input pad of the inverter chain ( $V_{\text{dd}} = 2\text{ V}$ ) and the noise level was measured at the output pad of the low-noise amplifier. The noise level for the ordinary SIMOX substrate was –75 dBm, which cannot be ignored for a highly-sensitive RF circuit. For the high-resistance SIMOX substrate, on the other hand, the noise was clearly reduced to below the measurable level (–85 dBm).

It has also been confirmed that substrate noise from the digital circuit can be sufficiently reduced, even with an ordinary SIMOX substrate, by surrounding the analog circuit with an SOI guard ring and applying a positive bias to it to form a depletion layer below the buried oxide layer (Fig. 2.81). Using this guard ring technique, NTT have made a single-chip 3.5 Gb/s optical transceiver chip on a CMOS/SIMOX process [6].

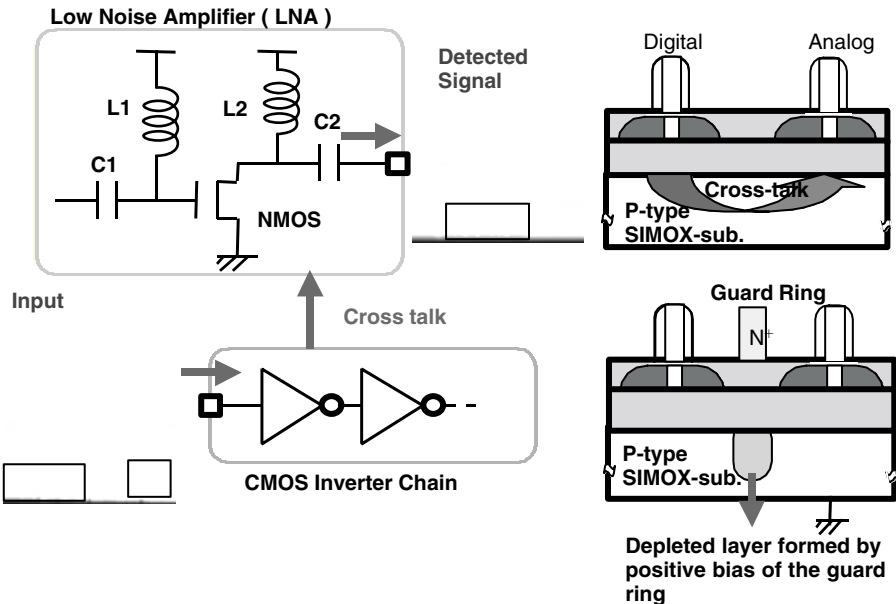

FIGURE 2.103 Cross talk evaluation circuit.

## Conclusion

An application example of an LSI chip that employs SOI devices has been described here. Against the backdrop that the SOI CMOS process has been recognized as a key technology for increasing the performance and reducing the power consumption of logic LSI circuits, there is a strong need by information distribution services for LSI chips of higher performance and lower power consumption, improvement of the quality of thin-film SOI substrates based on Si substrates, lower cost, and development of suitability for mass production. Furthermore, progress in explaining the physical phenomena of SOI devices is progressing, and another major factor is the establishment of control technology in both device design and circuit design for the characteristics that bulk Si devices do not have, especially the floating body effect. On the other hand, it is said that future LSI chips will be oriented to the system-on-a-chip era, in which memory circuits, RF circuits, analog circuits, etc., will reside on the same chip, rather than digital logic circuits alone. Although SOI structures are effective in reducing cross talk, as has already been described, problems exist concerning the establishment of a precise circuit model of the devices, which is necessary for application of SOI devices to analog circuits as well as ascertaining the influence of the floating body effect on circuit precision. It is also necessary to continue with studies on countermeasures for memory pass gate leakage in DRAM, SRAM, etc.

In the future, if progress in finer designs leads to the 0.1  $\mu\text{m}$  era, in which the standard LSI supply voltage will be reduced to about 1 V, we believe that the superiority of SOI CMOS over Si CMOS will become even more remarkable.

## High-Speed, Low-Power Emitter Coupled Logic Circuits

- 3.1 [Active Pull-Down ECL Circuits](#)
- 3.2 [Low-Voltage ECL Circuits](#)

Emitter-coupled logic (ECL) circuits have often been employed in very high-speed VLSI circuits. However, a passive pull-down scheme in an output stage results in high power dissipation as well as slow pull-down transition. Gate stacking in a current switch logic stage keeps ECL circuits from operating at low power supply voltages. In this section, a high-speed active pull-down scheme in the output stage, as well as a low-voltage series-gating scheme in the logic stage will be presented. The two circuit techniques can be employed together to obtain multiple effects in terms of speed and power.

### 3.1 Active Pull-Down ECL Circuits

---

An ECL inverter circuit is depicted in [Fig. 3.1](#), together with the simulated output voltage and pull-down current waveforms. As shown in the figure, the pull-down transition time increases much more rapidly than the pull-up transition time as the load capacitance increases. This slow pull-down transition time, and consequently unbalanced pull-up and pull-down switching speed, can cause an erroneous operation of the circuit due to signal skew or because of a racing condition.

The figure also demonstrates the disadvantageous power consumption of the circuit. The circuit requires a constant pull-down current  $I_{EF}$ . This power is consumed even when the gate output is not being switched. To reduce this power loss, the current  $I_{EF}$  must be reduced. However, reducing the current  $I_{EF}$  causes the pull-down transition time to increase to an unacceptable level. This high power dissipation and slow pull-down transition of ECL circuits has long been known to limit their VLSI applications. The power-speed limitation comes primarily from the passive pull-down scheme in the emitter-follower stage.

Various active pull-down schemes have been proposed [1–5] where a capacitor is utilized to couple a transient voltage pulse to the base of a pull-down npn transistor. An ac-coupled active-pull-down ECL (AC-APD-ECL) circuit [3] is depicted in [Fig. 3.2](#). The steady-state dc current can be kept an order of magnitude lower than in the conventional ECL gate. As for the transient action,  $C_X$  and  $R_B$  determine the magnitude of the transient collector current of transistor QD.  $C_E$  and  $R_E$  determine the time while transistor QD turns on. These capacitors and resistors should be optimized for a specific loading condition, since they determine the dynamic pull-down current. The dynamic pull-down current is predetermined for a given design. In other words, there is a finite range of loading, outside of which proper operation of the circuit cannot be ensured.

FIGURE 3.1 Conventional ECL circuit.

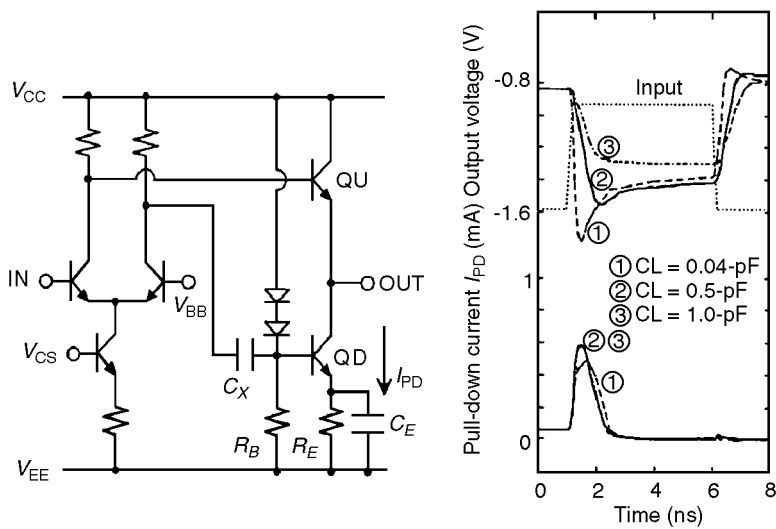

FIGURE 3.2 AC-APD-ECL circuit that is optimized to drive a 0.5-pF loading ( $C_X = 0.2$  pF,  $C_E = 1.0$  pF,  $R_B = 170$  k $\Omega$ ,  $R_E = 50$  k $\Omega$ ).

Simulated output voltage and pull-down current waveforms of the AC-APD-ECL circuit are also shown in Fig. 3.2. The circuit is optimized for a 0.5-pF loading. The simulation is performed under the 0.5-pF loading, as well as under much lighter loading, 0.04 pF, and much heavier loading, 1.0 pF. The dynamic pull-down current does not change according to the loadings. With the smaller loading, the excess pull-down current is consumed as crossover current at the end of the pull-down transition, resulting in waste of power. The excess pull-down current also causes unfavorable undershoot in the output. With the larger loading, a slowly discharging tail results, because the dynamic pull-down current is insufficient for the loading. The slowly discharging tail is dictated by the steady-state current.

FIGURE 3.3 LS-APD-ECL circuit.

Because the circuit loading condition is uncertain with cell library design methodology, large dynamic and steady-state, pull-down current are used in a macrocell to cover wide range of loadings, thus diminishing the overall power savings. The need of additional devices, such as capacitors (typically several hundreds of fF) and large resistors (typically several tens of kilohm), also causes significant area penalty and added process complexity. The increase of the cell size implies increased interconnection delay, thus degrading the chip performance.

Another example of the active pull-down scheme is a level-sensitive active pull-down ECL (LS-APD-ECL) circuit [6], as shown in the circuit schematic depicted in Fig 3.3. No additional device, such as a capacitor or a large resistor, is required. On the contrary, the circuit is a rearrangement of the conventional ECL circuit, using exactly the same devices. Therefore, the circuit can be implemented directly on existing ECL gate arrays with no area penalty. The only addition is a regulated bias voltage  $V_{REG}$  that should be biased to one  $V_{BE}$  below the “low” level.

Circuit operation is illustrated in Fig. 3.4 when the input signal is switched from “high” to “low” so that the output rises to “high.” When “low” input signal is applied, transistor Q1 is turned off and transistor Q2 is turned on, so that the current  $I_{CS}$  switches from the left side branch to the right side branch of the current switch logic stage. Consequently, the potential at node A goes up, which turns transistor QU on strongly. This allows a large charging current to flow and causes OUT to rise from “low” to “high”. Before QU switches on, the potential at node B is “low,” because  $I_{CS}$  does not flow on the right side branch initially so the potential at node B is the same as that at OUT. After QU switches on, the portion of the QU charging current corresponding to  $I_{CS}$  flows into Q2. As a result, the potential at node B drops, causing transistor QD to turn off. Once QD switches off, the major part of the charging current,  $I_{PULL-UP}$ , flows into OUT, so that the potential at OUT rises quickly. When the potential at OUT reaches the “high” level, QU turns off gradually. At the same time, the potential at node B reaches the “low” level again, gradually turning QD on. Accordingly, when the potential at OUT reaches the “high” level,  $V_{OH}$ , both QU and QD turn on slightly, and a small steady-state current,  $I_{SS(H)}$ , flows.

Pull-down action is illustrated in Fig. 3.5. In response to the input “high” signal, transistor Q1 is turned on and transistor Q2 is turned off, so that the current  $I_{CS}$  flows on the left side branch of the current switch logic stage. As a result, the potential at node A drops, causing QU to turn off initially. As Q2 turns off, the potential at node B goes up to turn QD on strongly. Consequently, a large discharge current,

FIGURE 3.4 Pull-up action of LS-APD-ECL circuit.

FIGURE 3.5 Pull-down action of LS-APD-ECL circuit.

$I_{PULL-DOWN}$  flows through QD into  $V_{REG}$ , resulting in fast pull-down of the output. As the potential at OUT approaches the “low” level, the potential at node B approaches the “low” level, causing QD to gradually turn off again. At the same time, QU turns on gradually. When OUT reaches the “low” level,  $V_{OL}$ , both QU and QD turn on slightly, and a small steady-state current,  $I_{SS(L)}$ , flows.

In this way, the circuit self-terminates the dynamic pull-down action by sensing the output level. By comparing the output voltage and the pull-down current waveforms in Fig. 3.3 with those in Fig. 3.2, it is clear that the LS-APD-ECL circuit consumes less dc current than the AC-APD-ECL circuit and that the LS-APD-ECL circuit offers larger dynamic pull-down current whose level is self-adjusted in accordance with loading conditions. Therefore, proper and balanced output waveforms can be observed in the LS-APD-ECL circuit under a wide range of loading conditions.

The collector-emitter voltage of transistor Q2,  $V_{CE,Q2}$ , is given by

$$\begin{aligned} V_{CE,Q2} &= (V_{OL} - \alpha V_{sig}) - (V_{BB} - V_{BE}) \\ &= V_{BE} - (0.5 + \alpha) - V_{sig} \end{aligned} \quad (3.1)$$

where  $V_{sig}$  is the logic voltage swing and  $\alpha$  is a constant between  $-1$  and  $1$ . As shown in Fig. 3.4,  $\alpha$  is  $0$  when the output stays and increases when the output is rising. The maximum  $\alpha$  is dependent on the output rise time; the slower, the larger. SPICE simulation predicts the maximum  $\alpha$  is between  $0.2$  and  $0.4$  when  $I_{CS} = 70 \mu A$  and  $C_L$  ranged from  $0.1$  to  $1.25$  pF and temperature ranges from  $0^\circ C$  to  $80^\circ C$ . When  $V_{sig}$  is  $0.6$  V,  $V_{CE,Q2}$  may become as low as  $0.36$  V for an instance in switching, but never stays in the saturation region.

Only inverting structures are possible in the LS-APD-ECL circuit. If the input is fed to the base of Q2 to construct noninverting structures,  $V_{CE,Q2}$  is given by

$$\begin{aligned} V_{CE,Q2} &= (V_{OL} - \alpha V_{sig}) - (V_{OH} - V_{BE}) \\ &= V_{BE} - (1 + \alpha) - V_{sig} \end{aligned} \quad (3.2)$$

In order to keep Q2 out of the saturation region,  $V_{sig}$  should be lower than  $0.45$  V, which is impractical.

Because transistor QD self-terminates at the point where the output reaches  $V_{BE}$  above  $V_{REG}$ ,  $V_{OL}$  becomes a direct function of  $V_{REG}$ . On the other hand, as  $V_{REG}$  goes lower, both QU and QD turn on more deeply, resulting in larger steady-state current. Simulated  $V_{OH}$ ,  $V_{OL}$ ,  $I_{SS(H)}$ , and  $I_{SS(L)}$  dependence on  $V_{REG}$  are shown in Fig. 3.6. In order to keep enough noise margins between  $V_{OL}$  and the circuit threshold,  $V_{BB}$ ,  $V_{REG}$  should be lower than about  $-2.2$  V. At the same time, in order to restrict  $I_{SS(L)}$  to an acceptably low level,  $V_{REG}$  should be higher than about  $-2.4$  V. Accordingly,  $V_{REG}$  needs to be controlled very tightly around  $-2.3$  V within the small error indicated in the figure.

A  $V_{REG}$  voltage regulator circuit for the LS-APD-ECL circuit is presented in Fig. 3.7. An automated bias control (ABC) circuit [7] is employed to automatically adjust  $I_{SS(L)}$  constantly even under process deviation, power supply voltage change, and temperature change. A replica circuit of the LS-APD-ECL circuit generates a reference  $V_{REG}$  level,  $V_R$ , when  $I_{SS(L)}$  is one-eighth of the current  $I_{CS}$ . A monitored  $V_{REG}$

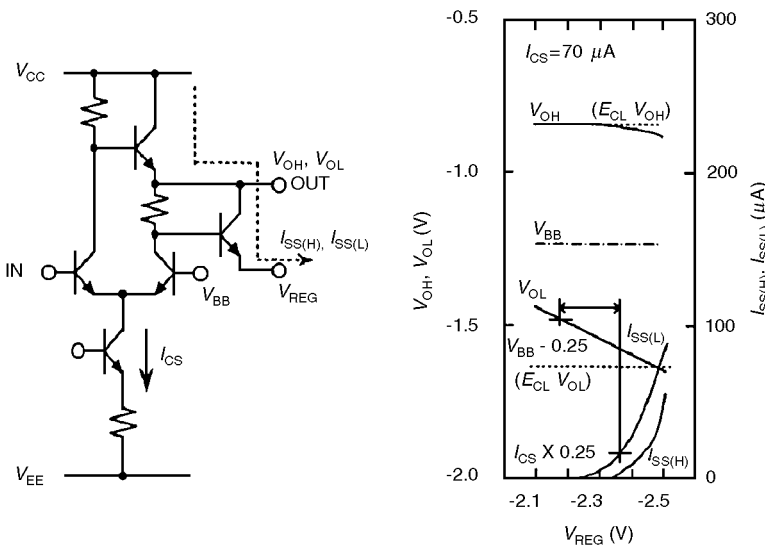

FIGURE 3.6 Output voltage and crossover current vs.  $V_{REG}$  in LS-APD-ECL circuit.

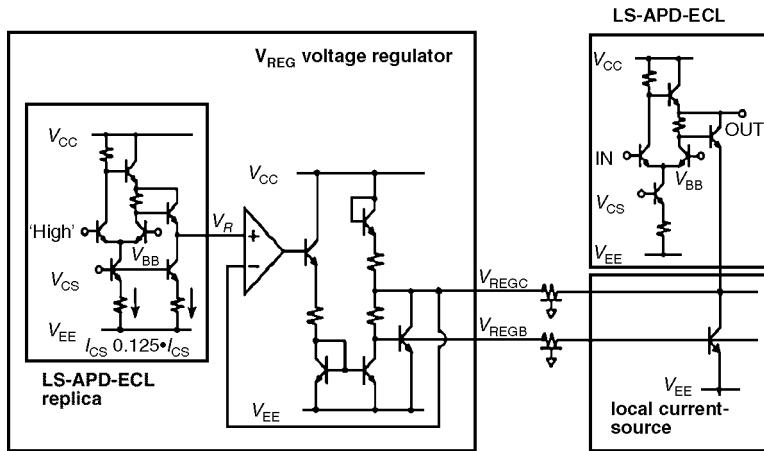

FIGURE 3.7  $V_{REG}$  voltage regulator circuit.

level and  $V_R$  are compared by an operational amplifier whose output controls  $V_{REG}$ . When the monitored  $V_{REG}$  level is lower than the target level  $V_R$ , the output potential of the op-amp rises, which increases the current in the  $V_{REG}$  voltage regulator and pushes the potential of  $V_{REG}$  up. On the contrary, when the monitored  $V_{REG}$  level is higher than the target level  $V_R$ , the potential of  $V_{REG}$  is controlled to go down. This way, the op-amp adjusts the  $V_{REG}$  level such that the LS-APD-ECL circuits which are hooked up to the  $V_{REG}$  lines have the same  $I_{SS(L)}$  as that in the replica circuit. The stability of the negative feedback loop in the  $V_{REG}$  regulator can be secured by a common method of compensation, narrow banding. A phase margin of 90 degrees is preserved when an external capacitor of 0.1  $\mu\text{F}$  is put on the  $V_{REG}$  lines.

The voltage regulator can be implemented in an I/O slot of a chip from which  $V_{REG}$  lines are provided to internal cells. Parasitic resistance along the  $V_{REG}$  lines, however, produces a significant voltage drop when large dynamic pull-down current from all the LS-APD-ECL cells is concentrated in one regulator. Therefore, a local current-source is provided in each LS-APD-ECL gate to distribute the pull-down current. Parasitic capacitance between the two lines,  $V_{REGC}$  and  $V_{REGB}$ , helps improve the transient response of the local current-source.

In Fig. 3.8 are depicted simulated dependence of the output voltages,  $V_{OH}$  and  $V_{OL}$ ; the steady-state currents,  $I_{SS(H)}$  and  $I_{SS(L)}$ ; and the circuit delays,  $T_{PLH}$  and  $T_{PHL}$ , on power supply voltage, temperature, and the number of the LS-APD-ECL gates. It is assumed in the simulation study that 8 mm by 8 mm chip area is covered by 16 by 16 mesh layout for  $V_{REGC}$  lines of 2  $\mu\text{m}$  width. The equivalent resistance between two far ends of the meshed  $V_{REG}$  lines is estimated to be 20  $\Omega$ . Even at the tip of the meshed  $V_{REG}$  lines, the tracking error can be controlled within a range of 30 mV, which is small enough to be within the allowed error range. Since the  $V_{REG}$  voltage regulator circuit controls the output voltage swing and the bias current of QU and QD constant, variation of the circuit delay can be kept very small even under the large changes in circuit conditions.

Simulated transient response of the LS-APD-ECL circuit with the  $V_{REG}$  voltage regulator circuit is depicted in Fig. 3.9 when 1100 LS-APD-ECL gates are hooked up to the  $V_{REG}$  voltage regulator, and 100 gates are switching simultaneously. Small bounce noise is observed at the  $V_{REG}$  lines, which, however, does not affect  $V_{OL}$  nor  $V_{OH}$  of staying gates, nor does it degrade the switching speed. The broken line in the figure is the output waveform of a gate placed near the  $V_{REG}$  voltage regulator, while the solid line is for a gate placed in the far end of the  $V_{REG}$  lines. Very little difference can be observed between them.

Layout of inverter gates with the conventional ECL and the LS-APD-ECL circuits are depicted in Fig. 3.10. They both are implemented on an ECL gate array [8]. The  $V_{REG}$  voltage regulator is implemented in an I/O slot from which  $V_{REG}$  lines are provided to internal cells. In a 9.6-mm by 9.5-mm chip, 24 types of gate chains are implemented for three loading conditions (fanout one plus metal interconnection of

As a reference, output waveform when  $V_{REG} = -2.3 \text{ V}$  is ideally supplied in broken lines ( $V_{out}'$ ).

0.02, 2.5, and 6.4 mm length) and three power options, for both the conventional ECL and the LS-APD-ECL circuits. The 2.5-mm metal interconnection has about 0.55 pF capacitance. The test sites are fabricated using a 1.2- $\mu\text{m}$ , 17-GHz, double-poly, self-aligned bipolar technology. Twelve wafers are fabricated in every process corner. Totally around 60,000 measurement points are obtained from 200 working samples. The logic voltage swing is 650 mV, and the power supply voltage is  $-5.2 \text{ V}$ .

Measured and simulated power-delay characteristics for the conventional ECL and the LS-APD-ECL circuits are shown in Fig. 3.11. The circles represent measurement data from several process splits. The solid lines represent the SPICE simulation results under a nominal condition. Good agreement is seen between the measurements and simulations.

FIGURE 3.10 Layout of inverter gate with ECL and LS-APD-ECL circuits.

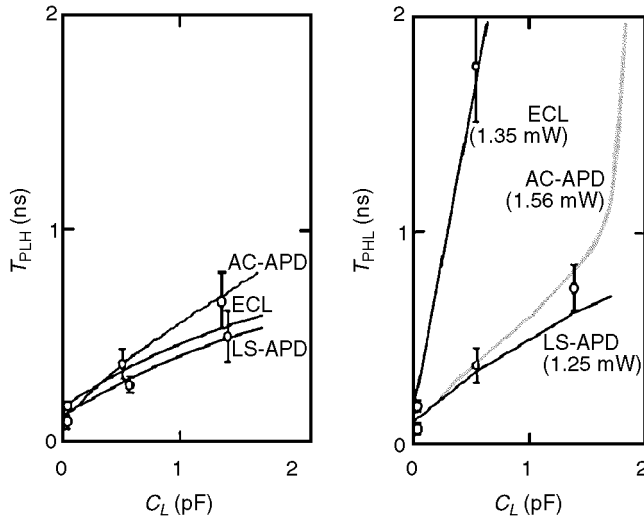

FIGURE 3.11 Power-delay characteristics for conventional ECL and LS-APD-ECL circuits.

The circuit under  $FO = 1$  plus  $C_L = 0.55$  pF (2.5 mm metal interconnection) loading condition, which is often seen in a typical chip design, offers 300 ps delay at a power consumption of 1 mW/gate. This is a 4.4 times speed improvement over the conventional ECL circuit. Furthermore, the circuit consumes only 0.25 mW for a gate speed of 700 ps/gate, which is a 1/7.8 power reduction compared with the conventional ECL circuit. A better speed improvement and power reduction can be achieved under heavier loading conditions. For example, under  $FO = 1$  plus  $C_L = 1.41$  pF (6.4 mm metal interconnection) loading condition, the speed improvement over the conventional ECL circuit is about 5.5 times at 1 mW/gate, and the power reduction is about 1/11 times at 1.2 ns/gate. Even with the lightest loading of  $FO = 1$  plus  $C_L = 0.01$  pF (0.02 mm metal interconnection), the LS-APD-ECL circuit outperforms the conventional ECL circuit. The speed improvement is about 2.2 times at 1 mW/gate, and the power reduction is about 1/2.8 times at 120 ps/gate.

In Fig. 3.12, measured and simulated delay versus capacitive loading for the conventional ECL, the AC-APD-ECL, and the LS-APD-ECL circuits are depicted. The AC-APD-ECL circuit is optimized for 0.5 pF loading, and therefore, for loadings heavier than 1.5 pF, the pull-down transition time degrades

**FIGURE 3.12** Delay vs. capacitive loading for ECL (1.35 mW/gate), AC-APD-ECL (1.56 mW/gate), and LS-APD-ECL (1.25 mW/gate) circuits. AC-APD-ECL circuit is optimized for a 0.5-pF loading. Error bar indicates three times standard deviation.

**FIGURE 3.13** Crossover current vs.  $I_{CS}$  in LS-APD-ECL circuit.

rapidly. On the contrary, the LS-APD-ECL circuit offers superior load driving capability under a wide range of loading conditions. The LS-APD-ECL circuit also provides balanced pull-up and pull-down switching speed to minimize signal skews.

The measurements of  $I_{SS(L)}$  versus  $I_{CS}$ , as plotted in Fig. 3.13, demonstrate that even under process deviation and parasitic resistance along the  $V_{REG}$  lines, the  $V_{REG}$  voltage generator keeps the steady-state current of the LS-APD-ECL circuits below one-fourth of  $I_{CS}$ .

The LS-APD-ECL circuit brings the minimum operating frequency at which ECL consumes less power than CMOS to within a range of frequencies commonly encountered in leading edge designs. Simulated power consumption versus operating frequency of sub-micron CMOS, the conventional ECL, and the LS-APD-ECL circuits are shown in Fig. 3.14. The probability of gate switching used in the simulation is 0.3, which is typically observed in VLSI circuits. The 1.2- $\mu\text{m}$  LS-APD-ECL under 5 V consumes less power

**FIGURE 3.14** Power consumption versus operating frequency of CMOS, ECL, and LS-APD-ECL circuits. The broken lines represent range of toggle frequencies of flip-flop that cannot be reached by the technology.

than  $0.5 \mu\text{m}$  CMOS under  $3.3 \text{ V}$  at an operating frequency higher than  $780 \text{ MHz}$ . In case of applications with higher probability of gate switching or with an advanced bipolar technology, the crossing frequency can further be reduced.

### 3.2 Low-Voltage ECL Circuits

Demand for low-power dissipation has motivated scaling of a supply voltage of digital circuits in many electronic systems. Reducing the supply voltage of ECL circuits is becoming important not only to reduce the power dissipation but also to have ECL and CMOS circuits work and interface together, under a single power supply on a board or on a chip.

Gate stacking in ECL is effective in reducing the power dissipation because complex logic can be implemented in a single gate with fewer current sources. This, however, brings difficulty in reducing the supply voltage. Various design techniques for low-voltage ECL have been reported before [9,10], but none of them allows a use of stacked differential pairs in three levels.

In conventional ECL circuits, input signals to the stacked differential pairs are shifted down by the emitter-follower circuit to keep all the bipolar transistors out of the saturation region.  $V_{IH}$  of the differential pairs in the  $n$ th level from the top is  $-n \cdot V_{BE}$ , where  $V_{BE}$  is the base-emitter voltage of a bipolar transistor in the forward-active region. As illustrated in Fig. 3.15, the minimum operating power supply voltage (minimum  $|V_{EE}|$ ) of a three-level series gating ECL circuit is  $4V_{BE} + V_{CS}$ , where  $V_{CS}$  is the voltage drop across a tail current source. This implies that scaling  $V_{BE}$  is the most effective means of reducing the minimum  $|V_{EE}|$ , but, in practice,  $V_{BE}$  does not scale linearly with technology and has remained constant. For  $V_{BE} = 0.9 \text{ V}$  and  $V_{CS} = 0.4 \text{ V}$ , the minimum  $|V_{EE}|$  is  $4.0 \text{ V}$ . On the other hand, the collector-emitter voltage ( $V_{CE}$ ) of the bipolar transistors is  $2V_{BE} - V_S (=1.5 \text{ V})$  in the top level and  $V_{BE} (=0.9 \text{ V})$  in the second and the third levels, where  $V_S$  is the signal voltage swing.  $V_{CE}$  can be reduced to  $0.4 \text{ V}$  without having a transistor enter the saturation region. This  $V_{CE}$  voltage headroom comes from the emitter follower circuit, shifting the signal levels down by  $V_{BE}$ .

Figure 3.16 illustrates a voltage level of signals in three-level series gating in a low-voltage ECL (LV-ECL) circuit [11]. In the LV-ECL circuit, the input signals to the top and the second levels are shifted up by current mode logic (CML) gates, and the input signals to the third level are directly provided. By adjusting the amount of the level shifting for the second level by a resistor  $R_S$ ,  $V_{CE}$  of the bipolar transistors is set to

FIGURE 3.15 Three-level series gating in conventional ECL circuit.

FIGURE 3.16 Three-level series gating in low-voltage ECL (LV-ECL) circuit.

$V_{BE} - V_S (=0.6 \text{ V})$  in the top level and  $0.5 V_{BE} (=0.45 \text{ V})$  in the second and the third levels. The minimum  $|V_{EE}|$  is  $2V_{BE} + V_{CS}$ , the same as that for a single-level ECL gate. By setting  $V_{CS} = 0.2 \text{ V}$ , the minimum  $|V_{EE}|$  of  $2 \text{ V}$  is achieved. In reality,  $V_{CE}$  may be as low as  $0.3 \text{ V}$  in switching, but never stays in heavy saturation region.

A schematic of a 4:1 MUX gate and a toggle flip-flop implemented in the LV-ECL circuit is shown in Figs. 3.17 and 3.18, respectively. Since the logic stage in the LV-ECL remains the same as that in the conventional ECL, all ECL circuits can be modified as the LV-ECL circuits.

Table 3.1 compares simulated power dissipation, circuit delay, and element count of the 4:1 MUX gate in LV-ECL with those in conventional ECL. Compared to the conventional ECL, speed and area penalties are very small in the LV-ECL, because level shifting is not required for the third-level inputs, the critical path in the conventional ECL. This compensates for the delay increase in the CML level-shifter.

A number of test circuits, such as a 4:1 multiplexer, a 1:4 demultiplexer, and a 16-bit ripple carry adder, are fabricated in a  $1.2 \mu\text{m}$ , 15 GHz bipolar technology to demonstrate the feasibility of the LV-ECL. As illustrated in Figs. 3.19 and 3.20, widely used architecture is used in the multiplexer and the demultiplexer. The test circuits are implemented on an existing ECL gate array to demonstrate that the LV-ECL circuit improves performance without design optimization of circuit or layout. Power dissipation, including

I/O Pads, is 60 mW for the multiplexer and 80 mW for the demultiplexer, both from  $-2\text{ V}$  power supply. The multiplexer occupies  $0.132\text{ mm}^2$ , and the demultiplexer occupies  $0.163\text{ mm}^2$ , both without I/O Pads.

Measured eye diagrams at the outputs are also presented in Figs. 3.19 and 3.20. Figure 3.21 shows the error-free maximum operating speed of 1.65 Gb/s for the multiplexer and 1.80 Gb/s for the demultiplexer. The LV-ECL circuit tolerates  $\pm 5\%$  variations in supply voltage with no significant degradation in speed. In these tests, a pseudo-random bit sequence of length  $2^{23} - 1$  is applied at the input.  $V_{OH}$  shows  $1.4\text{ mV}/^\circ\text{C}$  temperature dependence, the same as that in the conventional ECL.  $V_{OL}$  exhibits  $-0.7\text{ mV}/^\circ\text{C}$  over a range of  $0\text{--}75^\circ\text{C}$ , and  $3\text{ mV}/^\circ\text{C}$  for the range of  $75\text{--}125^\circ\text{C}$ . As a consequence, the output voltage swing is  $0.17\text{ V}$

If minimum  $|V_{EE}|$  is 2.2 V,  $V_{CS}$  can be 0.4 V and a bipolar current source circuit can be used instead of the resistor to provide much higher immunity to variations in supply voltage and temperature. SPICE simulation indicates tolerance to a  $\pm 10\%$  variations in supply voltage can be obtained and the output voltage swing is 0.3 V over the range of 0–125°C.

A 8:1 multiplexer and a 1:8 demultiplexer are designed in the same manner. In SPICE simulation, the power dissipation of the 8:1 multiplexer is 84 mW and that of the 1:8 demultiplexer is 136 mW, both from  $-2$  V power supply at the same maximum operating speed. Figure 3.22 shows that the LV-ECL circuit exhibits the lowest reported power-delay products in both 4-bit and 8-bit multiplexers and demultiplexers.

### 4.1 Introduction

---

When you buy a computer, you normally decide what to buy based on what the computer will do (performance) and on the cost of the computer (price). Price-performance is the normal trade-off in buying any computer.

Performance of a computer system is primarily determined by the speed of the processor. But, it may also depend on other features, such as the size of the memory, the size of the disk drives, speed of the graphics adapter, etc. You normally have a limited choice of speeds, sizes, and features that are available within an approximate price budget.

A personal computer (PC) of today is much more powerful than supercomputers of several years ago. The \$5 million CRAY-1 supercomputer of 1976 [1,2] was rated at about 100–250 million floating-point operations per second (MFLOPS) in performance. A \$1,400 PC in 2001 [3] has a performance of about 200–1000 MFLOPS. The price-performance improvements have been due to better computer manufacturing technologies and the large volume production of PCs, in the order of 100 million PCs compared with only 85 CRAY-1 computers produced.

The incredible improvement in performance of computers over time has meant that the price-performance trade-off normally improves dramatically even in a short period. The improvement trends have been predicted since 1965 by Moore's Law, which originally applied to the number of transistors on an integrated circuit doubling every 18 months [4]. The ability to predict the future price-performance of a computer system is often more important than knowing the current price of a computer, unless you need to buy your computer today. Therefore, the main thrust of this chapter is looking at historical price and performance trends to help predict the future.

Technologies other than processor speed have also been involved in the improving price-performance of computer systems. The capacity and cost of memory (currently using dynamic random access memory, i.e., DRAM), and the capacity and cost of magnetic disk drives are also critical. This chapter will concentrate on the price and performance of processors, memory, and storage.

**TABLE 4.1** Selected Categories of Computers

1960	1.0E+06	Mainframe	Corporate databases, transaction processing
1970	1.0E+07	Supercomputer	Nuclear weapons simulation, global challenge problems

The changing price-performance is seen in different ways: improved performance at the same price; same performance at a lower price; or, both improved performance and improved price. A ten-fold improvement in price-performance often gives a qualitative change that results in a different product category. For example, computers can be categorized in different ways, such as those given in [Table 4.1](#).

The price-performance of software is not discussed in this chapter. Software creation is mainly a labor-intensive activity. Therefore, the cost of creating software has been related to the cost of manpower, which is related to the rate of inflation. Some companies have outsourced software development to countries with lower labor rates, such as India. The second main factor in the cost of software is the number of people who buy a package. More sales result in lower costs for PC versions of software compared to software used on less common (bigger) computers.

## Price

The price and performance of a computer system appear to be easily definable items. But, neither price nor performance is well defined. Price is often adjusted historically for inflation. Price is often quoted in a specific currency. In global markets, changing currencies can affect pricing of components and products. In this chapter, the prices are given in United States dollars (\$) and are not adjusted for inflation.

Pricing is dependant on sales factors, such as discounts, marketing agreements, customer categories, etc. The size of the market for a product is also important for costs. Quantities affect the price based on writing off of development costs over the number of units, cost of setting up production lines, setting up maintenance and training operations, etc. Generally, computers or general technologies that are produced in large quantities are cheaper at the same performance level than less popular items.

A separate but important pricing issue is the difference between the entry price and unit pricing. For example, consider big disk drives versus floppy disk drives. The low entry price of a floppy disk drive opened a new market for low performance, high unit price (dollars per megabyte, or \$/MB) floppy drives. Big high-speed hard disk drives were more expensive to purchase, but were much lower in unit costs of \$/MB.

Computer systems are a collection of component parts, such as the CPU, memory, storage, power supply, etc. The cost of a computer system depends on the choice of the components, which change with time [5].

## Performance

The performance of computer technology depends on what you want the computer to do. Computers that are used for text processing do not need floating-point operations. Scientific computing needs heavy floating-point computation and typically high memory bandwidth.

Standard benchmark programs often exhibit a 2:1 performance range on a single computer. One comparison of the execution times of different benchmarks run on two specific computers gave performance ratios ranging from 0.54 to 17295 [6]. Performance is also dependent on the quality of the compiler or interpreter, the algorithms used, and the actual source language programs. The sieve of Erasothenes

benchmark took between 15.7 and 5115 s to run on various Z80 microprocessor systems [7]. Performance is usually based on processor performance. But, performance may be based on other features: graphics performance, sound quality, physical size, power consumption, main memory size, disk drive speed, or system configuration capability.

Speed of execution on a standard benchmark application is important for a CPU. The size in megabytes is the main measure for disk drives, although access time and data throughput are often important factors for disk drives as well. Also, nonfunctional features are often important performance features for practical computer systems. Typical nonfunctional features are: reliability, compatibility, scalability, and flexibility. These features are not as easy to measure as speed or size.

Generally, there is an upper limit to performance of a technology at any point in time: the fastest processor available, the biggest disk drive, etc. Exceeding this limit requires either the development of new technology, or parallel operation (multiple CPUs, multiple disk drives, etc.). Other constraints, such as physical size or operating power, may place an absolute upper threshold on performance. In practice, the main constraint is usually the price.

The performance of systems may be determined by marketing decisions of vendors. Rather than produce a variety of systems, a vendor may make one fast system, and slow the clock speed to produce a range of slower systems. Recently a computer vendor shipped a computer system with performance on demand—you pay to enable existing processors to be used. Thus, it may not always be possible to use the performance that is possible without paying an additional price.

## Applications

Computers in themselves are of little interest to most people. The importance is what the computer can do—the applications. A “killer app” is a computer program that causes a computer to become popular. VisiCalc, the first electronic spreadsheet program, was a killer app for the Apple II computer. Over the years there have been a number of important applications that have driven the sales of computers. Selected applications are listed in [Table 4.2](#) [8–22].

Applications normally change with time, as customers demand new features. Adding new features expands the size and usually slows the speed of the application. But, since hardware performance normally improves much more than the loss of speed due to new features, the overall application performance generally improves with time.

The characteristics of the main applications determine the important performance features for the supporting hardware technology. General-purpose computers must be capable of performing well on a variety of applications. Embedded systems may run only a single application. Business systems may require fast storage devices for transaction processing. Generally, however, fast speed, low cost, big memory and storage, and small physical size tend to be important for most applications.

## 4.2 Computer and Integrated Circuit Technology

Computers have used a variety of technologies: mechanics, electrical relays, vacuum tubes, electrostatics, transistors, integrated circuits, magnetic recording, and lasers. Changing technologies have allowed improved price-performance, resulting in faster speed, larger memories, smaller physical size, and lower cost. The main technologies where price-performance has increased dramatically are in processor performance, memory, and storage size.

The driver of current price-performance improvements is complementary metal oxide semiconductor (CMOS) integrated circuit production technology [23]. An integrated circuit starts as a \$300 slice of poly-silicon crystal. After processing, a 300 mm wafer is worth about \$5000, but may contain several hundred circuits, depending on the size of the circuit. The price of a specific circuit is dependant mainly on the size of the circuit. The size and complexity of the circuit are the main factors determining the yield of the circuit. Many circuits do not function properly due to impurities in the wafer or due to defects in the manufacturing process.

CMOS circuits make up the majority of all circuits for processors. Some special processes are required for producing specific types of circuits, such as memory chips, analog circuits, opto-electronic components, and ultra-high speed circuits. However, CMOS has become the main production technology over the last 20 years [24]. CMOS technology has improved significantly with time and will continue to improve over the next several years with some effort [25,26]. Wafer sizes have grown, and the sizes of features (line widths) on the circuit have been reduced. The speed and cost of CMOS circuits improve with smaller line sizes. As the feature size decreases by the scaling factor  $\alpha$ , the gate area and chip size decrease by  $\alpha^2$ , the speed increases (the gate delay decreases) by a factor of  $\alpha$ , and the power decreases by a factor of  $\alpha$  [23]. These scaling rules have been used for some time. However, with the small features sizes used now, other effects also limit the speed. Table 4.3 shows selected features about the improvement of integrated circuits over time [25–36].

The improvements in line widths, chip sizes, and speed should continue for several years. The International Roadmap for Semiconductors [36] outlines the expected improvements in technology. Samsung has already demonstrated a 4-GB DRAM chip [37]. Current fast production CMOS integrated circuit processes use line widths of 0.18  $\mu\text{m}$  and are moving to 0.13  $\mu\text{m}$  [38].

## 4.3 Processors

---

Early processors were based on mechanical devices. Later electro-mechanical relays were used to build computing devices [9]. Electronic digital computers were developed using vacuum tubes in the mid 1940s [10,11]. Transistors took over in early 1960s because of higher reliability, smaller size, and lower power consumption [17]. In the late 1960s, standard integrated circuits started to become available and were used in place of discrete transistors [19]. Integrated circuits allowed a high density of transistors, resulting in faster computers with lower price, lower power consumption, and higher reliability due to improved interconnections. The increasing complexity of integrated circuits, as outlined by Moore's Law, allowed building ever increasingly complex microprocessors since the early 1970s [29].

Processors have become categorized by application and particularly by cost and speed. In the 1970s, the main categories were: microcomputers, minicomputers, mainframes, and supercomputers. About 1990, the fastest microprocessors started to overtake the fastest processors in speed. This has meant that new categories are often used, as almost all computer systems are now microprocessors or collections of microprocessors.

The performance of processors is based mainly on the clock speed and the internal architecture. The clock speed depends primarily on the integrated circuit process technology. Internal pipelining [39], superscalar operation [40], and multiprocessor operation [41] are the main architectural improvements. RISC processors simplified the internal processor structure to allow faster clock operation [42,43]. Internal code translation has allowed complex instruction sets to execute as sets of micro-operations with RISC characteristics. The goal of architectural improvements has been to improve performance, measured by the execution time of specific programs. The execution time equals the instruction count times the number of clock cycles per instruction (CPI) divided by the clock speed. RISC processors increased the instruction count, but improved the CPI, and allowed building simpler processors with faster clock speeds. Fast processors became much faster than the memory speed. Cache memory is used to help match the slower main memory with the faster CPU speed. Increased processor performance comes with increased complexity, which is seen as increased number of transistors on the processor chip. In current processor chips, the on-chip cache memory is sometimes larger than the processor core. Future processor chips are likely to have multiple processor cores and share large on-chip caches.

Processors have been designed to operate on various word sizes. Some early computers worked with decimal numbers or variable-sized operands. Most computers used different numbers of binary digits; 4, 8, 12, 18, and 36 bits were used in some computers. Most current computers use either 32 bits or 64 bits word-lengths. The trend is toward 64 bits, to allow a larger addressing range. Comparing the performance of different word-length computers may be difficult. Smaller word-lengths allow faster operation in a cheap processor with a small number of transistors and minimal internal wiring. But, processors with more address bits allow building larger and more complex programs, and allow easy access to large amounts of data. A common pitfall of designing general purpose computers has been to provide too small an address space [43]. Generally, word size and addressing space of processors have been increasing with time, driven roughly by the increasing complexity of integrated circuits.

Early microprocessors had small 4 or 8 bit word-lengths (see [Table 4.4](#)). The size of the early integrated circuits limited the number of transistors and thus word-length. The very cheapest current microprocessors use small word-lengths to minimize costs. The most powerful current general purpose microprocessors have 64 bit word-lengths, although the mass market PCs still use 32 bit processors. [Table 4.4](#) shows some of the features of selected Intel microprocessors [32,34,35,44,45].

The fastest processors are now microprocessors. The latest Pentium 4 processor (in March 2001) has a clock speed of 1.5 GHz. The distance that light travels in one clock cycle at 1.5 GHz (667 ps) is about 20 cm.

Electric signals are slower than light. This means that the dimensions that a signal must travel within a clock cycle are very small, and almost certainly must be within a single integrated circuit package to achieve results within a single cycle.

Computer systems, which exceed the processing performance of the fastest microprocessor, must use multiple processors in parallel. Multiple processors on a single chip are starting to appear [46]. PCs with multiple processors are becoming more frequent, and many operating systems support multiprocessor operation. The largest computers [47] are collections, or clusters of processors.

## Measuring Processor Performance

No single number can accurately represent the performance of a processor. But, there is a need to have such a number for general comparisons [48].

Processor performance was originally measured by the time required to add two numbers [49,50]. In 1966, Knight [51] built a more complex model to compare 225 computers starting with the Harvard Mark I. He generated performance measures for scientific applications and for commercial applications and calculated price-performance information. His plots showed the improving price-performance with time. Other early approaches to measuring performance included benchmarks, synthetic programs, simulation, and the use of hardware monitors [52].

Standard benchmark programs started to become popular for estimating performance with the creation of the Whetstone benchmark in 1976 [53,54]. Other benchmark programs were widely used, such as Dhrystone for integer performance [55] and the sieve of Eratosthenes [7] for simple microprocessor performance.

Computerworld reported computer system performance and prices for many years [56–69]. The company's tables reported performances compared systems with standard computers, such as the IBM 360/50 [56,57] or IBM 370/158-3 [58–66]. The IBM 370/158-3 was roughly a 1 million instructions per second (MIPS) machine. MIPS and MFLOPS were widely used as performance measures. But, MIPS and MFLOPS are not well regarded due to the differences in what one instruction can perform on different systems. Even the conversion between thousands of operations per second (KOPS) and MIPS is fuzzy [70].

The Standard Performance Evaluation Corporation was set up as a nonprofit consortium to develop good benchmarks for computing applications [71]. The initial CPU performance benchmark, the SPECmark89, used the VAX 11/780 performance as the base rating of 1 SPECmark. The benchmark consisted of several integer and floating point oriented application program sections, selected to represent typical CPU usage. The SPECmark was a geometric mean of the ratios of execution time taken on the target machine compared with the base machine (VAX 11/780). This was an excellent quality benchmark for measuring CPU

performance. Extensive lists of SPECmark89 results were reported [72]. Over time, people optimized their compilers to get uncharacteristically good performance from some parts of the benchmark. The SPEC consortium then created a new pair of benchmarks, SPECint92 and SPECfp92, using new application program code. The cpu92 benchmarks measured typical integer performance, typical of system programming and office uses of computers, and floating point performance typical of scientific computing. These benchmarks also used the VAX 11/780 = 1 as the base machine. As well, base and rate versions of the cpu92 benchmarks were defined. The base measures required using a single setting for the compilers for running the benchmarks, rather than optimizing the compiler for each component program. The rate benchmarks measured the throughput of the computer by running multiple copies of the programs and measuring the completion time. SPECrate is a good measure of performance for a multiprocessor system. Extensive results are available for SPECint92, SPECfp92, SPECint\_base92, SPECfp\_base92, SPECint\_rate92, SPECfp\_rate92, SPECint\_rate\_base92, and SPECfp\_rate\_base92 [73].

SPEC released new versions of the CPU benchmarks in 1995 and in 2000 [71]. The new benchmark versions were created for two main reasons: to ensure that compiler optimizations for the older versions did not mask machine performance and to use larger programs that would exercise the cache memory hierarchy better. SPECint95 and SPECfp95 use the Sun SPARCstation 10/40 as the base machine instead of the VAX 11/780. Extensive results have been collected for the SPECcpu95 benchmarks [74]. The SPECcpu2000 benchmarks are relative to a 300-MHz Sun Ultra5\_10, which is rated as 100 [71]. SPECcpu2000 results, which include base and peak versions of cint and cfp with the rate results, are listed at the SPEC Web site [75]. The difference in base machines among the SPECcpu benchmarks makes direct comparisons of performance difficult. However, the SPECcpu benchmarks are the best measures available for general processor performance.

Many other benchmarks exist and are used for comparing performance: SPEC has many other benchmarks [76]; LINPAC [77] is used for comparing very large computers; STREAM [79] compares memory hierarchy performance; the Transaction Processing Council [80] has created several benchmarks for commercial applications; etc. The main advice to people buying computers is to use the actual application programs that they will be running to evaluate the performance of computer systems. But, some standard number to describe system performance is always a good starting point. Table 4.5 lists the performance and price for several selected computer systems over time. Note that the performance ratings should only be used as a rough indicator, and should not be used to directly compare specific machines. Similarly, the prices may correspond to very different configurations of machines.

The performance estimates have been normalized to a single comparison number for each computer. The number is a rough MIPS estimate, where a VAX 11/780 is considered to be a 1-MIPS processor. Estimates of prices were available for over 300 systems. Price-performance ratios were calculated in MIPS per dollar. These are plotted against the year and are shown in Fig. 4.1. The data in Fig. 4.1 and Table 4.5 were calculated from many sources [1,12,13,16,17,19,47,49,51,56–75,81–97].

## 4.4 Memory and Storage—The Memory Hierarchy

---

The memory hierarchy includes the registers internal to the processor, various levels of cache memory, the main memory, virtual memory, disk drives (secondary storage), and tape (tertiary storage). Memory devices are used for a variety of functions. Basically, any computer system needs a place from which a program with its data is executed. There is a need for storing program files and data files. Files need to be backed up, with the ability to move the backup files to another location for safety. A mechanism is needed to support the distribution of programs and data files. Not all devices are suitable for all functions. Some devices are used mainly to get an increase in performance. The remaining functions are generally necessary for general-purpose computer systems, and some device must be selected to implement each function. Table 4.6 lists the storage functions, and several categories of memory and storage device used over time to implement the functions. For example, nonvolatile memory cartridges could be used for all of the storage functions necessary for a computer system, if speed, capacity, and price were satisfactory.

The price-performance characteristics of different memory and storage technologies help determine their roles in computer systems. The main trade-off is between access time and cost (measured in \$/MB). Figure 4.2 shows a rough 2001 pricing (in \$/MB) of various memory and storage media versus access time. Both the media cost and access times of devices generally improve with time. But, the main improvements are in the cost of storage capacity with time.

## Primary Memory

Primary memory is made up of the main memory and cache hierarchy. The role of cache memory is to match the fast speed of the processor to the slower main memory. In earlier processors, there was little speed mismatch. Recent microprocessors are much faster than main memory, and the speed mismatch is growing [79]. Cache memory is much more expensive per byte than main memory, but is much faster. In the memory hierarchy, the important speed factor for cache memory is the latency or access time. The cache needs to keep the CPU's instruction queue and data registers filled at the speed of the CPU. For bulk main memory, the important speed factor is bandwidth, to be able to keep the cache memory filled. To accomplish this, the slower main memory normally uses a wide data path to transfer data to the cache. Most recent microprocessors

use multiple levels of cache to smooth the speed mismatch. Memory system design for multiprocessor systems is complicated by needs of coherent cache and memory consistency [43]. Current fast processors can lose in the order of one half of their performance due to the imperfect behavior of the memory system.

Main memory in electronic digital computers began as flip-flops implemented using vacuum tubes. Other early memory devices were mercury ripple tank, electrostatic tube storage, and magnetic drum storage (IBM 650). Magnetic core memory was developed in the Whirlwind project and was cost effective for a long period, until integrated circuit RAM devices replaced core memory in the late 1970s.

Static RAM, which is used for cache memories, normally uses 4–8 transistors to store 1 bit of information. Dynamic RAM, which is used for bulk main memory, normally uses a single transistor and a capacitor for each bit. This results in DRAM being much cheaper than SRAM. SRAM was used in some early microcomputers because the design of small memories was much easier than using DRAM.

The speed of memory has been improving with time. But, the improvements have been much slower. Table 4.7 shows the cost and access times (speed) of selected memory devices over time. New versions

FIGURE 4.3 Cost of memory with time.

of DRAM memory devices have been developed to improve on both bandwidth and latency. Standard DRAM has progressed through fast-page mode (FPM) DRAM, to extended-data out (EDO) DRAM, to synchronous SDRAM, RAMBUS, dual-data rate (DDR), DDR2, and quad data rate (QDR). The newer synchronous designs attempt to maximize the bandwidth per pin so that fast high bandwidth transfers of data are possible from main memory to the cache memory.

The price of memory has dropped dramatically with time. At the same time, the size of memory in computer systems has grown. The cost of the memory used in a typical 2001 PC (64 MB) would have cost about \$10 million in 1975. Figure 4.3 shows the decreasing cost of memory (in \$/MB) over time.

The data for Fig. 4.3 and Table 4.7 come from several sources. Phister [14] gives data for early computers up to the mid 1970s. Memory prices were collected from advertisements in various magazines through different periods: *Radio-Electronics* (1975–78), *Interface Age* (1979–1983), *BYTE* (1984–1997), and *PC Magazine* (1997–2001). The magazines were scanned to find the lowest price per bit for memory mounted on boards, or SIMMs, or DIMMs for easy installation in a computer system. Summaries of recent data are harder to collect because advertisements with price information have mainly moved to the Internet, where historical information is not retained.

Note the small increases in memory prices in 1988, 1994, and again in 2000 in Fig. 4.3. The short-term rises in the price of memory were unexpected, because in the long term the improvement in integrated circuit technology keeps forcing the price down. Thus, short term memory pricing can be difficult to predict. But, longer term pricing is fairly predictable. It takes several years for new memory chip generations to move from the laboratory to mass production. Currently, 256 Mbit memory chips are production devices. But, a prototype 4 Gbit DRAM memory chip was constructed by Samsung [37], using a 0.10- $\mu\text{m}$  process with an overall size of 643 mm<sup>2</sup>. Production 4 Gbit memory chips are likely after 2005.

## Secondary Memory

The size of secondary memory has also increased dramatically, as the price of disk storage dropped. The first hard disk drive was the IBM 305 RAMAC developed in 1956. It held a total of 5 MB on fifty 24-in. disk platters. Fixed disk drives allowed fast access to data and were much cheaper per byte than using fixed head magnetic drum memories. Next, removable pack disk drives were developed. Removable disk packs had low cost per byte based on media cost. But, the high cost of the drive meant that cost of the online files were higher. The relative advantages and disadvantages of removable pack drives versus fixed

disk drives meant that removable packs were widely used in the 1960s and 1970s. Fixed disk drives became more common after the mid 1970s, mainly due to their lower cost of storage.

The main performance factor for disk drives is the cost of storage in dollars per megabyte. Data is stored in circular tracks on disk surfaces. The more bits per inch along the track and the more tracks per inch across the surface, the higher the storage capacity of the disk surface [98]. Adding more disk platters, with two surfaces per platter, increases the storage capacity of the drive.

The main measures of speed are: seek time, rotation speed, and data transfer rate. The seek time is the time to move the read/write head to the track. The rotation speed determines the time for the disk to rotate to the start of the data. The maximum media transfer rate is the speed at which the data is read from the disk, which depends on the rotational speed and the density of bits along the track. Several other factors affect the operational speed of a disk drive. These include: head settling time; head switching time; disk controller performance; internal disk cache size, organization, and management; disk controller interface; and data access patterns (random versus sequential access).

Disk drive development currently concentrates on improving the density of information on the disk drive, increasing the rotational speed of the disk platters, speeding up the motion of the read/write heads, improving the disk cache performance, and speeding up the disk transfer rate with faster controllers.

Early large computer disk drive technology improved by a factor of 10 in price per megabyte about every 11 years [5] compared with about five years for main memory. But, the cost of disk drive units was high [99]. Floppy disk drives dramatically reduced the entry level cost for magnetic storage, although the unit cost (\$/MB) was high. The development of small hard disk drives for the PC accelerated the rate of improvement in price-performance.

Early disk drives were about 1000 times cheaper per megabyte than main memory. Recent disk drives are about 20–50 times cheaper than main memory. Figure 4.4 shows the improving in the cost of disk capacity with time. Table 4.8 gives characteristics for selected hard disk drives. The data for Fig. 4.4 and Table 4.8 are taken from several sources. Phister [14] provides disk price and performance data for early disk drives. Pricing data for floppy disk drives and more recent hard disk drives were collected from advertisements in *Interface Age* magazine (1979–1984), *BYTE* (1983–1997), and *PC Magazine* (1997–2001). The advertisements were scanned periodically to find the lowest cost capacity. Technical specification for many drives were taken from the Tech Page Web site [100] and Web sites for Maxtor [101] and IBM [102].

RAID technology improved the number of random input–output operations that could be performed per second (IOPS) [43]. RAID also improved the reliability for collections of small standard disk drives compared with large system disk drives. Large system disk drives have generally been replaced with standard small, high capacity, high performance 3.5 in. disk drives. These are used singly in desktop

personal computers and in multiple drive configurations with RAID controllers in large computer systems. Smaller drives were developed for portable laptop computers, mainly 2.5-in. drives and 1-in. drives for smaller PDA and portable devices. However, solid-state flash memory cartridges are starting to replace small capacity disk drives. Although they are more expensive per megabyte, they have a lower entry price, are physically smaller than disk drives, and are more rugged for portable operation. Currently, 3.5-in. hard disk drives are the main production drives with the best price and performance characteristics.

## Tertiary Memory

Tertiary storage is used mainly for backing up files and for transportation and distribution of programs and data. The major concern here is for storage for file backup and restore. Magnetic tape is the main storage medium used for tertiary storage. However, punched cards, paper tape, removable disk packs, and optical disks have been used. Packaged magnetic tape cartridges are the most popular format of tape for backup.

Backup includes frequently incremental and full backup copies created in a backup pattern [103]. Often there may be 20–40 tapes retained in a backup cycle for a single file system. Media cost is therefore very important. It can take a few hours to read or write one tape cartridge. Therefore, transfer speed of data from the computer to the tape is also important. After creating a backup tape, it is useful to verify that the tape was written correctly. It is necessary to remember that the reason for making a backup is to be able to restore the data at some future time.

IBM created the IBM 701 tape drive in 1952. Reel-to-reel tapes were popular until about 1990. Helical scan cartridges and linear scan tape cartridges became popular about that time. Early QIC tapes had similar storage cost to magnetic tape drives. Later, Exabyte 8-mm tape drives and 4-mm digital audio

tape (DAT) cartridges were used for low-cost storage. The digital linear tape (DLT) cartridge became the most popular backup tape format. Similar to 8 mm, DAT, and other tape formats, DLT has undergone a number of revisions to increase the tape capacity and to improve the data throughput rate. The latest SuperDLT has a capacity of 113 GB on one cartridge and a throughput rate of 11 MB/s (about three hours to write one tape). The main consideration is that a backup tape system must keep pace with the increase in storage capacity of disk drives. The other device types listed in [Table 4.6](#) for backup have generally not met the low cost of media required for large-scale backup.

## 4.5 Computer Systems—Small to Large

---

A typical general-purpose computer system consists of a processor, main memory, disk storage, a backup device, and possibly interface devices such as a keyboard and mouse, graphics adapter and monitor, sound card with microphone and speakers, communications interface, and a printer. The processor speed is normally used to characterize the system—a 1.5 GHz Pentium-4 system, etc. But, the processor is only a portion of the cost of the system [5]. Using a slightly faster processor will likely cause little change in the performance seen by the owner of a personal computer, but is important for a multiuser server.

General-purpose desktop PCs for single users are common. PCs are cheap because millions are produced per year by many competing vendors. Millions of portable laptops, notebooks, and PDA devices are also sold every year. Currently, the laptops and notebooks are more expensive than desktop computers because of a more expensive screen and power management requirements. Workstations are similar to personal computers, but are produced in smaller quantities, with better reliability and packaging. Workstations are more expensive than PCs primarily due to the smaller quantities produced.

Servers have special features for supporting multiple simultaneous users, such as more rugged components, ECC memory, swappable disk and power supplies, and a good backup device. They normally have some method of adding extra processors, memory, storage, and I/O devices. This means more components and more expensive components than in a typical PC. There is extra design work required for the extra features even if not used, and there are fewer servers sold than PCs. Thus, servers of similar capability will be more expensive.

In large servers, reliability and expandability are very important, because several hundred people may be using them at any time. Designing very high-speed interconnect busses to support cache coherence across many processors sharing common memory is expensive. Special bus interconnect circuitry is required for each board connecting to the system. Large servers are sold in small quantities, and the design costs form a large percentage of the selling price. Extensive reliability testing means that the large servers are slower to use the latest, fastest CPUs, which may be the same as are used in PCs and workstations. Additional processors or upgraded processors may directly increase the number of users that can be supported, making the entire system more valuable. Often, chip manufacturers charge double the price for the fastest CPU they produce, compared with a 10% lower speed CPU. People pay the premium for the overall system performance upgrade, particularly in the server market.

Another approach to improving computer system performance is to cluster a few computers [104]. Cooperative sharing and fail-over is one type of cluster that provides enhanced reliability and performance. Other clusters are collections of nodes with fast interconnections to share computations. The TOP500 list [47] ranks the fastest computer systems in the world based on LINPACK benchmarks. The top entries contain many thousand processors.

Beowulf clusters [105] use fairly standard home PCs to form affordable supercomputers. These clusters scale in peak performance roughly with price. But, like most cluster computers, they are difficult to program for obtaining usable performance on real problems.

An interesting approach to low-cost computational power is to use the unused cycles from underutilized PCs. The SETI@home program distributed client programs to PCs connected to the Internet to allow over 2 million computers to be used for computations that were distributed and collected by the SETI program [106]. SETI@home is likely the largest distributed computation problem in existence and forms the largest computational system.

## 4.6 Summary

---

The performance of computer systems has increased dramatically over time, and it is likely to continue for many years. The price of computers has dropped in the same period, both generally and for entry-level systems. These price-performance improvements have created new opportunities for low-cost applications of computers, and created a market for millions of PCs per year.

Price and performance are not easy to define except in specific applications. We can generally predict approximate price and performance levels of general-purpose computers and their main components. But, the predictions based on historical trends and current estimates are subject to large variations. The actual performance of a computer depends on what the user wants the computer system to do, and how well, or how fast the computer does that task. The price depends on the circumstances of the purchase.

It is usually possible to trade-off price for performance and vice-versa within ranges. You can buy a faster processor up to a point. Beyond the maximum speed, it is necessary to use multiple processors to obtain more performance. The optimal price-performance for a computer system is likely to be what the majority of people are buying (an entry-level PC), bought only when it is necessary to use it. For bigger systems, use collections of shared memory or distributed microprocessors. Alternatively, for SETI@home, use other people's computers.

It is a truism that computers have become ubiquitous and portable in the modern world: Personal Digital Assistants, as well as many various kinds of mobile computing devices are easily available at low cost. This is also true because of the ever increasing presence of the Wide World Web connectivity. One should not forget, however, that these life changing applications have only been made possible by the phenomenal

advances that have been made in device fabrication and more importantly in the architecting of these individual components into powerful systems.

In the 1980s, advances in computer architecture research were most pronounced on two fronts: on the one hand, new architectural techniques such as RISC made their appearance and revolutionized single processor design and allowed high performance for the single chip microprocessors which first came out as system components in the 1970s. At the same time, large-scale parallel processors became mature and could be used by researchers in many high-end, computationally intensive, scientific applications.

In recent times, the appetite of Internet surfers has been fueling the design of architectures for powerful servers: in Section 5.1 “Server Computer Architecture,” Siamack Haghighi emphasizes the unique requirements of server design and identifies the characteristics of their applications.

In Section 5.2, Binnl Matthews describes the VLIW (Very Long Instruction Word) processor model, compares it to more traditional approaches of Instruction Level Parallelism extraction, and demonstrates the future of VLIW processors, particularly in the context of multimedia applications.

Similarly, multimedia applications have promoted a dual architectural approach. In Section 5.3 “Vector Processing,” Krste Asanovic traces the ancestry of vector processors to the supercomputers of the 1980s (Crays, Fujitsu, etc.) and describes the modern applications of this architecture model.

Architectures cannot be evaluated independently of the underlying technology. Indeed, nowadays, while deep-submicron design rules for VLSI circuit are allowing increasing numbers of devices on the same chip, techniques of multiprocessing are seeing additional applications in different forms which range from Networks Of Workstations. Portability, all the way to multiprocessing on a chip, is the topic of Section 5.4 “Multiprocessing, Multiprocessing,” by Manoj Franklin.

Taking concurrent processing to the next level, Donna Quammen surveys parallel systems in Section 5.5 “Survey of Parallel Systems,” including large-scale tightly coupled parallel processors.

Finally, in Section 5.6 “Virtual Memory Systems,” Bruce Jacob surveys the concepts underlying virtual memory systems and describes the tremendous advances this approach has undergone since first being proposed in the late 1960s.

### Introduction

Widespread availability of inexpensive Internet access and powerful computers has resulted in considerable business productivity improvement. Electronic automation of business operations and Internet communication has resulted in many profitable electronic or “e” business models such as e-commerce. The cost-saving potential has required many modern companies to automate their traditional manual customer interface operations and processing through Web technologies. Businesses rely on enterprise information technology (IT) computing and communication infrastructure as a backbone for their operations. It is estimated that the current e-commerce revenues exceed hundreds of billions of dollars in the U.S. alone.

Availability of robust, reliable, secure, and cost-effective IT infrastructure is one of the key drivers of the new Internet-based businesses. Customer usage models and applications also affect IT infrastructure performance, operation, and cost. IT infrastructure hardware and software requirements can be met cost effectively with client–server computing paradigm. Although not a new idea, availability of inexpensive high performance microprocessors, scalable computing and storage systems, and high bandwidth networks make client–server computing model an ideal fit. Shared data storage and backup, infrastructure cost, reliability, serviceability, and availability are some of the other reasons for adoption of client–server computing. Powerful central processing units (CPU), reliable and available memory system, scalable input/output (I/O), advanced software, and services and packaging are some of the elements of servers. This chapter will highlight some of the architecture, design, deployment, usage model, and application of servers.

# Client-Server Computing

Client-server computing was developed to address cost-effective computing and communication capability. Clients use low cost terminals to make service requests from servers. In this manner, server costs and services are shared between all users and minimized. Figure 5.1 depicts client-server information processing model.

In late 1970s and early 1980s, business computing and communication infrastructure needs were met via one or more centralized mainframes connected to user terminals via networks. Figure 5.2 illustrates this model. In most cases, client low-computing-need program processes are executed on the terminals while mainframe servers execute the more expensive request-handling programs. The mainframe servers provided a centralized resource for most computing needs as well as other tasks such as data storage, external network interfaces, and task management. In late 1980s and early 1990s, the enterprise IT evolved due to advent of personal computers (PCs) fueled by the availability of inexpensive powerful microprocessors. In the new IT infrastructure, many of the tasks previously provided by the servers were processed locally by the PCs.

In late 1990s and now, explosive growth of Internet as the common communication medium has resulted in yet another change to the IT infrastructure. Due to advent of World Wide Web (WWW) and other related technologies, many e-commerce businesses electronically automate customer request processing. Some of the characteristics of the new environment are:

- Simple and robust user interfaces (typically Web-based services) for customer entry request entry and response display
- High-speed networks for data transmission
- Powerful centralized systems to handle data storage, transaction processing, and inventory management

## Server Types

Servers are optimized for cost, performance, support, and the usage model. An e-commerce transaction-processing server will require fast network interface for quick user response, powerful central processing unit (CPU) to handle database management, and scalable architecture for possible future enhancements. An e-commerce server needs to be reliable and secure, without securing issues such as fraud, to ensure good customer experience. A variety of servers such as proxy, Web cache, data processing, communication, video, file, and compute are used.

A server needs to be optimized for most frequently used applications and the usage model. Typical server configurations have several high performance CPUs, large system memory size, and support for high-speed I/O for storage systems and network interfaces. As an example, a file server is cost-optimized by using several CPUs, high-speed network interface and extensive storage subsystems. Using more powerful CPUs than a file server and large amount of system memory are the optimizations used for a compute server. A compute server may be further optimized to run specific applications such as transaction processing. Configuration of the hardware elements and software tuning are used to ensure peak performance and lowest-cost infrastructure.

## Server Deployment Considerations

Optimal server deployment requires many requirements. For example, Internet service providers' (ISP) servers have extensive communication network capabilities. In this section, some of these issues will be detailed.

### Server Features

A term commonly used to address many of the physical issues in server design is reliability, availability, and serviceability (RAS). RAS and other elements are:

1. **Reliability:** Customers expect reliable and robust services continually. Providing Internet services to customers such as banking and brokerage services requires special consideration. During business hours, if server goes offline, the revenue loss and potential liability may be significant. The majority of servers include various forms of reliability detecting and enhancing features. Alternatively, multiply redundant server configurations can be used to improve reliability of the infrastructure. Many application and operating system software providers include reliability features for their server products. Failure prevention solutions include:
  - Reducing probability of a failure through additional hardware and software features (some of the techniques used are independent operating system images on each server node and error correcting code (ECC) hardware features)
  - Minimizing the effect of failures by designing hardware and software robustness features such as fault isolation and provisioning
  - ECC memory scrubbing to detect and correct single bit errors that cause system crash due to accumulation of soft memory errors
  - System management interrupts handlers that allow special software to interface with hardware error detection and fault isolation independent of the underlying operating system
  - High performance and fault tolerant storage architectures such as redundant array of independent disks (RAID) are used to ensure data and operational integrity.
2. **Availability:** With the rapid growth of electronic businesses, companies need to ensure that their systems are running 24 h everyday. Some business server's downtime costs are in the order of millions of dollars. Traffic capacities beyond the system capability and component failures are two of the many sources of system failure. Modern servers are designed to accommodate ever-increasing traffic and system capacity by using more extensive I/O capability, powerful CPUs, and large system memory. Online management systems are also used to ensure system resources are not exhausted or overdriven. Using duplicate resources such as power supplies, CPU, and even multiply redundant

servers can mitigate component failures. Capability to quickly detect and remedy failures need to be included in various server hardware and software elements. Scheduled maintenance and upgrade of hardware and software elements can also ensure availability of servers.

3. **Serviceability:** Uninterrupted operation of business servers requires frequent and routine services before a fault occurs. Built-in failure prevention mechanisms include real-time diagnostic tools and alerting services to quickly and easily identify and resolve faults. New features such as hot plug and play also improves ease of service. Hot add allows installation of new hardware without interrupting server power. Hot replace allows changing faulty subsystems without needing to power down a server. Other services such as scheduled down time to do off-line enhancement are also used.
4. **Scalability:** High performance IT infrastructure can be scaled in two ways. One way is to deploy systems with more CPUs and more powerful I/O capability. The second way is to connect multiple servers using clustering technology. A combination of both approaches is also used.
5. **Manageability:** Issues that need to be addressed are:
  - Monitoring performance and tuning key applications and systems
  - Planning for capacity expansion for new users or services
  - Automatic or manual load balancing, distribution, and task scheduling for efficient operation of the enterprise resources and applications
  - Handling situations requiring increased alerting and management capabilities
  - Installation and configuration of system and services are rapid and easy to do (this is especially important for tasks such as system management, recommendation, and application of software and hardware upgrades)
  - Using notification and preventive action to keep system up and performing optimally
  - Recovering rapidly from service outages
  - Remote or local server management, even when part of the system may not be functioning.
6. **Security:** In routine and emergency cases, user access to system resources and facilities such as user authentication, intrusion detection, and privileged access needs to be provided. Cryptographic technologies such as encryption and decryption are frequently used to enhance overall system security. In many cases, cooperation with local and government officials may be required as part of intrusion prevention and detection.

## Operation

Additional operational issues also need consideration. Some of these factors are: Space: Many servers are modularly built. A typical server board contains several CPUs, system interconnect chipset, and other peripherals. Data centers, for example, may house several hundred server modules housed in cabinets or racks. Physical sizing of racks as well as maintenance and management of wiring to a server is a major challenge. The proximity of data center to major customer sites also needs to be considered. The overall cost of operating a data service center housing server needs to comprehend all these overheads as part of the economy of the provided service. Other considerations may include packaging of servers based on space requirements such as provision for high-density servers (large number of CPUs and I/O).

1. **Power:** A typical server board requires several hundred watts of power. Providing power to a server rack containing modular servers is a challenge. Power provisioning includes inclusion of services for proper handling of outage, uninterrupted power supply, or backup battery operation.
2. **Thermal:** Server modules generate large amounts of heat. Large server installations need to properly plan and accommodate heat generation and dissipation issues. In many cases, thermal constraints are the limiter for server capacity expansion. Other infrastructure costs such as air conditioning services to handle heat dissipation may also be prohibitive. Since thermal issues are rapidly expanding, most new servers have specialized technologies to lower power consumption. Development of low-power CPUs and chipsets that do not require active cooling are examples of technologies that aim to address thermal issues.

### Total Cost of Ownership

Another consideration, in the selection of enterprise servers, is the total cost of ownership or TCO. This metric is used to capture the cost of the IT infrastructure including operation, hardware and software purchases, services and downtimes. It is quite possible that for some enterprise application one or more of these factors becomes dominant. For example, in business critical online brokerage services, downtimes may be in the order of millions of dollars per hour. Evaluation of downtime costs versus other costs may easily justify the cost of additional and backup servers. In such a case, server clustering is used to improve TCO.

### Server Clustering

Many business applications such as manufacturing, financial, healthcare, and telecommunication require mission or business critical servers for their operation. An example is telecommunication billing and record keeping. Mission critical servers are designed with two or more servers physically connected to provide automated fail over. If one server crashes, the other servers can take over, keeping key applications running. Server clustering can be used to mitigate hardware (servers, storage arrays, networking hardware), operating system and cluster software, database, other application and human error failures. A variety of hardware and software automatic fault detection, isolation, and fail-over mechanisms are needed and used by various server manufacturers in the development of mission critical servers.

### Server Architecture

In this section, some of the more generic hardware, software server architecture design issues will be detailed. The hardware and software interaction and usage model issues will also be discussed.

### Hardware Architecture

Even though it is possible to build servers from full custom very large scale integrated (VLSI) devices or chips, economic issues govern use of commodity hardware whenever possible. Figure 5.3 illustrates common server hardware architecture. The main building block components in a server are the CPU, system memory, system bus, system interconnection or bridging devices, and peripheral subsystems.

#### CPU

Most servers contain several CPUs. For economy reasons, many servers choose to use CPUs readily available such as those used in desktop PCs or workstations. A high performance server CPU contains very fast execution capability. Multiple processors can be built using variety of mechanisms. The most popular multiprocessor (MP) architecture is symmetric multiprocessor (SMP). Figure 5.4 illustrates this architecture. SMP systems use several CPUs interconnected through a common system bus to access shared system resources such as system memory and the peripherals.

Depending on the application of the server, CPUs with different addressing capability can be used. Cost-effective servers can be developed using 32-bit processors. Servers built with 64-bit processors are

FIGURE 5.3 Server hardware architecture.

**FIGURE 5.4** Symmetric multiprocessor architecture.

also available and are used for applications requiring large data sets. Each CPU processing core consists of several arithmetic and logic units (ALU), multi-ported register files, floating point multipliers, and branch execution units. Most widely used CPU architecture can execute instructions out of order (OOO) and several operations at a time (super scalar).

Server applications operate on many instruction and data sets. During program execution, the same instruction and data elements may be repeatedly used. High-performance CPU execution rate requires high instruction and data bandwidth. Caches are used to store and operate on the most frequently used instruction and data as well as provide high bandwidth for fast execution. A high-performance server CPU contains several levels of hardware caches. Each cache may consist of separate instruction and data caches or an integrated instruction and data cache. Caches are numbered in increasing order, starting from one from the processing core toward system memory. The size of each cache in the order of increasing number is several times that of a lower level cache. Current server microprocessors use L3 or L4 caches to achieve highest level of performance. Cache size, associativity, line size, and replacement policy are determined by the characteristics of the desired applications running on the server using performance simulation models. Caches costs are determined by the state-of-the-art VLSI processing technology, implementation, and power dissipation considerations.

The number of CPUs used in a server is determined by the server performance requirement and design limitations. Most server designs contain several sockets for optional future CPU enhancement. Multiple CPUs provide more computing performance. Architecture and design of high performance MP architectures is still an active area of research.

Cost considerations also demand sharing of expensive resources such as system memory or peripheral storage devices. High-performance arbitrated access to common system resources by all CPUs is another topic of current research in server design.

### **System Memory**

One of the critical subsystems in a server is the system memory. System memory consists of several banks of dynamic random access memory (DRAM) modules. The larger the number of independent memory banks, the larger is the total bandwidth available to system devices requesting memory access (such as CPUs and peripheral devices). There are a variety of DRAM memory configurations such as single in-line memory module (SIMM) or dual in-line memory module (DIMM). Current servers can have several gigabytes of system memory.

Due to need for improved reliability and robustness, server system memory use fault tolerance features such as ECC. Errors can happen for a variety of reasons such as DRAM memory soft error rate (SER) or errors in transmission signaling among various chips. Another robustness measure is the number of error bits than can be detected and corrected. Low-end servers use single error correct double error detect (SECDED). Another robustness feature is chipkill. Chipkill enables isolation and correction of multi-bit faults such as failure of a single memory chip.

Finally, because server system memory may be large, auto-initialization of memory values to known values such as during power up may be required. Other robustness features include memory mirroring,

redundant memory-bit steering, and soft-error scrubbing. Depending on the desired level of robustness, a design may include one or several error detection and correction features.

### Peripheral Subsystem

Due to extensive computational capability, servers peripheral subsystem is much more elaborate than their desktop counterparts. Server peripherals include hard disk storage, fast network interface controllers (NIC) and other archival storage devices. Traditional computer interfaces such as boot Flash memory, keyboard, mouse, and graphics interfaces are also available. Example peripheral features are:

- Data storage and retrieval: Server storage and archival systems can be centralized or distributed. High performance and fault tolerant disk storage access is available using redundant array of independent disks (RAID) technology. There are also networked storage systems available.
- Network Interface: High-performance server communication links use gigabit or higher-speed Ethernet technology.
- Clustering interfaces: These interfaces are provided to support server clustering. One type of interface uses switching fabric technologies to enable connection of several server nodes.
- Direct attach interfaces: Proprietary interfaces for connection of servers is also another available technology. This interface is optimized for larger data transfer sizes compared to switched fabric approaches.
- Other peripherals interfaces such as keyboard, mouse, and graphics display device are also provided.
- Interconnection of peripheral subsystems with system memory and CPUs can be accomplished in a variety of ways. Depending on cost considerations, some systems use specialized chips to provide open standard solutions such as peripheral component interface (PCI) bus. PCI bus can be used to accommodate several peripheral devices such as network card and small computer serial interface (SCSI) solutions for hard disk and archival storage. More modern solutions provide open or proprietary switching fabrics that can be used to connect to peripheral devices. One advantage of the use of switching fabrics is the ability to scale servers to larger sizes by expanding switch fabric for additional devices such as storage devices. [Figure 5.5](#) depicts a server configuration using switching fabric components.
- Whatever the solution, the overall solution has to satisfy high throughput, support for large or small data transfer, and low latency access operation. PCI solutions need to account for various

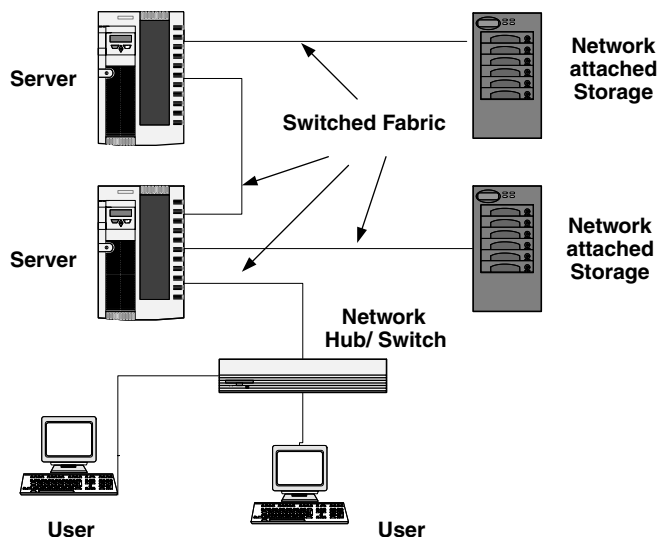

FIGURE 5.5 Switching fabric usage.

peripheral packet transfer size differences and shared bandwidth issues. Switching fabric solutions that use technologies, such as virtual connection or circuit switching, need to carefully architect solutions that meet connection channel setup, tear down, and blocking rates as well as quality of service (QOS) for real-time, multimedia data.

- Additional peripheral or system hardware solutions for specialized functions such as encryption and decryption may also be available.

### ***System Interconnect***

Design and implementation of system interconnect to support communication between multiple CPUs, system memory, and the peripheral subsystem is a challenging task. The solution has to satisfy several requirements.

System interconnect has to provide high bandwidth, low latency access between CPUs (or system bus) and the system memory. If there is insufficient bandwidth or large memory latency, the overall server performance will degrade. Some of the design choices are multiple fast and wide memory channels, memory interleave, and high-speed pipelined CPU-to-system interconnect bus.

System interconnect has to provide efficient and high bandwidth access between the system memory and the peripheral subsystem. If there is insufficient bandwidth for memory to peripheral subsystems, high performance transfer of pre- or post-processed data to network interface will not be possible. The same issue may plague the storage subsystems. The access latency for peripheral subsystems may not be as critical as that required by CPUs. The main reason for this is that peripheral accesses such as disk storage are typically pre-fetched or scheduled before they are needed.

Because system memory is a shared resource, memory traffic balancing is critical. If the CPU is favored in system memory access, there may not be sufficient bandwidth available from the peripheral subsystem to fill or empty required data. As a result, the CPU will ultimately be data starved. Favoring peripheral access to the main memory may be detrimental to nonstalled CPU operation. To make matters worse, the balancing of the traffic from CPU and the peripheral subsystem to system memory is application dependent and even varying within an application. For example, at boot time large amount of data transfer from peripheral such as hard disk may be needed. On the other hand, high throughput transaction processing may require favoring CPU to memory bandwidth demands. Optimized arbitration policy for access to main memory is determined through extensive computer simulations that include dynamic models of the application, operating system (OS) services and hardware components.

Other issues such as high speed signaling and dissipated power in VLSI components may also be factors. Careful balance of all these factors is critical for optimized system interconnect.

### **Software Architecture**

High performance server operation is also affected by the server software architecture. Two software components that need optimization are peripheral device drivers and the operating system. Peripheral device drivers need to be optimized for efficient and high performance data transfer to and from system memory. Operating system software may need to be optimized to better utilize the capability of CPUs (such as cache sizes), system memory capacity, and interprocess communication between multiple CPUs. The operating system may also be optimized to efficiently handle scheduling of tasks among multiple CPUs.

Clustered servers use independent OS for each server node. Clustered solutions may also use different OS. Internetworking issues in such heterogeneous environment is another software architecture issue. Many OS and software programs also use advanced caching techniques for high performance data access.

### **Applications and Usage Models**

A variety of applications are available for servers such as database management, transaction processing, inventory management, and decision support. Many users also use an application differently. For example, a user may be updating the database with recent entries while others are trying to access and use the database. Each usage model and application has a specific system demand characteristics. Robust IT infrastructure ensures that the servers, network, and client architecture are tuned and optimized for the

majority of the users. Hardware optimizations include selection of CPU, system memory type and size, VLSI interconnection chips, peripheral storage size, speed and features, and network interface speed and features. Software tuning mechanisms include optimizing compilers supporting multithreading and optimized libraries.

Server applications can be characterized in several ways. Some applications require large communication bandwidth between CPUs, system memory, and storage devices. Other applications require more execution processing capability by the CPUs. Finally, some servers, such as Web cache, may require high-performance network interfaces. Hardware and software tuning mechanism satisfies most of these and other requirements.

## Challenges in Server Design

Many challenges exist in the advancement of server designs. Some of the major issues such as physical and architectural considerations have already been mentioned. Below are several additional challenges that also need to be addressed:

1. Developing scalable solutions that meet the needs of a variety of users cost effectively is an active areas of research and development. Scalable architecture elements, such as CPU and system interconnection, memory, peripheral subsystem, and CPUs, are needed.
2. Development of applications that can benefit more users and take advantage of multiprocessor or clustered systems is another area of active research and development.
3. Development of additional high performance hardware and software technologies to enable large number of users sharing the IT infrastructure for new usage models is another active area. New usage model examples include support for variety of clients such as handheld devices and other information appliances.
4. Development of scalable and high performance networking technology to interconnect server components and clusters is also actively being pursued.
5. Research and development of security solutions that do not affect overall system performance, stop intrusion, and enhance user needs is another area of increasing importance.

## Summary

We reviewed many aspects of server infrastructure planning, selection, system design, and development. Critical requirements such as RAS were described. Server element architecture such as CPU, memory, and peripherals were discussed. Scalable solutions, software architecture, and applications were discussed, and avenues of current and future research and development are also described.

## 5.2 Very Large Instruction Word Architectures

### What Is a VLIW Processor?

Recent high performance processors have depended on instruction level parallelism (ILP) to achieve high execution speed. ILP processors achieve their high performance by causing multiple operations to execute in parallel, using a combination of compiler and hardware techniques. Very long instruction word (VLIW) is one particular style of processor design that tries to achieve high levels of ILP by executing long instruction words composed of multiple operations. The long instruction word called a “MultiOp,” consists of multiple arithmetic, logic, and control operations each of which would probably be an individual operation on a simple RISC processor. The VLIW processor concurrently executes the set of operations within a MultiOp, thereby achieving ILP. The remainder of this article discusses the technology, history, uses, and the future of such processors.

## Different Flavors of Parallelism

Improvements in processor performance come from two main sources: faster semiconductor technology and parallel processing. Parallel processing on multiprocessors, multicomputers, and processor clusters has traditionally involved a high degree of programming effort in mapping an algorithm to a form that can better exploit multiple processors and threads of execution. Such reorganization has often been productively applied, especially for scientific programs. The general-purpose microprocessor industry on the other hand has pursued methods of automatically speeding up existing programs without major restructuring effort. This led to the development of ILP processors that try to speed up program execution by overlapping the execution of multiple instructions from an otherwise sequential program.

We will call a simple processor that fetches and executes one instruction at a time a simple scalar processor. A processor with multiple functional units has the potential to execute several operations in parallel. If the decision about which operations to execute in an overlapped manner is made at run time by the hardware, it is called a super scalar processor. To a simple scalar processor, a binary program represents a plan of execution. The processor acts as an interpreter that executes the instructions in the program one at a time. From the point of view of a modern super scalar processor, an input program is more like a representation of an algorithm for which several different plans of execution are possible. Each plan of execution specifies when and on which function unit each instruction from instruction stream is to be executed.

The ILP processors differ in the manner in which the plan of execution is derived, but it typically involves both the compiler and the hardware. In the current breed of high performance processors like the Intel Pentium and the Ultra Sparc, the compiler tries to expose parallelism to the processor by means of several optimizations, the net result of which is to place as many independent operations as possible close to each other in the instruction stream. At run time, the processor examines several instructions at a time, analyzes the dependences between instructions, and keeps track of the availability of data and hardware resources for each instruction. It tries to schedule each instruction as soon as the data and functional units it needs are available. The processor's decisions are often further complicated by the fact that operations like memory accesses often have variable latencies that depend on whether a memory access hits in the cache or not. Because such processors decide which functional unit should be allocated to which instruction as execution progresses, they are said to be dynamically scheduled. Often, as a further performance improvement, such processors allow later instructions that are independent to execute ahead of an earlier instruction, which is waiting for data or resources. In that case the processor is said to be out of order.

Branches are common operations in general-purpose code. On encountering a branch, a processor must decide whether or not to take the branch. If the branch is to be taken, the processor must start fetching instructions from the branch target. To avoid delays due to branches, modern processors try to predict the outcome of branches and execute instructions from beyond the branch. If the processor predicted the branch incorrectly, it may need to undo the effects of any instructions it has already executed beyond the branch. If a super scalar processor uses resources that may otherwise go idle to execute operations the result of which may or may not be used, it is said to be speculative.

Out of order speculative execution comes at a significant hardware expense. The complexity and nonscalability of the hardware structures used to implement these features could significantly hinder the performance of future processors. An alternative solution to this problem is to simplify processor hardware and transfer some of the complexity of extracting ILP to the compiler and run time system—the solution explored by VLIW processors.

Joseph Fisher, who coined the acronym VLIW, characterized such machines as architectures that issue one long instruction per cycle, where each long instruction called a MultiOp consists of many tightly coupled independent operations each of which executes in a small and statically predictable number of cycles. In such a system the task of grouping independent operations into a MultiOp is done by a compiler or binary translator. The processor freed from the cumbersome task of dependence analysis has to merely execute in parallel the operations contained within a MultiOp. This leads to simpler and faster

processor implementations. In later sections, we will see how VLIW processors try to deal with the problems of branch and memory latencies and implement their own kind of speculation. But, first, we present a brief history of VLIW processors.

## A Brief History of VLIW Processors

For various reasons which were appropriate at that time, early computers were designed to have extremely complicated instructions. These instructions made designing the control circuits for such computers difficult. A solution to this problem was microprogramming, a technique proposed by Maurice Wilkes in 1951. In a microprogrammed CPU, each program instruction is considered a macroinstruction to be executed by a simpler processor inside the CPU. Corresponding to each macroinstruction, there will be a sequence of microinstructions stored in a micro code ROM in the CPU. One particular style of microprogramming where bits in a typically very wide microinstruction are directly used as control signals within the processor is called horizontal microprogramming.

In contrast, vertical microprogramming uses a shorter microinstruction or series of microinstructions in combination with some decoding logic to generate control signals. Microprogramming became popular as a way of implementing the control for a CPU after IBM adopted it for its system/360 series.

Even before the days of the first VLIW machines, several processors and custom computing devices used a single wide instruction word to control several functional units working in parallel. However, these machines were typically hand-coded and the code for such machines could not be generalized to other architectures. The basic problem was that compilers at that time looked only within basic blocks to extract ILP. Basic blocks are often short and contain many dependences and therefore the amount of ILP that can be obtained inside a basic block is quite limited.

Joseph Fisher, a pioneer of VLIW, while working on PUMA, a CDC-6600 emulator, was frustrated by the difficulty of writing and maintaining 64 bit horizontal micro code for that processor. He started investigating a technique for global micro code compaction—a method to generate long horizontal micro code instructions from short sequential ones. Fisher soon realized that the technique he developed in 1979, called trace scheduling, could be used in a compiler to generate code for VLIW like architectures from a sequential source since the style of parallelism available in VLIW is very similar to that of horizontal micro code. His discovery led to the design of the ELI-512 processor and the Bulldog trace-scheduling compiler.

Two companies were founded in 1984 to build VLIW-based mini supercomputers. One was Multiflow started by Fisher and his colleagues from Yale University. The other was Cydrome founded by Bob Rau, who was another VLIW pioneer, and his colleagues. In 1987, Cydrome delivered its first machine, the 256 bit Cydra 5, which included hardware support for software pipelining. This feature based on Bob Rau's research can be found in Intel Itanium processors today. In the same year, Multiflow delivered the Trace/200 machine, which was followed by the Trace/300 in 1988 and Trace/500 in 1990. The 200 and 300 series used a 256-bit instruction for 7 wide issue, 512 bits for 14 wide issue, and 1024 bits for 28 wide issue. The 500 series only supported 14 and 28 wide issue. Unfortunately, the early VLIW machines failed commercially. Cydrome closed in 1998 and Multiflow closed in 1990.

Since then, VLIW processors have seen a revival and some degree of commercial success. Some of the notable VLIW processors of recent years are IA-64 or Itanium from Intel, the Crusoe processor from Transmeta, the Trimedia media processor from Philips and TMS320C62x DSPs from Texas Instruments. Some important research machines designed during this time include the Playdoh from HP labs, Tinker from North Carolina State University, and the imagine stream and image processor currently being developed at Stanford University.

## Defoe: An Example VLIW Architecture

Rather than describe the properties of a VLIW architecture, we now introduce the Defoe. The Defoe is an example processor used in this section to give the reader a feel for VLIW architecture and programming. Though it does not exist in reality, its features are derived from those of several existing VLIW processors. Later sections that describe IA-64 and Crusoe will contrast those architectures with Defoe.

FIGURE 5.6 Defoe architecture.

## Functional Units

Defoe is a 64-bit architecture with the following functional units.

- Two load/store units
- Two simple ALUs that perform add, subtract, shift, and logical operations on 64-bit numbers and packed 32-, 16-, and 8-bit numbers; in addition, these units also support multiplication of packed 16 and 8 bit numbers.
- One complex ALU that can perform multiply and divide on 64 bit integers and packed 32-, 16-, and 8-bit integers
- One branch unit that performs branch, call, and comparison operations

There is no support for floating point. Figure 5.6 shows a simplified diagram of the Defoe architecture.

## Registers

Defoe has a set of 64 programmer visible general purpose registers which are 64 bits wide. Register R0 always contains 0. There is no support for register renaming like in a super scalar architecture.

## Predication

Predicate registers are special 1 bit registers that specify a true or false value. There are 16 programmer visible predicate registers in the Defoe named PR0 to PR15. All operations in Defoe are predicated, i.e., each operation specifies a predicate register in the PR field. The instruction is always executed. Logically, if the predicate is false, the results are discarded or the side effects of the instruction do not happen. In practice, for reasons of efficiency, this may be implemented by computing a result, but writing back the old value of the target register. Predicate register 0 always contains the value 1 and cannot be altered. Specifying PR0 as the predicate performs unconditional operations. Comparison operations use predicate registers as their target register.

## Instruction Encoding

Defoe is a 64-bit compressed VLIW architecture. By compressed, we mean that rather than use a fixed size MultiOp and waste slots by filling in NOPs when no suitable operation can be scheduled in a slot within a MultiOp we use variable length MultiOps. Individual operations are encoded as 32-bit words. A special stop bit in the 32-bit word indicates the end of an instruction word (Fig. 5.7). Common arithmetic operations also have an immediate mode, where a sign or zero extended 8 bit constant may be used as

Stop bit (1 bit)	Predicate (4 bits)	Opcode (9 bits)	Rdest (6)	Rsrc1 (6)	Rscr2 (6)
---------------------	-----------------------	--------------------	--------------	--------------	--------------

FIGURE 5.7 Instruction encoding.

an operand. For larger constants of say 16, 32, or 64 bits, a special Nop pattern may be written into opcode field of the next operation and the low order bits may be used to store the constant. In that case, the predecoder concatenates the bits from two or more different words to assemble a constant.

### Instruction Dispersal and Issue

A traditional VLIW, with a fixed encoding for MultiOps, has no need to disperse operations. However, when using a compressed format like that of the Defoe, there is a need to expand the operations and insert Nops for functional units to which no operation is to be issued. To make the dispersal task easy we make the following assumptions:

- A few bits in the opcode specify the type of functional unit (i.e. load/store, simple arithmetic, complex arithmetic or branch) the operation needs.
- The compiler ensures that the instructions that comprise a MultiOp are sorted in the same order as the functional units in the processor.
- For example, if a MultiOp consists of a load, a 32-bit divide, and a branch, then the ordering (load, multiply, branch) is legal, but the ordering (load, branch, multiply) is not.
- The compiler ensures that all the operations in the same MultiOp are independent.
- The compiler ensures that the functional units are not over subscribed. For example, two loads in a MultiOp are legal, but three is not.
- It is illegal to not have a stop bit in a sequence of more than six instructions.
- Basic blocks are aligned at 32-byte boundaries.

Apart from reducing wastage of memory, another reason to prefer a compressed format VLIW over an uncompressed one is that the former provides better I-cache utilization. To improve performance, we use a predecode buffer that can hold up to eight uncompressed MultiOps. The dispersal network can use a wide interface (say 512 bits) to the I-cache to uncompress up to 2 MultiOps every cycle and save them in the predecode buffer. Small loops of up to 8 MultiOps (maximum 48 operations) may repeatedly hit in the predecode buffer. It may also help lower the power consumption of a low power VLIW processor. Defoe supports in order issue and out of order completion. Further, all the operations in a MultiOp are issued simultaneously. If even one operation cannot be issued, issue of the whole MultiOp stalls.

### Branch Prediction

Following the VLIW philosophy of enabling the software to communicate its needs to the hardware, branch instructions in Defoe can advise the processor about their expected behavior. A 2-bit hint associated with every branch may be interpreted as follows.

Opcode Modifier	Meaning
Stk	Static prediction. Branch is usually taken.
Sntk	Static prediction. Branch is usually not taken.
dtk	Dynamic prediction. Assume branch is taken if no history is available.
dntk	Dynamic prediction. Assume branch is not taken if no history is available.

Implementations of the Defoe architecture may provide branch prediction hardware, but are not required to. If branch prediction h/w is provided, static branches need not be entered in the branch history table, thereby freeing up resources for dynamically predicted branches.

## Score Board

To accommodate branch prediction and variable latency of memory because of cache hits and misses, some amount of score boarding is required. Though we will not describe the details of the scoreboard here, it should be emphasized that the scoreboard and control logic for a VLIW processor such as the Defoe are much simpler than that of a modern super scalar processor because of the lack of out of order execution and speculation.

## Assembly Language Syntax

The examples that follow use the following syntax for assembly language instructions.

```
(predicate_reg) opcode.modifier Rdest = Rsource1, Rsource2
```

If the predicate register is omitted, PR0 will be assumed. In addition, a semicolon following an instruction indicates that the stop bit is set for that operation, i.e., that operation is the last one in its MultiOp. The prefix “!” for a predicate implies that the opcode actually depends on the logical not on the value of the predicate register.

### Example 1

This example demonstrates the execution model of the Defoe by computing the following set of expressions:

```
a = x + y - z
b = x + y - 2 * z
c = x + y - 3 * z
```

Register assignments: r1 = x, r2 = y, r3 = z, r32 = a, r33 = b, r34 = c

Line #	Code	Comments
1.	add r4 = r1, r2	// r4 = x + y
2.	shl r5 = r3, 1	// r5 = z << 1, i.e. z * 2
3.	mul r6 = r3, 3 ;	// r6 = z * 3. Stop bit.
4.	sub r32 = r4, r3	// r5 = a = gets x + y - z
5.	sub r33 = r4, r5 ;	// r33 = b = x + y - 2 * z. // Stop bit.
6.	sub r34 = r4, r6 ;	// r34 = c = x + y - 3 * z. // Stop bit.

The first three lines are followed by a stop bit to indicate that those three operations constitute a MultiOp and that they should be executed in parallel. Unlike a super scalar processor where independent operations are detected by the processor, the programmer/compiler has indicated to the processor by means of the stop bit that these three operations are independent. In a real processor, the multiplication will have a greater latency, perhaps four cycles. In that case we have two different ways of scheduling this code. Because Defoe already uses score boarding to deal with variable load latencies, it is only natural for the scoreboard to stall issue for three cycles after issuing the first MultiOp. In a more traditional VLIW, the compiler will insert three MultiOps consisting of just NOP after the first MultiOp. Lines 4–6 illustrate the way scheduling in the presence of structural hazards work on a VLIW. The compiler is aware that Defoe has only two simple integer ALUs. So, even though line 6 is independent of lines 4 and 5, it needs to wait for another cycle and be issued as a separate MultiOp. In a super scalar processor, these actions will be done by the hardware at run time.

## Example 2

This example contrasts the execution of an algorithm on Defoe and a super scalar processor (Intel Pentium). The C language function `absdiff` computes the sum of absolute difference of two arrays A and B which contain 256 elements each.

```
int absdiff(int *A, int *B)
{
    int sum, diff, i;
    sum = 0;
    for(i = 0; i<256; i++)
    {
        diff = A[i] - B[i];
        if(A[i] >= B[i])
            sum = sum + diff;
        else
            sum = sum - diff;
    }
    return sum;
}
```

A hand-assembled version of `absdiff` in Defoe assembly language is shown below. For clarity, it has been left unoptimized. An optimizing compiler will unroll this loop and software schedule it.

Register assignment: On entry, `r1 = a`, `r2 = b`. On exit, `sum` is in `r4`.

Line #	Code	Comment
1.	<code>add r3 = r1, 2040</code>	// r3 = End of array A
2.	<code>add r4 = r0, r0 ;</code>	// sum = r4 = 0

10.	<code>(pr2) add r4 = r4, r7</code>	// if A[i] >= B[i] // sum = sum + diff
11.	<code>(!pr2) sub r4 = r4, r7</code>	// else sum = sum - diff
12.	<code>(pr1) br.sptk .L1 ;</code>	

The corresponding code for an Intel processor is shown below. This is a snippet of actual code generated by the GCC compiler.

```

The level of parallelism available in the Defoe listing lines 3–7 (5 issue) can be achieved on a super scalar processor only if the processor can successfully isolate the five independent operations fast enough to issue them all during the same cycle. Dependency checking in h/w is extremely complex and adds to the delay of super scalar processors. The x86, which is a register deficient CISC architecture, also incurs additional penalties because of register renaming and CISC to internal RISC format translation.

Another important point is that the Defoe listing contains only one branch on line 12, whereas the x86 listing contains three branches. On a VLIW processor, in some cases, using predicated instructions may eliminate jumps. In both listings, line 9 corresponds to the comparison of  $A[i]$  and  $B[i]$ . The super scalar had to do a conditional jump based on the result of the comparison. The VLIW on the other hand used the result of the comparison to set a predicate, which selectively executed either an add or a subtract and nullified the other. This technique of converting a control dependence to data dependence is called “if conversion.” The benefits go beyond the single cycle saved by not doing a jump like in the case of the super scalar processor. The jumps on lines 10 and 12 in the second listing depend on the condition code which, in turn, depends on the data. Such data dependent branches are difficult to predict. Assuming that  $A[i] < B[i]$  and  $A[i] \geq B[i]$  are equally likely, the super scalar processor is likely to experience a branch misprediction and the resulting branch penalty half of the time.

Further, going by the VLIW philosophy of communicating performance critical information from the software to the hardware, the final branch on line 12 uses the opcode modifier “sptk” to inform the processor that the branch is statically predicted to be taken. For that particular loop, a VLIW processor can therefore predict the loop accurately 255 times out of 256 loop iterations without any hardware branch predictor. Even when a hardware branch predictor is available, the instruction advises the processor not to waste a branch history table entry on that branch since its behavior is already known at compile time.

## The Intel Itanium Processor

The Itanium processor is Intel’s first implementation of the IA-64 ISA. IA-64 is an ISA for the EPIC (Explicitly Parallel Instruction Computing) style of VLIW developed jointly by Intel and HP. It is a 64-bit, 6 issue VLIW processor with 4 integer units, 4 multimedia units, 2 load/store units, 2 extended precision floating point units, and 2 single precision floating point units. This processor running at 800 MHz on a 0.18- $\mu\text{m}$  process has a 10-stage deep pipeline.

Unlike the Defoe, the IA-64 architecture uses a fixed bundled instruction format. Each MultiOp consists of one or more 128 bit bundles. Each 128 bit bundle consists of three operations and a template. Unlike the Defoe where the opcode in each operation specifies a type field, the template encodes commonly used combinations of operation types. Allowed operation types are shown in Table x. Since the template field is only 5 bits wide, bundles do not support all possible combinations of instruction types. Much like the Defoe's stop bit, in the IA-64, some template codes specify where in the bundle a MultiOp ends. In IA-64 terminology, MultiOps are called instruction groups. Like Defoe, the IA-64 uses a decoupling buffer to improve its issue rate. Though the IA-64 registers are nominally 64 bits wide, there is a hidden 65th bit called NaT (Not a Thing). This is used to support speculation. There are 128 general purpose registers and another set of 128, 82 bit wide floating point registers. Similar to the Defoe, all operations on the IA-64 are predicated. However, the IA-64 has 64 predicate registers.

The IA-64 register mechanism is more complex than the Defoe's because it implements support for software pipelining using a method similar to the overlapped loop execution support pioneered by Bob Rau and implemented in the Cydra 5. On the IA-64, general-purpose registers GPR0 to GPR31 are fixed. Registers 32–127 can be renamed under program control to support a register stack or to do modulo scheduling for loops. When used to support software pipelining, this feature is called register rotation. Predicate registers 0–15 are fixed, while predicate registers 16–63 can be made to rotate in unison with the general purpose registers. The floating point registers also support rotation.

A modulo scheduled loop is similar to a pipelined functional unit. In a pipelined functional unit, each stage can hold a computation and successive items of data may be applied to the functional unit before previous data is completely processed. In a similar manner, in a modulo scheduled loop, the loop body may be logically split into several stages. The compiler can schedule multiple iterations of a loop in a pipelined manner as long as data outputs of one stage flow into the inputs of the next stage in a pipeline. Traditionally, this required unrolling the loop and renaming the registers used in successive iterations. The IA-64 reduces the overhead of such a loop and avoids the need for register renaming by rotating registers forward. After one rotation, the value that was in register  $X$  will be found in register  $X + 1$ . When used in conjunction with predication, this allows a natural expression of software pipelines similar to their hardware counterparts.

The IA-64 supports software directed control and data speculation. To do control speculation, the compiler moves loads before its controlling branch. The load is then flagged as a speculative load. The processor does not signal exceptions on a speculative load. If the controlling branch is later taken, the compiler uses a special check operation to see if an exception occurred. If an exception occurred, the check operation transfers control to exception handling code.

To support data speculation, the processor supports a special kind of load called an advance load. If the compiler cannot disambiguate between the addresses of a store and a later load, it can issue an advance load ahead of the store. The processor uses a special hardware structure called the ALAT to keep track of whether a later store wrote to the same location as the advance load. Later, in the original location of the load, the compiler uses a special check operation to see if a store invalidated the result of an advance load. If so, the check operation transfers control to special recovery code.

Similar to the Defoe, the IA-64 also supports both static and dynamic hints for branches. It also makes use of hardware branch prediction. There are also hints in load and store instructions that inform the processor about the cache behavior of a particular memory operation.

The IA-64 also includes SIMD instructions suitable for media processing. Special multimedia instructions similar to the MMX and SSE extensions of 80x86 processors treat the contents of a general purpose register as two 32-bit, four 16-bit, or eight 8-bit operands and operate on them in parallel.

To improve performance, the IA-64 architecture includes several features that are not found in a traditional VLIW architecture. The Intel Itanium processor is probably the most complex VLIW ever designed. It is a matter of debate whether some of the control complexity of the IA-64 is justifiable in a VLIW architecture and whether the enhancements actually improve performance enough to justify their complexity. Next, we will look at a simpler VLIW processor that has been designed with a totally different goal—that of reducing power consumption.

## The Transmeta Crusoe Processor

Even though very little information is publicly available at the time of this writing about the architecture of the Crusoe series of processors from Transmeta Corp., it represents a very interesting point in the history of VLIW processors. Traditionally, VLIW processors have been designed with the goal of maximizing ILP and performance. The designers of the Crusoe on the other hand needed to build a processor with moderate performance compared to current desktop processors, but with the additional restriction that their CPU consume very little power since it is intended for mobile applications and that it should be able to efficiently emulate the ISA of other processors, particularly the 80x86 and the Java virtual machine.

The designers came to the conclusion that features like out of order issue and dynamic scheduling consumed more power than could justify the performance benefits they provided. They set out to replace such complex ways of gaining ILP with simpler and more power efficient alternatives. The end result was a simple VLIW architecture. Long instructions on the Crusoe are either 64 or 128 bits. A 128-bit instruction word called a molecule in Transmeta parlance encodes four operations called atoms. The molecule format directly determines how operations get routed to functional units. The Crusoe has two integer units, a floating point unit, a load/store unit, and a branch unit. Similar to the Defoe, the Crusoe has 64 general-purpose registers and supports strictly in order issue. Unlike the Defoe, which uses predication, the Crusoe uses condition flags, which are identical to those of the x86 for ease of emulation.

Binary x86 programs, firmware, and operating systems are emulated with the help of a run time binary translator called code morphing software. This makes VLIW software compatibility a non issue. Only the native code morphing software needs to be changed when the Crusoe architecture or ISA changes. As a power and performance optimization, the hardware and software together maintain a cache of translated code. The translations are instrumented to collect execution frequencies and branch history, and this information is fed back to the code morphing software to guide its optimizations.

To correctly model the precise exception semantics of the x86 processor, the part of the register file that holds x86 register state is duplicated. The duplicate is called a shadow copy. Normal operations only affect the original registers. At the end of a translated section of code, a special commit operation is used to copy the working register values to the shadow registers. If an exception happens while executing a translated unit, the run time software uses the shadow copy to recreate the precise exception state. Store operations are implemented in a similar manner using a store buffer. The Crusoe provides alias detection hardware and data speculation primitives, which are quite similar to those of the IA-64.

## Scheduling Algorithms for VLIW

The difficulty of programming VLIW processors by hand should be evident even from the simple Defoe programming examples. One reason programming VLIWs is more difficult than writing code for a super scalar processor is that the program for a super scalar processor is inherently sequential and it is left to the hardware to extract parallelism from the sequential program. On the other hand, when generating code for a VLIW processor the assembly language programmer or the compiler is faced with the task of extracting parallelism from a sequential algorithm and scheduling independent operations concurrently. For this reason, instruction scheduling algorithms are critical to the performance of a VLIW processor. So, we describe three important scheduling algorithms next starting with the trace scheduling algorithm which started off the VLIW style of architectures.

### Trace Scheduling

Compilers for the first ILP processors used a 3-phase method to generate code. The passes were:

- Generate a sequential program. Analyze each basic block in the sequential program for independent operations.
- Schedule independent operations within the same block in parallel if sufficient hardware resources are available.
- Move operations between blocks when possible.

This 3-phase approach fails to exploit much of the ILP available in the program for two reasons.

- Oftentimes, operations in a basic block are dependent on each other. Therefore, sufficient ILP may not be available within a basic block.
- Arbitrary choices made while scheduling basic blocks make it difficult to move operations between blocks.

Trace scheduling is a profile driven method developed by Joseph Fisher to circumvent this problem. In trace scheduling, a set of commonly executed sequence of blocks is gathered together into a trace and the whole trace is scheduled together.

The trace scheduling algorithm works as follows:

1. Generate a possibly unoptimized version of the program, run it on sample input and collect statistics. Estimate the probability of each conditional branch.
2. From the basic block level data precedence graph of the program (also commonly called DAG for Directed Acyclic Graph), select a loop-free linear sequence of basic blocks, which have a high probability of execution. Such a sequence is called a trace. The compiler may use other optimizations like loop unrolling or procedure inlining to generate DAGS from which suitable traces can be selected.
3. Consider the trace as if it were a basic block. Build a DAG for it, considering branches like all other operations. If an operation controlled by a conditional jump could over write a value that is live on the off-trace edge, add an edge that makes the operation dependent on the branch so that the operation cannot be moved ahead of the branch. Also, add edges to preserve the relative order of conditional branches.
4. Schedule the resulting DAG as if it were a basic block doing register allocation and functional unit selection, as each operation is scheduled.
5. Generate compensation codes for mistakes made by considering the trace as a basic block. In particular:
  - a. If an operation that used to precede a conditional branch in the sequential code is moved after that branch, then add a copy of that operation preceding the off-trace target of the conditional jump.
  - b. If an operation that succeeded a point of entry into the trace from outside the trace is moved ahead of that point of entry, then copy of that operation must be placed outside the trace on the path that leads to that point of entry.
  - c. Ensure that rejoins that used to enter the trace enter at the new trace only at a point after which no operation is found in the new trace that were not below the rejoin point in the old trace.
6. Link the new trace back into the old DAG.
7. After scheduling the very first trace, new operations would have been added to the original DAG. Pick a different frequent trace and schedule it. Repeat till the DAG has been covered using disjoint traces, and no unscheduled operations remain.

## Trace Scheduling-2

Trace scheduling-2 goes beyond trace scheduling in that it allows nonlinear code motion, i.e., it allows operations from both sides of a conditional branch to be moved above the branch. Trace scheduling usually misses code motions that are speculative or moves operations from one trace to another. Trace scheduling-2 on the other hand uses an expected value function called speculative yield, to consider the cost of speculative execution and decide whether or not to move operations from one block to another. Unlike trace scheduling, which operates on a linear sequence of blocks, the newer algorithm works by picking clusters of operations where each cluster is a maximal set of operations that are connected without back edges in the flow graph of the program. The actual details of the algorithm are beyond the scope of this section.

## Super Block Scheduling

Super block scheduling is a region-scheduling algorithm developed in conjunction with the Impact compiler at the University of Illinois. Similar to trace scheduling, super block scheduling is based on the premise that to extract ILP from a sequential program, the compiler should perform code motion across multiple basic blocks. Unlike trace scheduling, super block scheduling is driven by static branch analysis, not profile data. A super block is a set of basic blocks in which control may enter only at the top, but may exit at more than one point. Super blocks are identified by first identifying traces and then eliminating side entries into a trace by a process called tail duplication. Tail duplication works by creating a separate off-trace copy of the basic blocks in between a side entrance and the trace exit and redirecting the edge corresponding to the side entry to the copy. Traces are identified using static branch analysis based on loop detection, heuristic hazard avoidance, and heuristics for path selection. Loop detection identifies loops and marks loop back edges as taken and loop exits as not taken. Hazard avoidance uses a set of heuristics to detect situations, such as ambiguous stores and procedure calls, that could cause a compiler to use conservative optimization strategies and then predicts the branches so as to avoid having to optimize hazards. Path-selection heuristics use the opcode of a branch, its operands and the contents of its successor blocks to predict its direction if no other method already predicted the direction of the branch. These are based on common programming patterns like the fact that pointers are unlikely to be NULL, floating point comparisons are unlikely to be equal, etc. Once branch information is available, traces are grown and super blocks created by tail duplication followed by scheduling of the super block. Studies have shown that static analysis based super block scheduling can achieve results that are comparable to profile-based methods.

## The Future of VLIW Processors

VLIW processors have enjoyed moderate commercial success in recent times as exemplified by the Philips Trimedia, TI TMS320C62x DSPs, Intel Itanium, and to a lesser extent the Transmeta Crusoe. The role of VLIW processors, however, has changed since the days of Cydrome and Multiflow. Even though early VLIW processors were developed to be scientific super computers, newer processors have been used mainly for stream, image and digital signal processing, multimedia codec hardware, low-power mobile computers, and for running commercial servers. VLIW compiler technology has made major advances during the last decade; however, most of the compiler techniques developed for VLIW are equally applicable to super scalar processors as well. Stream and media processing applications are typically very regular with predictable branch behavior and large amounts of ILP. They lend themselves easily to VLIW style execution. The ever increasing demand for multimedia applications will continue to fuel development of VLIW technology; however, in the short term, super scalar processors will probably dominate in the role of general-purpose processors. Increasing wire delays in deep sub-micron processes will ultimately force super scalar processors to use simpler and more scalable control structures and seek more help from software. It is reasonable to assume that in the long run, much of the VLIW technology and design philosophy will make its way into main stream processors.

## 5.3 Vector Processing

---

*Krste Asanovic*

### Introduction

For nearly 30 years, vector processing has been used in the world's fastest supercomputers to accelerate applications in scientific and technical computing. More recently vector-like extensions have become popular on desktop and embedded microprocessors to accelerate multimedia applications. In both cases, architects are motivated to include data parallel instructions because they enable large increases in performance at much lower cost than alternative approaches to exploiting application parallelism. This chapter reviews the development of data parallel instruction sets from the early SIMD (single instruction, multiple data) machines, through the vector supercomputers, to the new multimedia instruction sets.

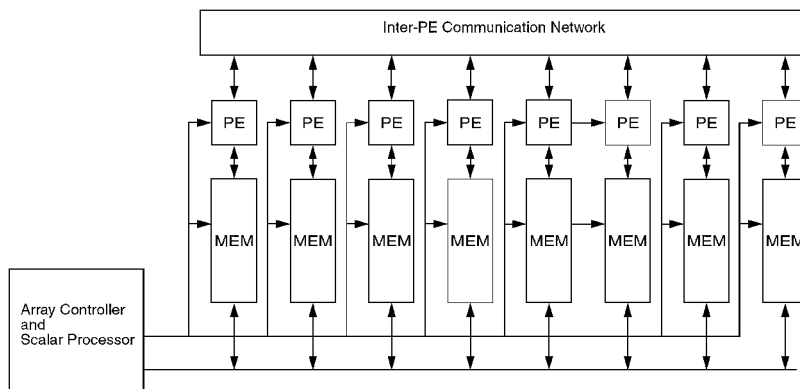

### Data Parallelism

An application is said to contain data parallelism when the same operation can be carried out across arrays of operands, for example, when two vectors are added element by element to produce a result vector. Data parallel operations are usually expressed as loops in sequential programming languages. If each loop iteration is independent of the others, data parallel instructions can be used to execute the code. The following vector add code written in C is a simple example of a data parallel loop:

```
for (i=0; i<N; i++)
    C[i] = A[i] + B[i];
```

Provided that the result array C does not overlap the source arrays A and B, the individual loop iterations can be run in parallel. Many compute-intensive applications are built around such data parallel loop kernels. One of the most important factors in determining the performance of data parallel programs is the range of vector lengths observed for typical data sets. Vector lengths vary depending on the application, how the application is coded, and also on the input data for each run. In general, the longer the vectors, the greater the performance achieved by a data parallel architecture, as any loop startup overheads will be amortized over a larger number of elements.

**FIGURE 5.8** Structure of a distributed memory SIMD (DM-SIMD) processor.

The performance of a piece of vector code running on a data parallel machine can be summarized with a few key parameters.  $R_n$  is the rate of execution (for example, in MFLOPS) for a vector of length  $n$ .  $R_\infty$  is the maximum rate of execution achieved assuming infinite length vectors.  $N_0$  is the number of elements at which vector performance reaches one half of  $R_\infty$ .  $N_0$  indirectly measures startup overhead, as it gives the vector length at which the time lost to overheads is equal to the time taken to execute the vector operation at peak speed ignoring overheads. The larger the  $N_0$  for a code kernel running on a particular machine, the longer the vectors must be to achieve close to peak performance.

## History of Data Parallel Machines

Data parallel architectures were first developed to provide high throughput for supercomputing applications. There are two main classes of data parallel architectures: distributed memory SIMD (single instruction, multiple data [1]) architecture and shared memory vector architecture. An early example of a distributed memory SIMD (DM-SIMD) architecture is the Illiac-IV [2]. A typical DM-SIMD architecture has a general-purpose scalar processor acting as the central controller and an array of processing elements (PEs) each with its own private memory, as shown in Fig. 5.8. The central processor executes arbitrary scalar code and also fetches instructions, and broadcasts them across the array of PEs, which execute the operations in parallel and in lockstep. Usually the local memories of the PE array are mapped into the central processor's address space so that it can read and write any word in the entire machine. PEs can communicate with each other, using a separate parallel inter-PE data network. Many DM-SIMD machines, including the ICL DAP [3] and the Goodyear MPP [4], used single-bit processors connected in a 2-D mesh, providing communication well-matched to image processing or scientific simulations that could be mapped to a regular grid. The later connection machine design [5] added a more flexible router to allow arbitrary communication between single-bit PEs, although at much slower rates than the 2-D mesh connect. One advantage of single-bit PEs is that the number of cycles taken to perform a primitive operation, such as an add can scale with the precision of the operands, making them well suited to tasks such as image processing where low-precision operands are common. An alternative approach was taken in the Illiac-IV where wide 64-bit PEs could be subdivided into multiple 32-bit or 8-bit PEs to give higher performance on reduced precision operands. This approach reduces  $N_0$  for calculations on vectors with wider operands but requires more complex PEs. This same technique of subdividing wide datapaths has been carried over into the new generation of multimedia extensions (referred to as MX in the rest of this chapter) for microprocessors. The main attraction of DM-SIMD machines is that the PEs can be much simpler than the central processor because they do not need to fetch and decode instructions. This allows large arrays of simple PEs to be constructed, for example, up to 65,536 single-bit PEs in the original connection machine design.

Shared-memory vector architectures (henceforth abbreviated to just “vector architectures”) also belong to the class of SIMD machines, as they apply a single instruction to multiple data items. The primary difference in the programming model of vector machines versus DM-SIMD machines is that vector machines allow any PE to access any word in the system’s main memory. Because it is difficult to construct machines that allow a large number of simple processors to share a large central memory, vector machines typically have a smaller number of highly pipelined PEs.

The two earliest commercial vector architectures were CDC STAR-100 [6] and TI ASC [7]. Both of these machines were vector memory–memory architectures where the vector operands to a vector instruction were streamed in and out of memory. For example, a vector add instruction would specify the start addresses of both source vectors and the destination vector, and during execution elements were fetched from memory before being operated on by the arithmetic unit which produced a set of results to write back to main memory.

The Cray-1 [8] was the first commercially successful vector architecture and introduced the idea of vector registers. A vector register architecture provides vector arithmetic operations that can only take operands from vector registers, with vector load and store instructions that only move data between the vector registers and memory. Vector registers hold short vectors close to the vector functional units, shortening instruction latencies and allowing vector operands to be reused from registers thereby reducing memory bandwidth requirements. These advantages have led to the dominance of vector register architectures and vector memory–memory machines are ignored for the rest of this section.

DM-SIMD machines have two primary disadvantages compared to vector supercomputers when writing applications. The first is that the programmer has to be extremely careful in selecting algorithms and mapping data arrays across the machine to ensure that each PE can satisfy almost all of its data accesses from its local memory, while ensuring the local data set still fits into the limited local memory of each PE. In contrast, the PEs in a vector machine have equal access to all of main memory, and the programmer only has to ensure that data accesses are spread across all the interleaved memory banks in the memory subsystem.

The second disadvantage is that DM-SIMD machines typically have a large number of simple PEs and so to avoid having many PEs sit idle, applications must have long vectors. For the large-scale DM-SIMD machines,  $N_*$  can be in the range of tens of thousands of elements. In contrast, the vector supercomputers contain a few highly pipelined PEs and have  $N_*$  in the range of tens to hundreds of elements.

To make effective use of a DM-SIMD machine, the programmer has to find a way to restructure code to contain very long vector lengths, while simultaneously mapping data structures to distributed small local memories in each PE. Achieving high performance under these constraints has proven difficult except for a few specialized applications. In contrast, the vector supercomputers do not require data partitioning and provide reasonable performance on much shorter vectors and so require much less effort to port and tune applications. Although DM-SIMD machines can provide much higher peak performances than vector supercomputers, sustained performance was often similar or lower and programming effort was much higher. As a result, although they achieved some popularity in the 1980s, DM-SIMD machines have disappeared from the high-end, general-purpose computing market with no current commercial manufacturers, while there are still several manufacturers of high-end vector supercomputers with sufficient revenue to fund continued development of new implementations. DM-SIMD architectures remain popular in a few niche special-purpose areas, particularly in image processing and in graphics rendering, where the natural application parallelism maps well onto the DM-SIMD array, providing extremely high throughput at low cost.

Although data parallel instructions were originally introduced for high-end supercomputers, they can be applied to many applications outside of scientific and technical supercomputing. Beginning with the Intel i860 released in 1989, microprocessor manufacturers have introduced data parallel instruction set extensions that allow a small number of parallel SIMD operations to be specified in single instruction. These microprocessor SIMD ISA (instruction set architecture) extensions were originally targeted at multimedia applications and supported only limited-precision, fixed-point arithmetic, but now support single and double precision floating-point and hence a much wider range of applications. In this chapter, SIMD ISA extensions are viewed as a form of short vector instruction to allow a unified discussion of design trade-offs.

## Basic Vector Register Architecture

Vector processors contain a conventional scalar processor that executes general-purpose code together with a vector processing unit that handles data parallel code. Figure 5.9 shows the general architecture of a typical vector machine. The vector processing unit includes a set of vector registers and a set of vector functional units that operate on the vector registers. Each vector register contains a set of two or more data elements. A typical vector arithmetic instruction reads source operand vectors from two vector registers, performs an operation pair-wise on all elements in each vector register and writes a result vector to a destination vector register, as shown in Fig. 5.10. Often, versions of vector instructions are provided that replace one vector operand with a scalar value; these are termed vector–scalar instructions. The scalar value is used as one of the operand inputs at each element position.

**FIGURE 5.9** Structure of a vector machine. This example has a central vector register file, two vector arithmetic units (VAU), one vector load/store unit (VMU), and one vector mask unit (VFU) that operates on the mask registers. (Adapted from Asanovic, K., *Vector Microprocessors*, 1998. With permission.)

**FIGURE 5.10** Operation of a vector add instruction. Here, the instruction is adding vector registers 1 and 2 to give a result in vector register 3.

The vector ISA usually fixes the maximum number of elements in each vector register, although some machines such as the IBM vector extension for the 3090 mainframe support implementations with differing numbers of elements per vector register. If the number of elements required by the application is less than the number of elements in a vector register, a separate vector length register (VLR) is set with the desired number of operations to perform. Subsequent vector instructions only perform this number of operations on the first elements of each vector register. If the application requires vectors longer than will fit into a vector register, a process called strip mining is used to construct a vector loop that executes the application code loop in segments that each fit into the machine's vector registers. The MX ISAs have very short vector registers and do not provide any vector length control. Various types of vector load and store instruction can be provided to move vectors between the vector register file and memory. The simplest form of vector load and store transfers a set of elements that are contiguous in memory to successive elements of a vector register. The base address is usually specified by the contents of a register in the scalar processor. This is termed a unit-stride load or store, and is the only type of vector load and store provided in existing MX instruction sets.

Vector supercomputers also include more complex vector load and store instructions. A strided load or store instruction transfers memory elements that are separated by a constant stride, where the stride is specified by the contents of a second scalar register. Upon completion of a strided load, vector elements that were widely scattered in memory are compacted into a dense form in a vector register suitable for subsequent vector arithmetic instructions. After processing, elements can be unpacked from a vector register back to memory using a strided store.

Vector supercomputers also include indexed load and store instructions to allow elements to be collected into a vector register from arbitrary locations in memory. An indexed load or store uses a vector register to supply a set of element indices. For an indexed load or gather, the vector of indices is added to a scalar base register to give a vector of effective addresses from which individual elements are gathered and placed into a densely packed vector register. An indexed store, or scatter, inverts the process and scatters elements from a densely packed vector register into memory locations specified by the vector of effective addresses.

Many applications contain conditionally executed code, for example, the following loop clears values of  $A[i]$  smaller than some threshold value:

```
for (i=0; i<N; i++)
    if (A[i] < threshold)
        A[i] = 0;
```

Data parallel instruction sets usually provide some form of conditionally executed instruction to support parallelization of such loops. In vector machines, one approach is to provide a mask register that has a single bit per element position. Vector comparison operations test a predicate at each element and set bits in the mask register at element positions where the condition is true. A subsequent vector instruction takes the mask register as an argument, and at element positions where the mask bit is set, the destination register is updated with the result of the vector operation, otherwise the destination element is left unchanged. The vector loop body for the previous vector loop is shown below (with all stripmining loop code removed).

```
lv va, (ra)           # Load slice of vector A from memory
cmp.lt.vs va, rt      # Set mask where A[i] < threshold
move.vs.m va, r0      # Clear elements of A[i] under mask
sv va, (ra)           # Store updated slice of A to memory
```

## Vector Instruction Set Advantages

Vector instruction set extensions provide a number of advantages over alternative mechanisms for encoding parallel operations. Vector instructions are compact, encoding many parallel operations in a single short instruction, as compared to superscalar or VLIW instruction sets which encode each individual operation using a separate collection of bits.

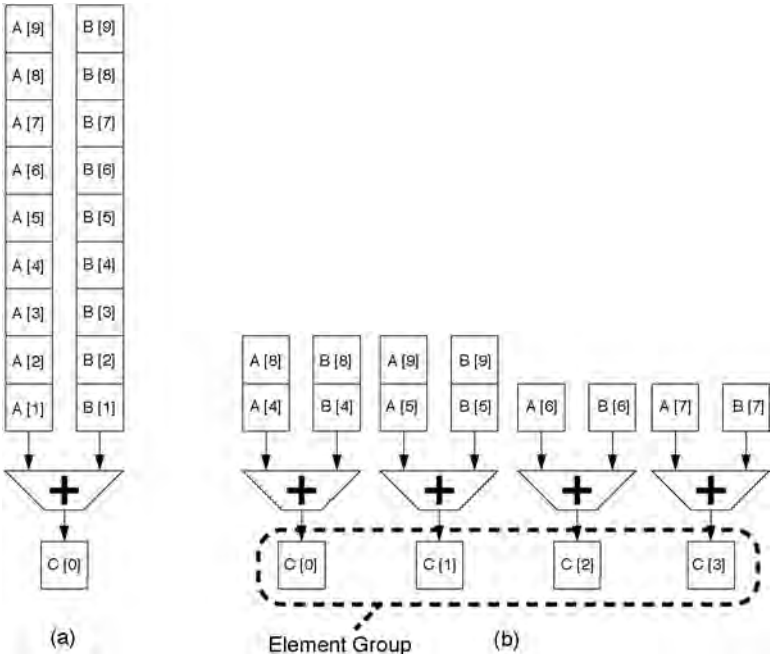

They are also expressive, relaying much useful information from software to hardware. When a compiler or programmer specifies a vector instruction, they indicate that all of the elemental operations within the instruction are independent, allowing hardware to execute the operations using pipelined execution units, or parallel execution units, or any combination of pipelined and parallel execution units, without requiring dependency checking or operand bypassing for elements within the same vector instruction. Vector ISAs also reduce the dependency checking required between two different vector instructions. Hardware only has to check dependencies once per vector register, not once per elemental operation. This dramatically reduces the complexity of building high throughput execution engines compared with RISC or VLIW scalar cores, which have to perform dependency and interlock checking for every elemental result. Vector memory instructions can also relay much useful information to the memory subsystem by passing a whole stream of memory requests together with the stride between elements in the stream.

Another considerable advantage of a vector ISA is that it simplifies scaling of implementation parallelism. As described in the next section, the degree of parallelism in the vector unit can be increased while maintaining object-code compatibility.

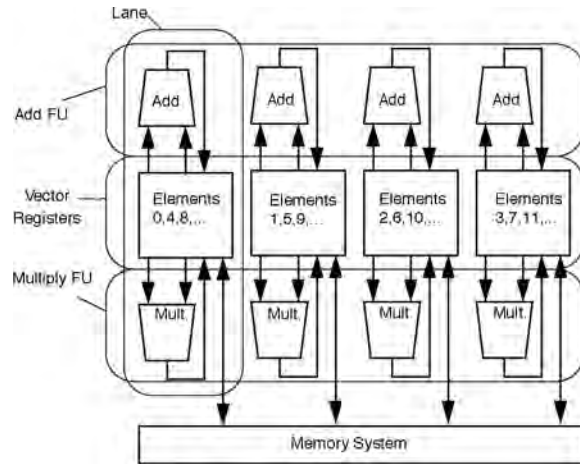

**Lanes: Parallel Execution Units**

Figure 5.11(a) shows the execution of a vector add instruction on a single pipelined adder. Results are computed at the rate of one element per cycle. Figure 5.11(b) shows the execution of a vector add instruction using four parallel pipelined adders. Elements are interleaved across the parallel pipelines allowing up to four element results to be computed per cycle. This increase in parallelism is invisible to software except for the increased performance.

Figure 5.12 shows how a typical vector unit can be constructed as a set of replicated lanes, where each lane is a cluster containing a portion of the vector register file and one pipeline from each vector

**FIGURE 5.11** Execution of vector add instruction using different numbers of execution units. The machine in (a) has a single adder and completes one result per cycle, while the machine in (b) has four adders and completes four results every cycle. An element group is the set of elements that proceed down the parallel pipelines together. (From Asanovic, K., *Vector Microprocessors*, 1998. With permission.)

**FIGURE 5.12** A vector unit constructed from replicated lanes. Each lane holds one adder and one multiplier as well as one portion of the vector register file and a connection to the memory system. The adder functional unit (adder FU) executes add instructions using all four adders in all four lanes.

functional unit. Because of the way the vector ISA is designed, there is no need for communication between the lanes except via the memory system. The vector registers are striped over the lanes, with lane 0 holding all elements 0,  $N$ ,  $2N$ , etc., lane 1 holding elements 1,  $N + 1$ ,  $2N + 1$ , etc. In this way, each elemental vector arithmetic operation will find its source and destination operands located within the same lane, which dramatically reduces interconnect costs.

The fastest current vector supercomputers, NEC SX-5 and Fujitsu VPP5000, employ 16 parallel 64-bit lanes in each CPU. The NEC SX-5 can complete 16 loads, 16 64-bit floating-point multiplies, and 16 floating-point adds each clock cycle.

Many data parallel systems, ranging from vector supercomputers, such as the early CDC STAR-100, to the MX ISAs, such as AltiVec, provide variable precision lanes, where a wide 64-bit lane can be subdivided into a larger number of lower precision lanes to give greater performance on reduced precision operands.

## Vector Register File Organization

Vector machines differ widely in the organization of the vector register file. The important software-visible parameters for a vector register file are the number of vector registers, the number of elements in each vector register, and the width of each element. The Cray-1 had eight vector registers each holding sixty-four 64-bit elements (4096 bits total). The AltiVec MX for the PowerPC has 32 vector registers each holding 128-bits that can be divided into four 32-bit elements, eight 16-bit elements, or sixteen 8-bit elements. Some vector supercomputers have extremely large vector register files organized in a vector register hierarchy, e.g., the NEC SX-5 has 72 vector registers (8 foreground plus 64 background) that can each hold five hundred twelve 64-bit elements.

For a fixed vector register storage capacity (measured in elements), an architecture has to choose between few longer vector registers or more shorter vector registers. The primary advantage of lengthening a vector register is that it reduces the instruction bandwidth required to attain a given level of performance because a single instruction can specify a greater number of parallel operations. Increases in vector register length give rapidly diminishing returns, as amortized startup overheads become small and as fewer applications can take advantage of the increased vector register length.

The primary advantage of providing more vector registers is that it allows more temporary values to be held in registers, reducing data memory bandwidth requirements. For machines with only eight vector registers, vector register spills have been shown to consume up to 70% of all vector memory traffic, while increasing the number of vector registers to 32 removes most register spill traffic [9,10]. Adding more

vector registers also gives compilers more flexibility in scheduling vector instructions to boost vector instruction-level parallelism.

Some vector machines provide a configurable vector register file to allow software to dynamically choose the optimal configuration. For example, the Fujitsu VPP 5000 allows software to select vector register configurations ranging from 256 vector registers each holding 128 elements to eight vector registers holding 4096 elements each. For loops where few temporary values exist, longer vector registers can be used to reduce instruction bandwidth and stripmining overhead, while for loops where many temporary values exist, the number of shorter vector registers can be increased to reduce the number of vector register spills and, hence, the data memory bandwidth required. The main disadvantage of a configurable vector register file is the increase in control logic complexity and the increase in machine state to hold the configuration information.

## **Traditional Vector Computers versus Microprocessor Multimedia Extensions**

Traditional vector supercomputers were developed to provide high performance on data parallel code developed in a compiled high level language (almost always a dialect of FORTRAN) while requiring only simple control units. Vector registers were designed with a large number of elements (64 for the Cray-1). This allowed a single vector instruction to occupy each deeply pipelined functional unit for many cycles. Even though only a single instruction could be issued per cycle, by starting separate vector instructions on different vector functional units, multiple vector instructions could overlap in execution at one time. In addition, adding more lanes allows each vector instruction to complete more elements per cycle.

MX ISAs for microprocessors evolved at a time where the base microprocessors were already issuing multiple scalar instructions per cycle. Another distinction is that the MX ISAs were not originally developed as compiler targets, but were intended to be used to write a few key library routines. This helps explain why MX ISAs, although sharing many attributes with earlier vector instructions, have evolved differently. The very short vectors in MX ISAs allow each instruction to only specify one or two cycle's worth of work for the functional units. To keep multiple functional units busy, the superscalar dispatch capability of the base scalar processor is used. To hide functional unit latencies, the multimedia code must be loop unrolled and software pipelined. In effect, the multimedia engine is being programmed in a microcoded style with the base scalar processor providing the microcode sequencer and each MX instruction representing one microcode primitive for the vector engine.

This approach of providing only primitive microcode level operations in the multimedia extensions also explains the lack of other facilities standard in a vector ISA. One example is vector length control. Rather than use long vectors and a VLR register, the MX ISAs provide short vector instructions that are placed in unrolled loops to operate on longer vectors. These unrolled loops can only be used with long vectors that are a multiple of the intrinsic vector length multiplied by the unrolling factor. Extra code is required to check for shorter vectors and to jump to separate code segments to handle short vectors and the remnants of any longer vector that were not handled by the unrolled loop. This overhead is greater than for the stripmining code in traditional vector ISAs, which simply set the VLR appropriately in the last iteration of the stripmined loop.

Vector loads and stores are another place where functionality has been moved into software for the MX ISAs. Most MX ISAs only provide unit-stride loads and stores that have to be aligned on boundaries corresponding to the vector length, not just aligned at element boundaries as in regular scalar code. For example, a unit-stride load of four 16-bit quantities has to be aligned at 64-bit boundaries in most MX instruction sets, although in some cases hardware will handle misaligned loads and stores at a slower rate. To help handle misaligned application vectors, various shift and align instructions have been added to MX ISAs to allow misalignment to be handled as part of the software microcoded loop. This approach simplifies the hardware design, but unfortunately these misaligned vectors are common in application code, and significant slowdown occurs when performing alignment in software. This encourages the

use of loops optimized for certain operand alignments, which leads to an increase in code size and also in loop startup time to select the appropriate routine. In certain cases, the application can constrain the layout of the data elements to ensure alignment at the necessary boundaries, but typically this is only possible when the entire application has been optimized for these MX instructions, for example, in a dedicated media player. Strided and indexed operations are also usually coded as scalar loads and stores with a corresponding slowdown over full vector mode.

## Memory System Design

Perhaps the biggest difference between microprocessors and vector supercomputers is in the capabilities of the vector memory system. Vector supercomputers usually forgo data caches and rely on many banks of interleaved main memory to provide high memory bandwidth, while microprocessors rely on multilevel cache hierarchies to isolate the CPU from memory latencies and limited main memory bandwidth. A modern high-end vector supercomputer provides over 50 GB/s of main memory bandwidth per CPU, while high-end microprocessor systems provide only around 1 GB/s per CPU. For applications that require non-unit stride accesses to large data sets, the bandwidth discrepancy is even larger, because microprocessors access memory using long cache lines that waste bandwidth when there is little spatial locality. A modern vector CPU might sustain 16 or 32 non-unit stride memory operations every cycle pipelined out to main memory, with hundreds of outstanding memory accesses, while a microprocessor usually can only have a total of four to eight cache line misses outstanding at any time. This large difference in non-unit stride memory bandwidth is the main reason that vector supercomputers remain popular for certain applications, including car crash simulation and weather forecasting.

Traditional vector ISAs use long vector registers to help hide memory latency. MX ISAs have only very short vector registers and so require a different mechanism to hide memory latency and make better use of available main memory bandwidth. Various forms of hardware and software prefetching schemes have become popular with microprocessor designers to hide memory latency. Hardware prefetching schemes dynamically inspect memory references and attempt to predict which data will be needed next, fetching these into the cache before requested by the application. This approach has the advantage of not requiring changes to software, but can be inaccurate and can consume excessive memory bandwidth on mis-speculated prefetches.

Software prefetching can be very accurate as the compiler knows the reference patterns of each piece of code, but the software prefetch instructions have to be carefully scheduled so that data are not brought in too early, perhaps evicting useful data, or too late, which will leave some memory latency exposed. The optimal schedule depends on the CPU and memory system implementations, which implies that code optimized for one generation of CPU or one particular memory system.

For either hardware or software prefetching schemes, it is essential that the memory controller can support many outstanding requests, otherwise high memory bandwidths cannot be sustained from a typical high latency memory system.

## Future Directions

Microprocessor architects are continually searching for techniques that can take advantage of ever increasing transistor counts to improve application performance. Data parallel ISA extensions have proven effective on a wide range of applications, and hardware designs scale well to more parallel lanes. Existing supercomputers have sixteen 64-bit lanes while microprocessor MX implementations have expanded to two 64-bit lanes. It is likely that there will be further expansion of MX units to four or more 64-bit lanes. At higher lane counts, efficiencies drop, partly because of limited application vector lengths and partly because additional lanes do not help non-data parallel portions of each application.

An alternative approach to attaining high throughput on data parallel applications is to add more CPUs each with vector units and to parallelize loops at the thread level. This technique also allows

independent CPUs to run different tasks to improve system throughput. The main disadvantages of this multiprocessor approach compared to simply increasing the number of lanes are the hardware costs of additional scalar processor logic and the additional inter-CPU synchronization costs. The relative cost of adding more CPUs is reduced as lane counts grow, particularly when the cost of providing sufficient main memory bandwidth is considered. The inter-CPU synchronization cost is a more serious issue as it adds to vector startup latencies and can increase  $N_*$  dramatically, reducing the effectiveness of multiprocessors on shorter vectors. For this reason, vector supercomputers have added fast inter-CPU synchronization through dedicated shared semaphore registers. The Cray SV1 design makes use of these registers to gang together four 2-lane processors in software to appear as a single 8-lane processor to the user. It should be expected that some form of fast inter-CPU synchronization primitive will be added to ISAs as design move to chip-scale multiprocessors, as these primitives can also be applied to many types of thread-level parallel code.

Increased CPU clock frequencies and increased lane counts combine to dramatically increase the memory bandwidth required by a vector CPU. The cost of a traditional vector style memory system will become prohibitive even for high-end vector supercomputers. Even if the cost could be justified, the high memory latency of a flat memory system will hamper performance for applications that have lower degrees of parallelism and that can fit in caches, and a continued move towards cached memory hierarchies for vector machines is to be expected leading to a merging of vector supercomputer and microprocessor design points.

MX extensions for microprocessors have undergone considerable changes since first introduced. The current designs provide low-level arithmetic and memory system primitives that are intended to be used in hand-microcoded loops. These result in high startup overheads and large code size relative to traditional vector extensions as discussed above. A possible future direction that could merge the benefit of vector ISAs and out-of-order superscalar microprocessors would be to add vector-style ISA extensions, but have these interpreted by microcode sequencers that would produce internal elemental microoperations that would be passed through the regular register renaming and out-of-order dispatch stages of a modern superscalar execution engine. This is similar to the way that legacy CISC string operations are handled by modern implementations.

## Conclusions

Data parallel instructions have appeared in many forms in high-performance computer architectures over the last 30 years. They remain popular because many applications are amenable to data parallel execution, and because data parallel hardware is the simplest and cheapest way to exploit this type of application parallelism. As multimedia extensions evolve, they are likely to adopt more of the characteristics of traditional shared-memory vector ISAs to reduce loop startup overhead and decrease code size. However, these new multimedia vector ISAs will be shaped by the need to coexist with the speculative out-of-order execution engines used by the superscalar processors.

## 5.4 Multithreading, Multiprocessing

*Manoj Franklin*

### Introduction

A defining challenge for research in computer science and engineering has been the ongoing quest for faster execution of programs. There is broad consensus that barring the use of novel technologies such as quantum computing and biological computing, the key to further progress in this quest is to do parallel processing of some kind.

The commodity microprocessor industry has been traditionally looking to fine-grained or instruction level parallelism (ILP) for improving performance, with sophisticated microarchitectural techniques (such as pipelining, branch prediction, out-of-order execution, and superscalar execution) and sophisticated compiler optimizations. Such hardware-centered techniques appear to have scalability problems in the sub-micron technology era and are already appearing to run out of steam. According to a recent position paper by Dally and Lacy [4], “Over the past 20 years, the increased density of VLSI chips was applied to close the gap between microprocessors and high-end CPUs. Today this gap is fully closed and adding devices to uniprocessors is well beyond the point of diminishing returns.” We view ILP as the main success story form of parallelism thus far, as it was adopted in a big way in the commercial world for reducing the completion time of general purpose applications. The future promises to expand the “parallelism bridgehead” established by ILP with the “ground forces” of thread-level parallelism (TLP), by using multiple processing elements to exploit both fine-grained and coarse-grained parallelism in a natural way.

Current hardware trends are playing a driving role in the development of multiprocessing techniques. Two important hardware trends in this regard are single chip transistor count and clock speed, both of which have been steadily increasing due to advances in sub-micron technology. The Semiconductor Industry Association (SIA) has predicted that by 2012, industry will be manufacturing processors containing 1.4 billion transistors and running at 10 GHz [39]. DRAMs will grow to 4 Gbits in 2003. This increasing transistor budget has opened up new opportunities and challenges for the development of on-chip multiprocessing.

One of the challenges introduced by sub-micron technology is that wire delays become more important than gate delays [39]. This effect is predominant in global wires because their length depends on the die size, which is steadily increasing. An important implication of the physical limits of wire scaling is that, the area that is reachable in a single clock cycle of future processors will be confined to a small portion of the die [39].

A natural way to make use of the additional transistor budget and to deal with the wire delay problem is to use the concept of *multithreading* or *multiprocessing*<sup>1</sup> in the processor microarchitecture. That is, build the processor as a collection of independent *processing elements (PEs)*, each of which executes a separate *thread* or flow of control. By designing the processor as a collection of PEs, (a) the number of global wires reduces, and (b) very little communication occurs through global wires. Thus, much of the communication occurring in the multi-PE processor is *local* in nature and occurs through short wires.

In the recent past, several multithreading proposals have appeared in the literature. A few commercial processors have already started implementing some of these multithreading concepts in a single chip [24,34]. Although the underlying theme behind the different proposals is quite similar, the exact manner in which they perform multithreading is quite different. Each of the methodologies has different hardware

<sup>1</sup>In this section, we use the terms *multithreading*, *multiprocessing*, and *parallel processing* interchangeably. Similarly, we use the generic term *threads* whenever the context is applicable to processes, light-weight processes, and light-weight threads.

and software requirements and trade-offs. The objective of this chapter is to present a common framework for studying different multiprocessing and multithreading techniques, and to discuss existing multithreaded processors and futuristic proposals in the light of this framework. The following are some of the questions that are specifically addressed in the common framework:

- Parallel programming model
- Nature of threads
- PE Interconnects
- Role of the compiler

The introduction section has highlighted the importance of multithreading and multiprocessing. The rest of this chapter is organized as follows. The section on “Parallel Processing Software Framework” presents a common framework for studying different multithreading and multiprocessing approaches, and highlights software issues that are important to consider while examining them. The section on “Parallel Processing Hardware Framework” presents a common framework for studying parallel processor hardware configurations. The “Concluding Remarks” section provides a survey of existing multithreaded processors and proposals. In particular, it describes how multithreading is employed in the multiscalar processor, the superthreaded processor, the trace processor, the M-machine, and some of the other multithreaded microarchitectures. Finally, “Concluding Remarks” presents a qualitative comparison and discusses future trends.

## **Parallel Processing Software Framework**

In this section we discuss our framework for studying multithreading and multiprocessing. We also identify three key issues related to multithreading: thread granularity, parallel programming model, and program partitioning into threads. We shall discuss each of these issues in detail. Not all of these issues are entirely orthogonal to each other, and it is our objective to highlight how each issue bears on other related issues.

We define a *thread* as a flow of control through a program and that flow’s current state (represented by a current program counter, a call/return stack and, occasionally, some thread-private data). The central idea behind multithreading and multiprocessing is to have multiple flows of control within a process, allowing parts of the process to be executed in parallel. A process can have one or more threads doing its work. Threads that execute in parallel are invariably control-independent, in which case the decision to execute a thread does not depend on the other active threads. Thus, instructions that are control-dependent on a conditional branch invariably belong to the thread to which that branch belongs.

### **Parallel Programming Model**

An important attribute of any multiprocessing/multithreading system is its parallel programming model, embodied in a parallel language or programming environment. This model specifies the names (such as registers and memory addresses) the thread can access, the operations it can perform on the named data, and the ordering semantics among these operations, particularly those done by distinct threads. (In the simplest case, the model assumes multiprogramming, which has no inter-thread communication and synchronization.) First, we will discuss thread sequencing model, which specifies ordering constraints (if any) on multiple threads. Then, we discuss inter-thread communication, which deals with passing data values among two or more threads. Finally, we discuss synchronization aspects of the programming model, which cause running threads to wait for one another, and waiting threads to resume execution at the proper time. Orchestrating the inter-thread ordering often requires explicit synchronization operations when the ordering implicit in the basic operations is not sufficient.

### ***Thread Granularity and Management***

Thread-level parallelism (TLP) is more coarse-grained than ILP, and has wide variance in granularity. We categorize the TLP granularities into three levels as described below. Depending on the granularity,

thread management (including run-time thread scheduling) is done by the operating system or the run-time hardware.

- *Processes*: In this case, a thread is a process itself. Parallel processing then involves executing multiple processes in parallel, which is traditionally known as *multitasking* or *multiprogramming*. This is perhaps the most common form of parallel processing, as even most of the uniprocessor operating systems implement this (by time sharing). Multiple processes can be created using the `fork` system call. Processes can be thought of as heavy-weight threads, as their creation entails duplicating the memory address space, and can take hundreds of thousands of CPU clock cycles. Management and scheduling of processes is done by the operating system. In a multiprogramming environment, parallelly executing processes either do not communicate, or communicate through operating system features such as `pipes`.
- *Light-weight processes or threads*: A light-weight process (also called *thread*) has a granularity somewhat finer than a process. The concept of light-weighted processes has been implemented in a number of operating systems (SUN Solaris, IBM AIX, and Microsoft Windows NT), thread libraries, and parallel programming languages. Such threads are used in today's symmetric multiprocessor workstations and servers. An important characteristic is that these threads share a common memory address space, and are nonspeculative from the control point of view.
- *Fine-grain threads*: These threads are much smaller (of the order a few hundred instructions, at most) and are not generally known to the operating system. Thread management and scheduling are typically done by the run-time hardware. In many cases, such threads share a common register space, besides sharing a common memory address space. Furthermore, the threads are often speculative from the control point of view.

For a particular TLP granularity, the system performance will depend to a large extent on the nature of the application and the level of the memory hierarchy at which the PEs are interconnected.

**Thread Sequencing Model**

The commonly used model for control flow among threads is the *parallel threads* model (also called the *control operators based parallel control flow* model). In this model, a *fork* instruction or a variant specifies the creation of new threads and their starting addresses. The parent thread as well as the forked threads are allowed to execute in parallel until they reach a *join* instruction, after which only one of them can continue. Thus, the join operation serves as a synchronizing point. Apart from the join, other explicit synchronization operations can be introduced using *locks* and *barriers*. Computation inside each thread is based on sequential control flow. This thread sequencing model is illustrated in Fig. 5.13.

Compilers and programmers have made significant progress in parallelizing regular numeric applications for the parallel threads model; however, they have had little or no success in doing the same for highly irregular numeric or especially nonnumeric applications [18]. In such applications memory addresses

FIGURE 5.13 Parallelism profile for a parallel threads model.

are difficult (if not impossible) to statically predict—in part because they often depend on run-time inputs and behavior—that makes it extremely difficult for the compiler to statically prove whether or not potential threads are independent. Given the size and complexity of real non-numeric programs, parallelization appears to be an unrealistic goal if we stick to the parallel threads model. For such applications, we can use a different thread control flow model called *sequential threads* model. This model is closer to sequential control flow, and envisions a strict sequential ordering among the threads. That is, threads are extracted from sequential code and run in parallel, without violating the sequential program semantics. The control flow of the sequential code imposes an order on the threads and, therefore, we can use the terms *predecessor* and *successor* to qualify the relation between any given pair of threads. This means that inter-thread communication between any two threads (if any) is strictly in one direction, as dictated by the sequential thread ordering. Thus, no explicit synchronization operations are necessary, as the sequential semantics of the threads guarantee proper synchronization. This relaxation allows us to “parallelize” nonnumeric applications into threads without explicit synchronization, even if there is a potential inter-thread data dependence. Program correctness will not be violated if at run time there is a true data dependence between two threads. The purpose of identifying threads in such a model is to indicate that those threads are good candidates for parallel execution.

Examples for multithreading proposals using sequential threads are the multiscalar model [8,9,30], the superthreading model [35], the trace processing model [28,36], and the dynamic multithreading model [1]. When using the sequential threads model, we can have threads that are *nonspeculative* from the control point of view, as well as threads that are *speculative* from the control point of view. The latter model is often called *speculative multithreading (SpMT)*. This model is particularly important to deal with the complex control flow present in typical non-numeric programs. The multiscalar architecture [8,9,30] provided a complete design and evaluation of an SpMT architecture. Since then, many other proposals have extended the basic idea of SpMT [5,19,22,28,31,35,36]. One such extension is threaded multipath execution (TME) [38], in which the speculative threads are the alternate paths of hard-to-predict branches. A simple form of the SpMT model uses loop-based threads only [15,22].

### ***Inter-Thread Communication***

Inter-thread communication refers to passing data values between two or more threads. One of the key issues in a parallel programming model is the name levels at which sharing takes place between threads. Communication can take place at the level of register space, memory address space, and I/O space, with the registers being the level closest to the processor. If sharing can happen at a particular level, it can also happen at a more distant level. Parallel programming models can be classified into three categories, based on the sharing level that is closest to the processor:

- Shared register model
- Shared memory model
- Message passing model

In the *shared register model*, multiple threads share the same register space (or a portion of it). Inter-thread communication happens implicitly due to reads and writes to the shared registers (and to shared memory locations). This model typically uses fine-grain threads, because it is difficult to have long threads that communicate at the low level of registers, granularity is small. This class of parallel processors is fairly new and has evolved as an extension of single-threaded ILP processors. Examples are the multiscalar execution model [8,9,30], the trace execution model [28,36], and the dynamic multithreading model (DMT) [1].

In the *shared memory model*, multiple threads share a common memory address space (or a portion of it). Inter-thread communication occurs implicitly as a result of conventional memory access instructions to shared memory locations. That is, writes to a logically shared address by one thread are visible to reads of the other threads, provided there are no other prior writes to that address as per the memory consistency/synchronization model.

In the *message passing model*, inter-thread communication occurs only through explicit I/O operations called messages. That is, the inter-thread communication is integrated at the I/O level rather than at the memory level. The messages are of two kinds—*send* and *receive*—and their variants. The combination of a send and a matching receive accomplishes a pairwise synchronization event. Several variants of the above synchronization event are possible. Message passing has long been used as a means of communication and synchronization among cooperating processes. Operating system functions such as *sockets* serve precisely this function.

### **Inter-Thread Synchronization**

Synchronization involves coordinating the results of a set of parallel threads into some merged result. An example is waiting for one thread to finish filling a buffer before another begins using the data. Synchronization is achieved in different ways:

- *Control Synchronization*: Control synchronization depends only on the threads' control state and is not affected by the threads' data state. This synchronization method requires a thread to wait until other thread(s) reach a particular control point. Examples for control synchronization operations are *barriers* and *critical sections*. With barrier synchronization, all parallel threads have a common barrier point. Each thread is allowed to proceed after the barrier only after all of the spawned threads have reached the barrier point. This type of synchronization is typically used when the results generated by the spawned threads need to be merged. With critical section type synchronization, only one thread is allowed to enter into the critical section code at a time. Thus, when a thread reaches a critical section, it will wait if another thread is currently executing the same critical section code.
- *Data Synchronization*: Data synchronization depends on the threads' data values. This synchronization method requires a thread to wait at a point until a shared name is updated with a particular value (by another thread). For instance, a thread executing a `wait (x == 0)` statement will be delayed until `x` becomes zero. Data synchronization operations are typically used to implement *locks*, *monitors*, and *events*, which, in turn, can be used to implement *atomic operations* and *critical sections*. When a thread executes a sequence of operations as an atomic operation, other threads cannot access any of the (shared) names updated during the atomic operation until the atomic operation has been completed.

### **Coherence and Consistency**

The last aspect that we will consider about the parallel programming model is coherence and consistency when threads share a name space. Coherence specifies that the value obtained by a read to a shared location should be the latest value written to that location. Notice that when a read and a write are present in two parallel threads, coherence does not specify any ordering between them. It merely states that if one thread sees an updated value at a particular time, all other threads must also see the updated value from that time onward (until another update happens to the same location).

The consistency model determines the time at which a written value will be made visible to other threads. It specifies constraints on the order in which operations to the shared space must appear to be performed (i.e., become visible to other threads) with respect to one another. This includes operations to the same locations or to different locations, and by the same thread or different threads. Thus, every transaction (or parallel transactions) transfers a collection of threads from one consistent state to another. Exactly what is consistent depends on the consistency model. Several consistency models have been proposed:

- *Sequential Consistency*: This is the most intuitive consistency model. As per sequential consistency, the reads and writes to a shared address space from all threads must appear to execute serially in such a manner as to conform to the program orders in individual threads. This implies that the overall order of memory accesses must preserve the order in each thread, regardless of how instructions from different threads are interleaved. A multiprocessor system is *sequentially consistent* if it always produces results that are same as what could be obtained when the operations of all threads

are executed in some sequential order [20]. Sequential consistency is very restrictive and prevents the multiprocessor hardware from performing many optimizations to improve performance.

- *Weak Consistency*: This consistency model [6] relaxes the constraints imposed by sequential consistency by relating memory access order to synchronization points in the program. That is, sequential consistency is maintained among the synchronization accesses. In addition, a synchronization access serves as a barrier by enforcing that all previous memory accesses must be completed before performing a synchronization access, and no subsequent memory accesses can be performed before completing a synchronization access.

In addition to weak consistency, several other relaxed consistency models have been proposed—*release consistency* [12], *processor consistency* [13], etc.

### **Partitioning a Program into Threads**

Thread selection involves partitioning a control flow graph (CFG) into threads. Given a particular parallel programming model (inter-thread communication model as well as thread sequencing model), how should the parallelizer go about deciding where the thread boundaries should be? Perhaps the most important issue in multiprocessing/multithreading is the basis used for partitioning a program into threads. The criterion used for partitioning is very important, because an improper partitioning could in fact result in high inter-thread communication and synchronization, thereby degrading performance! True multithreading should not only aim to distribute instructions evenly among the threads, but also aim to minimize inter-thread communication by localizing a major share of the inter-instruction communication occurring in the processor to within each PE. In order to achieve this, mutually data dependent instructions are most likely allocated to the same thread. This is somewhat hard, because programs are currently written in control-driven form, which often causes individual strands of data-dependent instructions to be spread over a large segment of code. Thus, the partitioning software has to first construct the data flow graph (DFG), and then do the program partitioning. Notice that if programs were specified in data-driven form as in the dataflow computation model [17], taking data dependences into account would have been simpler.

Thread selection is a difficult problem, because we need to consider many issues such as PE utilization, load balancing, control independence of threads (thread prediction accuracy for SpMT models), and inter-thread data dependences. Often, trying to make optimizations for one area will have a negative effect on another.

### ***Who Does the Program Partitioning?***

Program partitioning can be done by the programmer, compiler, or run-time hardware. Depending on who does the partitioning, the type of analysis that can be done will be different.

- *Programmer*: In this approach, the programmer explicitly represents the threads in the high-level language program. In order to do this, three types of extensions are provided at the high-level language level: (i) multithreading library, (ii) language extensions, and (iii) compiler directives. Examples for this approach are EARTH [21] and XMT [37]. All of these use the parallel threads model. Notice that the compiler has to be modified to handle these extensions. The compiler does not, however, make decisions on where to do the partitioning. It is interesting to note that although conventional multiprocessors have been commercially available for quite some time, only a small fraction of the software has been written so far to exploit parallelism.
- *Compiler*: In this case, the compiler takes a sequential program and partitions it into threads. The main advantage of deferring program partitioning to the compiler is that it frees the programmer from reasoning about parallel threads. Its main advantages with respect to hardware-based partitioning are that it does not add to the complexity of the processor, and that it has the ability to perform complex pre-partitioning and post-partitioning optimizations that are difficult to perform at run-time. Compiler-directed partitioning algorithms are generally insensitive to the number of PEs in the processor, however, its partitioning decisions need to be conveyed to the

multithreaded hardware, possibly by making it part of the ISA (at the expense of incompatibility for existing binaries). Parallelizing compilers have been successful in parallelizing many numeric applications for the parallel threads model. As pointed out earlier, their success has not been spectacular when it comes to non-numeric applications and the parallel threads model. Several researchers are currently working on parallelizing compilers that parallelize such applications for the sequential threads model.

- *Hardware:* It is also possible to let the run-time hardware do the program partitioning. If partitioning decisions are taken by the hardware, the multithreaded processor provides object code compatibility to existing sequential code. Furthermore, it has the ability to adapt to run-time behavior. Hardware-based partitioning is typically done only if the thread granularity is small, and if sequential control flow is used. The main limitation is the significant impact it may have on clock cycle time. In order to simplify the dynamic partitioning hardware and to reduce the impact on clock cycle time, the partitioning job is often split into two parts—a static part (which is done by pre-processing hardware) and a dynamic part. The static part collects information that is static in nature (such as register dependences in a straightline piece of code) and stores it in a special i-cache structure, often after performing some additional processing. The dynamic part uses this information while deciding the final partitioning at run-time. Examples of multithreaded processors that use hardware-based partitioning are trace processor [28,36], speculative multithreading processor [22], and dynamic multithreading processor [1].

### ***Compiling for Multithreading***

Most of the multithreading approaches perform partitioning at compile time, possibly with some help from the programmer; it is somewhat unrealistic at this time to expect programmers to write only parallel programs. The hardware is also limited in its program partitioning capability. Therefore, the compiler has the potential to play a significant role in multithreading. Besides program partitioning, it can schedule threads as well as the instructions within threads.

The task of the compiler is to identify sufficient parallelism to keep the processors busy, while minimizing the effects of synchronization and communication latencies on the execution time of the program. To accomplish this objective, a parallelizing compiler typically performs the following functions:

1. Identify the parallelism inherent in the program. This phase has received the most attention in parallel compiler research to date [25,26]. Many varied program transformations have been developed to unearth parallelism buried in the semantics of sequential programs.
2. Partition the program into multiple threads for parallel execution. This is perhaps the most crucial phase. Many factors must be considered, such as inter-thread dependences, intra-thread locality, thread size, critical path, and deadlock avoidance.
3. Schedule the concurrent execution of threads; the final scheduling is often determined by the run-time environment. The compiler must assign threads to processors in a way that maximizes processor utilization without severely restricting the amount of parallelism to be exploited.
4. After program partitioning, the compiler can schedule the instructions in a thread so as to reduce inter-thread wait times. For instance, if a shared value is produced very late in one thread, but is needed very early in another thread, very little parallelism will be exploited by the hardware. This problem is likely to surface frequently, if the compiler assumed a single-threaded processor in the code generation phase. In such situations, post-partitioning scheduling can help minimize the waiting time of instructions by ensuring that shared values required in other threads are produced as early as possible. Post-partitioning scheduling is especially beneficial if PEs execute their instructions in strict serial order.

### ***Object Code Compatibility***

Another important issue, especially from the commercial point of view, is the level of compatibility that the multithreaded processor provides. We can think of three levels of compatibility in the context of multithreaded processors: full compatibility, family-wide compatibility, and no compatibility.

- *Full Compatibility*: In some multithreaded processors, the multithreading aspect is strictly a microarchitectural phenomenon and is invisible at the ISA level. Such processors provide full compatibility, i.e., both backward compatibility and forward compatibility. Existing executable binaries can be run on them, and their executable binaries can be run on existing processors. Furthermore, these processors also provide compatibility across all multithreading models (of the same ISA) that provide full compatibility. In these processors, the thread partitioning is done by offline hardware or run-time hardware. Fully compatible multithreaded processors have a higher chance for commercial success.
- *Family-Wide Compatibility*: Although full compatibility is desirable, some multithreaded processors opt for ISA-level changes so as to benefit from compiler techniques to extract additional performance. Processors in the family-wide compatibility category provide compatibility within its multithreading family. Thus, they do not require recompilation to be performed when the number of PEs is changed. Generally, these processors also provide limited backward compatibility (albeit at reduced performance). For example, if an existing binary executable is given to the multiscalar processor, it can execute the entire program as a single task. This will not give good performance, but it can run the old binaries.
- *No Compatibility*: In spite of the benefits of object code compatibility, some multithreaded processors, such as the M-machine, go in for significant changes at the ISA-level, which preclude any possibility of backward compatibility or family-wide compatibility. The motivation is to tap into sophisticated compiler techniques to extract performance.

Several techniques for binary translation have been proposed recently to address the object code compatibility problem. These include static approach as in the FX!32 [16], dynamic approach as in the DAISY [7] and hardware-based schemes such as DIF [23]. Object code compatibility may become a less important issue in the future when these techniques become more mature and efficient. This will also open up more opportunities to tap architecture specific optimizations for multithreading in the future.

## Parallel Processing Hardware Framework

The previous section discussed a common framework for parallel programming and compilation. This section discusses a common framework for parallel processing hardware. In our hardware framework, regardless of the specific implementation, a multithreaded processor consists of multiple PEs, possibly along with a few centralized resources such as the thread allocation mechanism and parts of the memory subsystem, as shown in Fig. 5.14. The PEs work independently of each other (subject only to inter-PE

FIGURE 5.14 A generic 4-PE multiprocessor.

synchronization) and usually contain multiple execution units (EUs). The PEs are interconnected by some network or through centralized resources such as register file and memory, for inter-PE communication.

Our definition of a PE is somewhat loose. On one extreme, the PEs in some multithreaded processors are separate processor-memory systems with their own instruction cache, decode unit, register file, and execution units; on the other extreme, the PEs in some multithreaded processors even share the execution units, as in the dynamic multithreading processor [1]. Such a loose definition allows us to discuss a wide spectrum of multithreaded processors under a common framework.

## Number of PEs and PE Organization

The number of PEs in a multiprocessor is an important hardware parameter. This number is strongly tied to the perceived parallelism in the targeted application domain, and also the nature of the threads. On one extreme, we have single-PE multithreaded processors that perform time sharing. On the other extreme, we have massively parallel processors (MPPs) consisting of thousands of PEs, which are the most powerful machines available today for many time-critical applications [4]. Because of the sharp increase in the number of transistors integrated in a single chip, there is significant interest in integrating multiple PEs in the same chip. This has been the motivation behind many of the SpMT processing models.

### *Processor Context Interleaving*

When the number of parallel threads exceeds the number of PEs, it is possible to time-share a single PE among multiple threads in a way that minimizes the time required to switch threads. This is accomplished by sharing as much as possible of the program execution environment between the different threads so that very little state needs to be saved and restored when changing threads. This type of low-overhead interleaving is given the name *multithreading* in many circles [2,3,17]. Interleaving-based multithreading differs from conventional multitasking (or multiprogramming) in that the concurrent threads share more of their environment with each other than do concurrent tasks under multitasking. Threads may be distinguished only by the value of their program counters and stack pointers while sharing a single address space and set of global variables. As a result, there is very little protection of one thread from another, in contrast to multitasking. Interleaving-based multithreading can thus be used for very fine-grain multitasking, at the level of a few instructions, and so can hide latency by keeping the processor busy after one thread issues a long-latency instruction on which subsequent instructions in that thread depend.

- *Cycle-level interleaving:* In this scheme, a PE switches to a different thread after each instruction fetch; i.e., an instruction of another thread is fetched and fed into the execution pipeline in the next clock cycle. Cycle-level interleaving is typically used for coarse-grain threads—processes or light-weight processes. The motivation for this is that it eliminates control and data dependences between the instructions that are simultaneously active in the pipeline. Thus, there is no need to build complex forwarding paths, permitting a simple and potentially fast pipeline. Furthermore, the context switch latency is zero cycles. Memory latency is tolerated by not scheduling a thread until the memory access has been completed. For this interleaving to work well, there must be as many threads as the worst-case latencies experienced by the instructions. Interleaving the instructions from many threads limits the processing speed of a single thread, thereby degrading single-thread performance. The most well-known examples of cycle-level interleaving processors are HEP [29], Horizon [33], and Tera MTA [2].
- *Block interleaving:* In this scheme, the instructions of a thread are executed successively until a long-latency event occurs, which causes a context switch. A typical long-latency operation is a remote memory access. Compared to the cycle-level interleaving technique, a smaller number of threads is sufficient, and a single thread can execute at full speed until the next context switch. The events that cause a context switch can be determined statically or dynamically.

When hardware technology allows more PEs to be integrated in a processor, PE interleaving becomes less attractive, because computational throughput will clearly improve when multiple threads execute in

**FIGURE 5.15** Organizing the PEs of a multithreaded processor as a circular queue.

parallel on multiple PEs instead of time-sharing a single PE. As we look into the future, and the prospect of a billion transistors on a single chip, it seems inevitable that microprocessors will have multiple PEs.

### **PE Organization**

The next issue of importance in a multithreaded processor is the organization of the PEs. This issue is strongly tied to the PE interconnect used. Most of the sequential threads model based processors organize the PEs as a circular queue, as shown in Fig. 5.15. The circular queue imposes a sequential order among the PEs, with the head pointer indicating the oldest active PE. When the tail PE is idle, a thread allocation unit (TAU) invokes the next thread (as per the sequential thread ordering) on the tail PE and advances the tail pointer. Completed threads are retired from the head of the PE queue, enforcing the required sequential ordering. Although this PE organization is tailored for sequential threads (from a sequential program), this multithreaded hardware can also execute multiple threads from different processes, if required.

An important issue that needs to be considered when organizing the PEs as a circular queue is *load balancing*. If some PEs have long threads assigned to them, and the rest have short ones, only modest performance will be obtained. If threads are not close to the same size, a short thread may complete soon and perform no useful computation while it waits for longer predecessor threads to retire. To get good performance, threads should be of uniform length.<sup>1</sup> One option to deal with load balancing, albeit with additional hardware complexity, is to let each physical PE have multiple virtual PEs and assign a thread to each of the virtual PEs.

### **Inter-PE Register Communication and Synchronization**

As discussed earlier, a few multithreading approaches have a shared register space for all threads, and the rest do not. When threads share a common register space, the thread sequencing model has always been the sequential threads model. Because the semantics of this model are in line with sequential control flow, synchronization happens automatically, once inter-PE register communication is handled properly.

### **Register File Implementation**

When threads do not share a common register space, it is straightforward to implement the register file (RF)—each PE can have its own register file, thereby providing fast register access. When threads share

<sup>1</sup>The actual, more stringent, requirement is that the thread execution times should be matched across all PEs. This is a more difficult problem, because it depends on intra- and inter-PE data dependences as well.

a common register space, it is important that we still provide a separate register file in each PE to support fast register access, as it is difficult for a centralized register file to provide a 1-cycle multi-port access time with today's high clock rates. This decentralization can be achieved in two ways, both of which provide faster register access times due to physical proximity and fewer access ports per physical register file.

- *RF Partitioning*: In this approach, each physical register file implements (or maps) an independent set of ISA-visible registers. Notice that a PE may occasionally need a register value stored in a nonlocal register file, in which case the value is fetched through an interconnection network that interconnects the PEs.
- *RF Replication*: With the replication scheme, a physical copy of the register file is kept in each PE, so that each PE has a local copy of the shared set register space. These register file replica maintain different *versions* of the register space, i.e., the multiple copies of the register file store register values that correspond to the processor state at different points in a sequential execution of the program. In general, replication avoids unnecessary communication; however, if not done carefully, it might increase communication by replicating data that is not used in the future. A multithreaded processor that uses the replication scheme is the multiscalar processor [9].

### **PE Interconnect for Register Values**

When threads share a common register space, and a distributed RF structure is used, an important hardware attribute is the type of interconnect used to send register values from one PE to another. The interconnects that have been proposed in the context of multithreaded processors are bus, ring (uni-directional and bi-directional), crossbar, mesh, and hypercube; of course, it is possible to use other types of interconnects as well.

**Bus:** The bus is a simple, fully connected network. However, it permits only one data transmission at any time, providing a bandwidth of only  $O(1)$ . In fact, the bandwidth scaling is worse than  $O(1)$  because of reduction in bus operating speed with the number of ports, due to increase in capacitance. Therefore, it may be a poor choice as an interconnect for inter-PE register communication, which may be nontrivial, especially when using a large number of PEs.

**Crossbar:** A crossbar interconnect also provides full connectivity from every PE to every other PE. It provides  $O(N)$  bandwidth, but the cost of the interconnect is proportional to the number of cross-points, or  $O(N^2)$ . When using a crossbar, all PEs are of same proximity to each other; hence the thread allocation algorithm becomes straightforward; however, a crossbar may not scale as easily as a ring or mesh. It is important to note that fast crossbars can be built on a single chip. With a crossbar-type interconnect, there is no notion of neighboring PEs, so all PEs become equally far away. Therefore, the cross-chip wire delays begin to dominate the inter-PE communication latency.

**Ring:** With a ring-type interconnect, the PEs are connected as a circular loop, and there is a notion of neighboring PEs and distant PEs. Routing in a ring is trivial because there is exactly one route between any pair of nodes (two routes if it is a bi-directional ring). The ring can be easily laid out with  $O(N)$  space using short wires (as depicted in Fig. 5.15), which can be easily widened. A ring is ideal if most of the inter-PE register communication can be localized to neighboring PEs (which is typically the case in a sequential threads processor that uses the circular queue PE organization [36]), but is a poor choice if a lot of communication happens across distant PEs. An advantage of the ring is that it easily supports the scaling up of the number of PEs, as allowed by technological advances.

**Mesh:** Rings generalize naturally to higher dimensions, including 2D grids and 3D cubes (with end-around connections). The main advantages of mesh are its regular structure and its ability to provide full connectivity between four neighboring PEs (as opposed to two PEs with the ring). Similar to a ring, a mesh can easily support the scaling up of the number of PEs. The mesh suffers from the same disadvantages of a ring in communicating with distant PEs. Moreover, thread allocation for a mesh topology is more complex than that for ring and crossbar.

## Inter-PE Memory Communication and Synchronization

When threads do not share a common memory address space (as in the message passing model), it is straightforward to provide a memory system for each PE, as we do not need to worry about inter-thread memory communication and synchronization.

### Memory System Implementation

When threads do share a common memory address space, the multithreaded processor needs to provide appropriate mechanisms for inter-thread memory communication as well as synchronization. One option is to provide a central memory system, in which all memory accesses roughly take the same amount of time. Such a system is called *uniform memory access (UMA)* system. An important class of UMA systems is the *symmetric multiprocessor (SMP)*.

A UMA system may provide uniformly slow access time for every memory access. Instead of slowing down every access, we can provide fast access time for most of the accesses by distributing the memory system (or at least the top portions of the memory hierarchy system). Shared memory multiprocessors that use partitioning are called *distributed shared memory (DSM)* systems. As with the register file structure, we can use two techniques—partitioning and replication—to distribute the memory.

- *Memory Partitioning*: Partitioning is useful if it is possible to confine most of the memory accesses made in one PE to its partition. Partitioning the top portion of the memory hierarchy may not be attractive, at least for irregular, non-numeric applications, because it may be difficult to do this confinement due to not knowing the addresses of most of the loads and stores at compile time. Partitioning of the lower portion of the memory hierarchy is often done, however, as this portion needs to handle only those accesses that missed in the PEs' local caches.
- *Memory Replication*: It is impractical to replicate the entire memory system. Therefore, only the top part of the memory hierarchy is replicated. The basic motivation behind replicating the top portion of the memory hierarchy among local caches is to satisfy most of the memory accesses made in a PE with its local cache. Notice that a replicated cache structure must maintain proper coherency among all the duplicate copies of data.

DSMs often use a combination of partitioning and replication, i.e., portions of the memory hierarchy are replicated and the rest are partitioned. One type uses replicated cache memories and partitioned main memories. One interesting variation is the *cache only memory architecture (COMA)* system. A COMA multiprocessor partitions the entire memory system across the PEs; however, there is no fixed partition assigned for a particular memory location. Rather, the partition associated with a memory location is dynamically changed based on the PEs that access that location. Several other shared memory organizations are also possible [3,17].

### Inter-PE Data Dependence Speculation

In the parallel threads model, synchronization of threads is carried out with the use of special mechanisms such as locks and barriers. In the sequential threads model, ensuring sequential semantics ensures proper memory synchronization. However, this means that when a load instruction is encountered in a PE, it has to ensure that its producer store has been already executed. This is difficult to determine if the producer store belongs to another thread, as memory addresses are calculated at run-time, and it is possible that the producer store instruction may not have even been fetched. In order to overcome this problem, sequential threads based processors incorporate some form of *thread-level data speculation* [11]. The idea is to speculate if a memory operation has to wait for inter-thread synchronization. This speculation can be as simple as predicting that the producer store has been already executed, or it can be more complex, based on past behavior of the load instruction. Below we discuss some of the hardware schemes proposed for carrying out thread-level data speculation.

- *Address Resolution Buffer (ARB)*: The ARB [11] is a hardware buffer for storing different versions of several memory locations as well as information regarding the loads and stores executed from the currently active threads. Each entry in the ARB buffers all versions of the same memory location.

**FIGURE 5.16** Block diagram of a multi-version cache in a sequential threads based multithreaded processor.

When a load request is issued for a particular memory address, the corresponding ARB entry is checked to see if a prior store has been done to the same address; if so, the value written by the latest store is returned by the ARB; if not, the request is sent to the next lower level of the memory hierarchy. In either case, the state information for that location is updated to reflect the fact that a load has been made by the current thread. When a store operation is performed, the ARB checks if any sequentially successor loads have been prematurely performed. If so, that is an incorrect data dependence speculation, and the ARB hardware initiates a recovery action such as partially re-executing the thread containing the incorrect load (and subsequent threads). A centralized hardware approach such as the ARB has the danger of increasing the load latency due to long latency incurred because of long wires.

- *Multi-Version Cache (MVC)*: The MVC uses a decentralized approach by using a local data cache (LDC) for each PE [10]. Each LDC thus stores a different version for each mapped memory location. The local data caches are interconnected by a unidirectional ring, as shown in Fig. 5.16. The loads and stores generated in a PE are serviced directly from its local data cache. When a load request is issued to a local data cache, it provides a value if it has a copy; otherwise, the request is sent to the next lower level of the memory hierarchy. In either case, the state information for that location in the data cache is updated to reflect the fact that a load has been made by the current thread. When a store operation is performed, the value is written in its local data cache. The last updates to each memory location (in a thread) are forwarded to the subsequent LDCs through the ring-type interconnect. When a forwarded value reaches an LDC, it checks for incorrect speculations and takes appropriate recovery actions.
- *Speculative Versioning Cache (SVC)*: The speculative versioning cache is similar to the multi-version cache in many respects [14]. It also keeps a separate private cache for each PE. The differences are mainly in the way the caches are connected and in the methodology by which the caches are kept coherent. SVC uses a bus interconnect for the caches a snooping bus based cache coherence protocol.

## Concluding Remarks

Multithreaded processors are the future of computer design. The ease of hardware replication has proven to be an ever-increasing impetus toward parallel processor implementations. The goal is to maintain high levels of parallelism (without increasing hardware complexity and the clock rate) by distributing the dynamic instruction stream among several processing elements. The combined issue rates of several processing elements allow large amounts of parallelism to be exploited.

Multithreading and multiprocessing, as with other complex engineering problems, undergo an ongoing process of reinventing, borrowing, and adapting.

**FIGURE 5.17** Complexity in multithreading/multiprocessing.

Looking forward to the future of multithreaded processors, the pace of change makes for rich opportunities and also for great challenges. Although it is difficult to precisely predict where this field will go, this final section seeks to outline some of the key areas of development in multithreaded processors. Whatever technological breakthroughs occur and whatever directions the market takes, the fundamental issues addressed in the “Parallel Processing Software Framework” section will still apply. The realization of multithreaded processors will still rest upon good techniques to perform thread selection, inter-PE communication, and synchronization. The core techniques for addressing these issues will remain valid; however, the way that they are employed will surely change as the critical parameters of clock speeds and wire delays continue to change.

It is difficult to obtain good performance without having *complexity* somewhere in the hardware-software multithreaded system! In a high-performance multithreaded processor, the complexity could be at the static partitioning side (programming or compiler), at the dynamic partitioning hardware side, or at the PE interconnect side. Figure 5.17 illustrates this concept. To support hardware scalability, complexity at the dynamic partitioning hardware and the PE interconnect act as hurdles. In the long run, as more transistors are integrated into a processor chip, it can be expected that the number of PEs would be scaled up. However, the trend towards higher clock rates will make it more difficult to support complexity in the dynamic partitioning hardware and in the PE interconnect.<sup>2</sup> Thus, the end result of the trends in high transistor count and high clock rates (which encourage multithreading/multiprocessing) is a shift towards doing more and more things statically, as opposed to dynamically. This means that program partitioning will eventually be done only at compilation time, and perhaps more and more at programming time.

## To Probe Further

Multiprocessing has been around for a long time, and so naturally the computer literature has an overabundance of articles and textbooks on this subject. The multiprocessing community consists of different camps, which often use different terminology for the same concepts. This lack of consensus makes it somewhat difficult to merge the ideas presented in different papers or books. Nevertheless, we

<sup>2</sup>Although it is possible to pipeline a crossbar interconnect so that it can accept new requests every cycle, the long inter-PE latency that it causes would increase the number of clock cycles required to execute a program, compared with what is obtained with scalable interconnects [27].

## 5.5 Survey of Parallel Systems

### Introduction

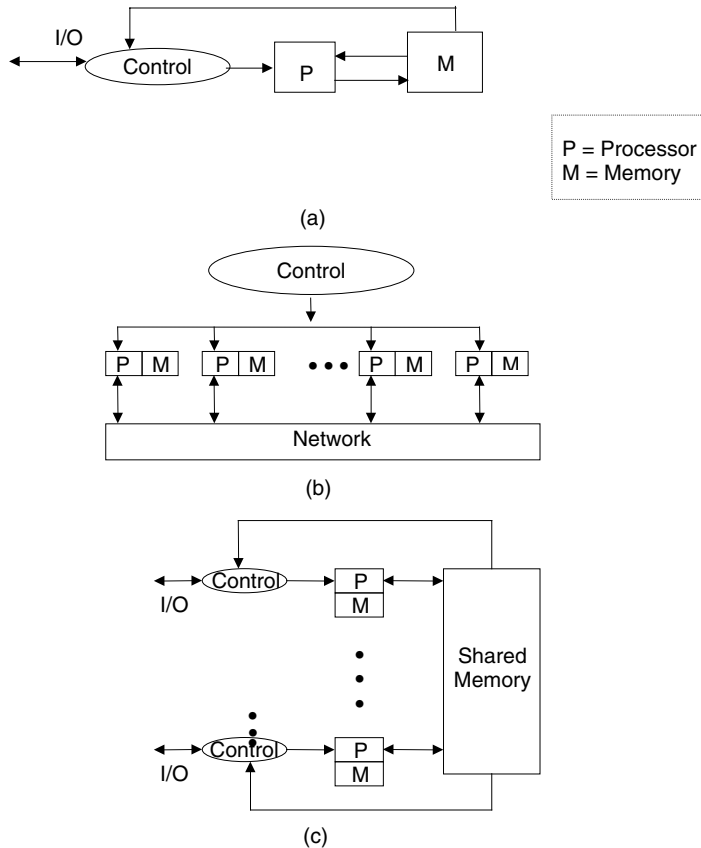

Computers have long been considered "a solution looking for a problem," but because of limits found by *complexity theory* and limits on computing power some problems that were presented could not be solved. Multimedia problems, image processing and recognition, AI application, and weather prediction may not be accomplished unless processing power is increased. There are many varieties of parallel machines, each has the same goal, to complete a task quickly and inexpensively. Modern physics has continually increased the speed and capacity of the media on which modern computer chips are housed, usually VLSI, and at the same time decreased the price. The challenge of the computer engineers is to use the media effectively. Different components may be addressed to accomplish this, such as, but not limited to:

- Functionality of the processors—floating point, integer, or high level function, etc.
- Topology of the network which interconnects the processors
- Instruction scheduling
- Position and capability of any master control units that direct the processors
- Memory address space
- Input/output features
- Compilers and operating systems support to make the parallel system accessible
- Application's suitability to a particular parallel system
- Algorithms to implement the applications

As can be imagined there is an assortment of chooses for each of these components. This provides for the possibility of a large variety of parallel systems. Plus more chooses and variations are continually being developed to utilize the increased capacity of the underlining media.

Mike Flynn, in 1972 [Flynn72], developed a classification for various parallel systems, which has remained authoritative. It is based on the number of instruction streams and the number of data streams active in one cycle. A sequential machine is considered to have *single instruction stream executing on a single data stream*; this is called *SISD*. An *SIMD* machine has a *single instruction stream executing on multiple data streams* in the same cycle. *MIMD* has *multiple instruction streams executing on multiple data streams* simultaneously. All are shown in Fig. 5.18. An *MISD* is not shown but is considered to be a *systolic array*.

Four categories of *MIMD* systems, *dataflow*, *multithreaded*, *out of order execution*, and *very long instruction words (VLIW)*, are of particular interest, and seem to be the tendency for the future. These categories can be applied to a single CPU, providing parallelism by having *multiple functional units*. All four attempt to use fine-grain parallelism to maximize the number of instructions that may be executing in the same cycle. They also use fine-grain parallelism to assist in utilizing cycles, which possibly could be lost due to large *latency* in the execution of an instruction. Latency increases when the execution of one instruction is temporarily staled while waiting for some resource currently not available, such as the results of a cache miss, or even a cache fetch, the results of a floating point instruction (which takes longer than a simpler instruction), or the availability of a needed functional unit. This could cause delays in the execution of other instructions. If there is very fine grain parallelism, other instructions can use available resources while the staled instruction is waiting. This is one area where much computing power has been reclaimed.

**FIGURE 5.18** (a) SISD uniprocessor architecture. (b) General SIMD with distributed memory. (c) Shared memory MIMD.

Two other compelling issues exist in parallel systems. *Portability*, once a program has been developed it should not need to be recoded to run efficiently on a parallel system, and *scalability*, the performance of a system should increase proportional to the size of the system. This is problematic since unexpected bottlenecks occur when more processors are added to many parallel systems.

### Single Instruction Multiple Processors (SIMD)

Perhaps the simplest parallel system to describe is an SIMD machine. As the name implies all processors execute the same instruction at the same time. There is one master control unit, which issues instructions, and typically each processor also has its own local memory unit. SIMD processors are fun to envision as a school of fish that travel closely together, always in the same direction. Once one turns, they all turn. In most systems, processors communicate only with a set of nearest neighbors; *grids*, *hypercubes*, or *torus* are popular. In the most generic system, shown in Fig. 5.18(b), no set communication pattern is dictated. Because different algorithms do better on different physical topologies (algorithms for sorting do well on tree structures, but array arithmetic does well on grids), reconfigurable networks are ideal but hard to actually implement. A variety of structures can be built on top of grids if the programmer is resourceful, but some processing power would be lost. It is difficult for a compiler to decide which substructure would be optimal to use. A mixture of a close connections supplemented with longer connections seems to be most advantageous. *MasPar* [MasPar91] has SIMD capability and uses a grid structure supplemented with longer connections. The *Thinking Machines CM-5* has SIMD capability using a *fat-tree* network, also a mix of closer and longer connections. The *PEC* network also has this quality [Kirkman91, Quammen96].

Of course, SIMD machines have limits. Logical arrays may not meet the physical topology of the processors but require folding or skewing. *If* statements may cause different paths to be followed on different processors, and since it is necessary to always have synchronization, some processing power will be lost. *Masks* are used to inhibit issued instructions on processors on which they should not be executed. A single control unit becomes a bottleneck as a SIMD system expands. If a SIMD system were very large, it would be desirable to be able to use it as a multiprogrammed machine where different programs would be allocated different "farms" of processors for their use as a dedicated array. A large SIMD system should be sub-dividable for disjoint multiuser applications. The operating system would have to handle this allocation.

On a SIMD computer a loop such as the one below can be translated to one SIMD instruction as is shown. The form  $A(1:N)$  means array  $A$  indexes 1 to  $N$ :

```
for I = 1 to N do
  A(I) = B(I) + C(I);      A(1:N) = B (I:N) + C(1:N);
endfor;
```

The code below would take four steps:

```
F(0) = 0;
for I = 1 to N do          F(0) = 0;
  A(I) = B(I)/C(I);      A(1:N) = B (I:N)/C(1:N);
  D(I) = A(I) * E(I);    D(1:N) = A(1:N) * E(1:N);
  F(I) = D(I) + F(I - 1); F(1:N) = D(1:N) + F(0:N - 1);
endfor;
```

Compilers can identify loops such as the ones presented above [Wolfe91]. However, many loops are not capable of executing in a SIMD fashion because of reverse dependencies. Languages have been developed for SIMD programming, which allows the programmer to specify data locations and communication patterns.

## Multiple Instruction Multiple Data (MIMD)

Perhaps the easiest MIMD processor to envision is a shared memory multiprocessor such as shown in Fig. 5.18(c). With this machine, all processors access the same memory bank with the addition of local caches. This allows the processors to communicate by placing data in the shared memory. However, sharing data causes problems. *Data* and *cache coherence* are of major concern. If one processor is altering data that another processor wishes to use, and the first processor is also holding the current updated value for this data in its cache, there is a need to guard access to the stale value which is being held in the shared memory. This creates a need for *locks* and *protocols* to protect communal data. Inefficient algorithms to handle cache coherence can cause delays, or invalidate results. In addition, if more than one processor wishes to access the same locked memory location, a fairness issue occurs as to which processor should be allowed first access after the location becomes unlocked [Hwang93]. Further delays in accessing the shared memory occur due to the use of a single bus. This arrangement is described as a uniform memory access (UMA) time approach and avoids worst-case communication scenarios possible in other memory arrangements.

To reduce contention on the bus as a MIMD memory system scales, a distributed memory organization can be used. Here, clusters of processors share common memories, and the clusters are connected to allow communications between clusters. This is called a NUMA (nonuniform memory access) organization [Gupta91]. If a MIMD machine is to be *scalable*, this approach must be used. Machines within the same cluster will be able to share data with less latency than machines housed on different memory banks. It will be possible to access all data. This creates questions as to which sets of data should be placed on which processor cluster. Compilers can help with this by locating a code that uses common data. If data is poorly placed, the worst-case execution time could be devastating.

Message passing systems, such as the *Transputer* [May87], have no shared memory but handle communications using message passing. This can cause high latency while waiting for requested data; however, each processor can hold multiple threads, and may be able to occupy itself while waiting for remote data. Deadlocks are a problem.

Another variation of memory management is cache only memory access (COMA). Memory is distributed, but only held in cache [Saulsbury95]. The Kendall Square machine [KSR91] has this organization. On the KSM distributed memory is held in the cache of each processor, which is connected by a ring. The caches of remote processors are accessed using this ring.

## Vector Machines

A *vector machine* creates a series of functional units and pumps a stream of data through the series. Each stage of the pipe will store its resulting data in a *vector register*, which will be read by the next stage. In this way the parallelism is equal to the number of stages in the pipeline. This is very efficient if the same functions are to be preformed on a long stream of data. The Cray series computer [Cray92] is famous for this technique. It is becoming popular to make an individual processor of a MIMD system a vector processor.

## Dataflow Machine

The von Neumann approach to computing has one control state in existence at one time. A program counter is used to point to the single next instruction. This approach is used in traditional machines, and is also used in most of the single processors of the multiple processor systems described earlier. A completely different approach was developed at the Massachusetts Institute of Technology [Dennis91, Arvind90, Polychronopoulos89]. They realized that the maximum amount of parallelism could be realized if at any one point *all instructions that are ready to execute* were executed. An instruction is *ready* to execute if the data that is required for its complete execution is available. Therefore, execution of an instruction is not governed by the sequential order, but by its readiness to execute, that is, when both operands are available. A table is kept of the instructions that are *about ready* to execute, that is, one of the two operands needed for the *assembly language level instruction* is available. When the second operand is found, this instruction is executed. The result of the execution is passed to a control unit, which will select a set of new instructions to be *about ready* to execute, or mark an instruction as *ready* (because the second operand needed has arrived).

This approach yields the maximum amount of parallelism. However, it runs into problems with “run away execution.” Too many instructions may be *about ready*, and clog the system. It is a fascinating approach, and machines have been developed. It has the advantage that no, or very little, changes need to be made to *old dusty decks* to extract parallelism. Steps can be made to avoid “run away execution.”

## Out of Order Execution Concept

An approach similar to the *dataflow* concept is called *out of order execution* [Cintra00]. Here again, program elements that are ready to execute may be executed. It has a big advantage when multiple functional units are available on the same CPU, but the functional units have different latency values. The technique is not completely new but similar to issuing a *load instruction*, which has high latency, well before the result of the *load* is required. By the time the *load* is completed the code has reached the location where it is used. Also a *floating point instruction*, again a class of instructions with high latency, is frequently started before *integer instructions* coded to execute first are executed. By the time the *floating point* is complete, its results are ready to be used. The compiler can make this decision statically. In *out of order execution* the hardware has more of a role in the decision of what to execute. This may include both the *then* and the *else* parts of an *if* statement. They can both be executed, but not be committed to until the correct path is determined. This technique is also called *speculative execution*. Any changes that have been made by a wrong path must be capable of being rolled *back*. Although this may seem to be extra

computation, it will decrease execution time if done well. Other areas of the program may also be executed, if it is determined that their execution will not affect the final result or *can be rolled back*. The temporary results may be kept in registers. The Alpha Computer [Kessler99] as well as the Intel Pentium Pro [Intel97] use this technique. This method is becoming popular to fully utilize increasingly powerful computers.

Compiler techniques can be used to try to determine which streams should be chosen for advance execution. If the wrong choice is made, there is a risk of extremely poor performance due to continual rollbacks. Branch prediction, either statically by the compiler, or dynamically by means of architecture prediction flags, is a useful technique for increasing the number of instructions, which may be beneficial to execute prematurely.

Since assembler instructions contain precise register addresses, set by the compiler, and it is unknown which assembler instructions will be caught in partial execution at the same time, a method called *register renaming* is used. A *logical* register address is mapped to a *physical* register chosen from a *free list*. The mapping is then used throughout the execution of the instruction, and released again to the *free list*.

## Multithreading

*Multithreading* [Tullsen95] is another method to hide the latency endured by various instructions. More than one chain, or thread, of execution is active at any one point. The states of different chains are saved simultaneously [Lo97, Miller90] in their own *state space*. Modern programs are being written as a collection of modules, either *threads* or *objects*. Because one of the main advantages of this form of programming is data modulization, many of these modules could be ready to execute concurrently. While the processor is waiting for one thread's data (for example, a cache miss or even a cache access), other threads, which have a full state in their dedicated space, can be executed. The compiler cannot determine which modules will be active at the same time, that will have to be done dynamically. The method is somewhat similar to the *multiprogramming* technique of changing context while waiting for I/O; however, it is at a *finer grain*. Multiple access lines to memory are beneficial since many threads may be waiting for I/O. The *Tera machine* [Smith90] is the prime example of this technique. This approach should help lead to Teraflops performance.

## Very Long Instruction Word (VLIW)

A VLIW will issue an instruction to multiple functional units in parallel. Therefore, if the compiler can find one operation for each of the functional unit internal to a processor (these instructions are usually RISC-like), which will be able to execute at the same time (that is, the data for their execution are statically determined to be available in registers), and none of the instructions depend on an instruction being issued in the same cycle, then you can execute them in parallel. All the sub-instructions will be issued by one long instruction. The name VLSI comes from the need that the instruction be long enough to hold multiple operation codes, one for each functional unit, which will be used, and the register identifiers, which they need. Unlike the three methods described previously, the compiler is responsible for finding instructions that do not interfere with each other and assigning the registers for these instructions [Rau93, Park97]. The compiler packs these instructions statically into the VLIW. The Intel iWarp can control a *floating point multiplier, floating point adder, integer adder, memory loader, increment unit, and condition tester* on each cycle [Cohn89]. The instruction is 96 bits long and can, with compiler support, execute nine instructions at once. The code for the following loop can be turned into a loop of just one VLSI instruction as opposed to a loop of at least nine RISC size instructions.

$$\begin{aligned} &\text{for } I := 0 \text{ to } N - 1 \text{ do} \\ &\quad A(2*I) := C + B(I)*D; \end{aligned}$$

It is difficult for a compiler to find instructions that can fill all the fields statically, so frequently some of the functional units go unoccupied. There are many techniques to find qualified instructions, and frequently the long instruction can be filled. One technique is to mine separate threads [Lam87, Bakewell91], another successful technique tries together several basic blocks into a *hyperblock*. The hyperblock has

one entrance but may have several exits. This creates a long stream of code, which would normally be executed sequentially, and allows the compiler to choose instructions over this larger range. Roll-back code must be added to the hyperblock's exit to undo the affects of superfluous code that was executed, but would not execute sequentially. Loops are frequently *unrolled*, several iterations considered as straight code, to form hyperblocks. *Branch prediction* can also help create beneficial hyperblocks.

A newer approach is to dynamically pack the VLIW, using a preprocessor that accesses multiple queues, one for each functional unit. Realize that using queues is similar to *out of order execution*.

## Interconnection Network

An interconnection network is a necessary component of all parallel processing systems. Several features govern the choice of a network. A scalable interconnection network for parallel processor would be ideal if it meets the following requirements for a large range of system sizes. For instance, it may be scalable by reasonably small increments from  $2^4$  to perhaps  $2^{20}$  processors.

- Have a low average and maximum diameter (the distance between the furthest two nodes) to avoid communication latency.
- Minimize routing constraints (have many routes from *A* to *B*).
- Have a constant number of I/O port (channels) per node to allow for expansion without retrofit.
- Have a simple wire layout to allow for expansion and to avoid wasting VLSI space.
- Be inherently fault tolerant.
- Be sub-dividable for disjoint multiuser applications.
- Be able to handle a large range of algorithms without undo overhead.

The most popular parallel networks—hypercube, quad tree, fat-tree, binary tree, mesh, and torus—fail in one or more of these items.

Meshes have a major disadvantage: they lack support for long distance connections. Hypercubes have excellent connectivity by guaranteeing a maximum distance between any two nodes of  $\log N$  where  $N$  is the number of nodes. Also, many paths exist between any two nodes making it fault tolerant and amenable to low contention. However, the number of I/O ports per node is  $\log N$ . As a system scales, each node would need to be retrofit to add additional ports. In addition, the wire layout is complex, making this network expensive in space. Tree structures are popular and have a maximum long distance connection of  $O(2 \log N)$ . Communications on a tree, however, can be complicated by the fact that although many neighbors are close, many can only communicate through the root. This causes contention at the root. Fat-trees reduce this contention by increasing the bandwidth, as the network approaches the root [Leiserson85].

The extreme ideal network would allow all nodes to connect to all others. This is not practical for large system. However, one class of networks, the *multistage network*, uses an internal switching system and allows constant access time between any two nodes. Several arrangements are available for multistage networks. All are similar. One such network, the *baseline network*, is shown in Fig. 5.19. It can be proved that a  $N$ -by- $N$  network can be totally connected with  $\log N$  switches steps [Seigel89]. Each step is through a row of switches, with  $N/2$  switches in each row. This requires quite a bit of hardware and does allow for a connection in  $\log N$  steps. This is not very scalable.

*Optical* technology [Yuan97] has shown to be promising for the implementation of all networks. Instead of a wire, an optical “beam” is used to make the connection. This is fast and has several advantages. One, a broadcast can be made from one node to many nodes at once (although, one node cannot receive many inputs at once), and two, the transmission can be sent through clear space.

## Conclusion

Parallel systems are going to become almost universal in computer systems. Desktop computers are now frequently being delivered with more than one CPU and definitely with more than one functional unit. The new models of SUN, MIPS, Intel, and Macintosh desktop computers currently are providing parallel

**FIGURE 5.19** An  $8 \times 8$  baseline network.

computing capabilities. This feature is no longer limited to just super computers. In order to use these systems efficiently, the consumer should be aware of how their programs are going to utilize the systems. Compilers, operating systems, and program design are all things that should be examined.

Most parallel processing is being aimed at hiding latency; however, embedded systems and super computing implementations also need the ability to execute separate lines of control running independently, which must communicate with each other. Embedded systems need this to assure the strict adherence to real-time deadlines. Super computer applications need the additional processing power.

This chapter section only briefly discussed this field. A full addressing of the field is covered in large volumes of books and journals. Topics, such as compiler techniques, dedicated languages, communication techniques, multi-user facilities, algorithms, memory hierarchies, I/O facilities, programming tools, fault tolerant, power consumption, and debugging technique, are only an abbreviated list of topics which need to be examined. Plus, each of these subtopics has many aspects. All computer users should certainly be aware of this field.

## 5.6 Virtual Memory Systems and TLB Structures

---

*Bruce Jacob*

### Virtual Memory, a Third of a Century Later

Virtual memory was designed in the late 1960s to provide automated storage allocation. It is a technique for managing the resource of physical memory that provides to the application an illusion of a very large amount of memory—typically, much larger than is actually available. In a virtual memory system, only the most often used portions of a process's address space actually occupy physical memory; the rest of the address space is stored on disk until needed. When the mechanism was invented, computer memories were physically large (one kilobyte of memory occupied a space the size of a refrigerator), they had access times comparable to the processor's speed (both were extremely slow), and they came with astronomical price tags. Due to space and monetary constraints, installed computer systems typically had very little memory—usually less than the size of today's on-chip caches, and far less than the users of the systems would have liked. The virtual memory mechanism was designed to solve this problem, by using a system's disk space as if it were memory and placing into main memory only the data used most often.

Since then, we have seen constant evolution (and revolution) in the computer industry. Typical micro-processors today have more on-chip cache than the core memory found in multimillion-dollar systems of yesterday and cost orders of magnitude less. Today, memory takes up very little space: you can easily hold a gigabyte of DRAM in your hand. In recent decades, processor designers have focused on improving speed while memory-chip designers have focused on improving storage size, and, as a result, memory is now extremely slow compared to processor speeds. Due to rapidly decreasing memory prices, it is usually possible to have enough memory in one's machine to avoid using the disk as a backup memory space. Many of today's machines generate 64-bit addresses, some even larger; most modern machines therefore reference 16 exabytes (16 giga-gigabytes) or more of data in their address space directly. The list goes on. In fact, one of the few things that has not changed since the development of virtual memory is the basic design of the virtual memory mechanism itself, and the one problem it was invented to solve—too little memory—is no longer a factor in most systems. However, the virtual memory mechanism has proven itself valuable in other areas besides extending the memory space. Today it is used in nearly every modern operating system because of the convenience offered by its features: It simplifies memory allocation and memory protection, and it provides an intuitive programming interface to the application—the “virtual machine” interface—that simplifies program design and provides a natural path to multitasking.

### Caching the Process Address Space

A process operates in its own little world; this is the *virtual machine* paradigm, illustrated in Fig. 5.20. Each running process generates addresses for loads and stores as if it has the entire machine to itself—as if the computer offers an extremely large amount of memory and no other processes are executing or consuming resources. This makes the job of the programmer and compiler much easier, because no details of the hardware or memory organization are necessary to build a program.

The operating system divides the process address space into equal-sized portions for ease of management; these divisions are called *virtual pages*. A page is usually a multiple of the unit of transfer that hard disks use, and in most operating systems ranges from several kilobytes to several dozen kilobytes. A page is never fragmented; if any data in a virtual page are in physical memory then all the data in that page are, and if any of the data in a virtual page are nonexistent or being held on disk then all the data are. When the word *page* is used in a verb form, it means to allow a section of memory to be virtual—to allow it

**FIGURE 5.20 The virtual machine paradigm.** A process operates in its own virtual environment, unaware that other processes are executing and contending for the same limited resources. The operating system views each process address space as a collection of pages that can be cached in physical memory, or left in backing store.

**FIGURE 5.21 Caching the process address space.** In the first view, a process is shown referencing locations in its address space. Note that all loads, stores, and fetches use virtual names for objects, and many of the requests can be satisfied by a cache hierarchy. The second view shows that the address space is not a linear object stored on some device, but is instead scattered across hard drives and dynamically allocated when necessary.

to move freely between physical memory and disk. This allows the physical memory to be used more efficiently: When a region of memory has not been used recently, the space can be freed up for more active pages, and pages that have been migrated to disk are brought back in as soon as they are needed again.

How is this done? The ultimate home for the process's address space is *backing store*, usually a disk drive; this is where the process's instructions and data come from and where all of its permanent changes go to. Every hardware memory structure between the CPU and the backing store is a cache for the instructions and data in the process's address space. This includes main memory—main memory is really nothing more than a cache for a process's virtual address space. A cache operates on the principle that a small, fast storage device can hold the most important data found on a larger, slower storage device, effectively making the slower device look fast. The large storage area in this case is the process address space, which can be many gigabytes in size. Everything in the address space initially comes from the program file stored on disk or is created on demand and defined to be zero. Figure 5.21 illustrates: There really is no linear array of data that houses the process address space. Its illusion is actually manufactured by the operating system through the virtual memory mechanism.

When a program first begins executing, the operating system copies a small portion of the process address space from the program file stored on disk into main memory. This typically includes the first page of instructions in the program and possibly a small amount of data that the program needs at startup. Then, as more instructions or data are needed, the operating system brings in pages from the process's address on demand. This process, called *demand paging*, is depicted in Fig. 5.22.

In step 1 of the figure, the operating system initializes a process address space and loads the first page of instructions into physical memory. The operating system then sets the hardware program counter to the first instruction in the program, which sets the process running. Assuming that one of the first few instructions references the initialized data area, the uninitialized data area, or the (so far nonexistent) stack, the operating system will have to bring in a page of data from the program file or create an

**FIGURE 5.22 Demand paging at process start-up.** In step 1, the operating system loads the first page of the process's instructions into physical memory, and sets the program counter to the first instruction in the program. This first instruction references a location in the process's data area, so in step 2 the operating system brings the corresponding data page into physical memory. The next instruction references a location on the process's stack, so in step 3 the operating system has allocated a stack page for the process and placed it into the process address space and main memory. Succeeding instructions reference more locations in the stack area, jump to instructions that lie outside of the initial page of instructions, and allocate extra data storage area on the heap. In step *N* (many steps later), these pages have been brought into main memory.

uninitialized-data page or stack page and link it into the process address space. This is shown in steps 2 and 3 of the figure. When a process references an item in its address space that is not currently in physical memory, the reference causes a *page fault*, and the operating system loads the necessary pages from backing store into main memory. Clearly, the term *demand paging* refers to the fact that pages are allocated or brought into physical memory on demand. Step *N* of the figure shows a process that has been executing for some time, as it has several pages of data in its stack area and several pages in its data area that were not there when the process began executing. All of these pages were dynamically allocated by the operating system as the process needed or asked for them.

As has been pointed out before, the process is unaware of the operating system activity that moves pages in and out of main memory on its behalf. It typically does not know whether or not any given page is memory-resident or where it is located if it is memory-resident. Figure 5.20 at beginning of the section illustrates this by showing a process address space from two points of view. The first point of view is from the process itself; in most operating systems a process sees its address space as a contiguous span of memory locations from minimum to maximum. Somewhere in the address space is the program's instructions, or *text*; somewhere else is the program's data. Most operating systems also create a stack area, a heap area, and possibly one or more dynamically loaded libraries containing system-supplied utilities such as input/output routines or networking functions. The advantage of the virtual machine paradigm is that these can be arranged in physical memory, which is most convenient, rather than having to fit things together like the pieces of a puzzle, as would be the case without address translation.

The second point of view in the figure is from the operating system. In reality, the process address space is not a large contiguous segment in physical memory but is partially cached by physical memory. Portions of the process address space are scattered about physical memory and are likely to be not contiguous at all. The process is unaware of where in the system any particular portion of its address space is being held; some portions can be on disk (for example, the portions of the program that have not been used yet), some can be in main memory, and some can be in hardware caches. The operating system maintains a map for each address space so that, for every virtual page in the address space, it can tell where in memory or on disk the page can be found. As the figure suggests, the virtual machine

**FIGURE 5.23 Virtual addresses.** A Virtual address is divided into two components: the virtual page number and the page offset. The virtual page number identifies the page's location within the address space. The page offset identifies a byte's location within the page. Bit widths are shown for a 32-bit address and a 4 kbyte page size.

**FIGURE 5.24 Page numbers (for 32-bit virtual addresses).** Every page in an address space is given a virtual page number (VPN). Every page in physical memory is given a physical page number, called a page frame number (PFN).

paradigm allows each process to behave as if it owns the entire machine; each process is protected from all others and does not even know that other processes exist—for example, a process cannot spoof the identity of another process, and the resource-management mechanisms implemented by the operating system to support the illusion that each process own all physical resources means that no process may dominate system resources. One of the many benefits of this organization is that it makes facilities such as multitasking very easy to implement, because process protection, resource sharing, and a clean division of process identity are provided as side effects of the virtual machine paradigm by definition.

The mapping information that tells the location of pages in memory or on disk is organized into *page tables*, which are collections of *page table entries (PTEs)*. Virtual addresses (shown in Fig. 5.23) are mapped at the granularity of *pages*; at its simplest, virtual memory is then a mapping of *virtual page numbers (VPNs)* to *page frame numbers (PFNs)*, shown in Fig. 5.24. “Frame” in this context means “slot”—physical memory is divided into frames that hold pages. The page table holds one PTE for every mapped virtual page; an individual PTE indicates whether its virtual page is in memory, on disk, or not allocated yet. The logical PTE therefore contains the VPN and either the page's location in memory (a PFN), or its location on disk (a disk block number). Depending on the organization, some of this information is redundant; actual implementations do not necessarily require both the VPN and the PFN. Later developments in virtual memory added such things as page-level protections; a modern PTE usually contains protection information as well, such as whether the page contains executable code, whether it can be modified, and if so by whom.

The mapping is a function; any virtual page can have only one location. However, the inverse map is not necessarily a function; it is possible and sometimes advantageous to have several virtual pages mapped

**FIGURE 5.25 Shared memory.** Shared memory allows processes to overlap portions of their address space while retaining protection for the nonintersecting regions; this is a simple and effective method for inter-process communication. Pictured are four process address spaces that have overlapped. The darker regions are shared by more than one process, while the lightest regions are still protected from other processes.

**FIGURE 5.26 How page tables support shared memory.** Two process address spaces are shown sharing several pages. Their page tables maintain information on where virtual pages are located in physical memory. The darkened pages are mapped to several locations; note that the darkest page is mapped at two locations in the same address space.

to the same page frame (to share memory between processes or threads, or to allow different views of data with different protections, for example). Shared memory is one of the more commonly used features of page tables. It is a mechanism whereby two address spaces that are protected from each other are allowed to intersect at points, still retaining protection over the nonintersecting regions. Several processes sharing portions of their address spaces are pictured in Fig. 5.25. The shared memory mechanism only opens up a pre-defined portion of a process's address space; the rest of the address space is still protected, and even the shared portion is only unprotected for those processes sharing the memory. For instance, in the figure, the region of A's address space that is shared with process B is unprotected from whatever actions B might want to take, but it is safe from the actions of any other processes. Shared memory is therefore useful as a simple, secure means for inter-process communication. Shared memory also reduces requirements for physical memory; for example, in most operating systems, the text regions of processes are shared whenever multiple instances of a single program are run, or when multiple instances of a common library are used in different programs.

The mechanism works by ensuring that shared pages map to the same physical page; this is done by simply placing the same page frame number in the page tables of two processes sharing a page. A simple example is shown in Fig. 5.26. Here, two very small address spaces are shown overlapping at several places, and one address space overlaps with itself; two of its virtual pages map to the same physical page.

**FIGURE 5.27 An idealized fully associative cache lookup.** A cache is comprised of two parts: the tags array and the data array. The tags act as a database; they accept as input a key (a virtual address) and output either the location of the item in the data array, or an indication that the item is not in the data array. A fully associative cache allows an item to be located at any slot in the data array, thus the input key is compared against every key in the tags array.

This is not just a contrived example; many operating systems allow this, and it is useful, for example, in the implementation of user-level threads.

## An Example Page Table Organization

So now the question is: How do page tables work? If we think of main memory as the data array of a cache, then the page table is the cache's corresponding *tags array*—it is a lookup table that tells one what is currently stored in the data array. The traditional design of virtual memory uses a fully associative organization for main memory: Any virtual object can be placed at (more or less) any location in main memory, which reduces contention for main memory and increases performance. An idealized fully associative cache is pictured in Fig. 5.27. A data tag is fed into the cache; the first stage compares the input tag to the tag of every piece of data in the cache. The matching tag points to the data's location in the cache. The goal of the page table organization is to support this lookup function as efficiently as possible.

To access a page in physical memory, it is necessary to look up the appropriate PTE to find where the page resides. This lookup can be simplified if PTEs are organized contiguously so that a page number can be used as an offset to find the appropriate PTE. This leads to two primary types of page table organization: the *forward-mapped* or *hierarchical page table*, indexed by the virtual page number, and the *inverse-mapped* or *inverted page table*, indexed by the physical page number (page frame number). Each design has its strengths and weaknesses. The hierarchical table supports a simple lookup algorithm and simple sharing mechanisms and can require a significant fraction of physical memory. The inverted table supports efficient hardware table-walking mechanisms and requires less physical memory than a hierarchical table but inhibits sharing by not allowing the mappings for multiple virtual pages to exist in the table simultaneously, if those pages map to the same page frame. Detailed descriptions of these can be found elsewhere [Jacob & Mudge 1998a].

Instead of describing all possible page table organizations, we will look in some detail at a concrete example: the virtual memory implementation of one of the oldest and simplest virtual memory systems, 4.3BSD Unix [Leffler et al. 1989]. The intent is to show how mapping information is used by the operating system and how the physical memory layout is organized. Version 4.3 of Berkeley Unix provides support for shared text regions, address space protection, and page-level protection. There is a separate page table for every process, and the page tables cannot be paged to disk. As we will see, address spaces are organized to minimize memory requirements.

BSD defines segments to be contiguous regions of virtual space. A process address space is composed of five primary segments: the *text* segment, holding the executable code; the *initialized data* segment, containing those data that are initialized to specific nonzero values at process start-up; the *bss* segment,

FIGURE 5.28 The 4.3BSD per-process virtual address space.

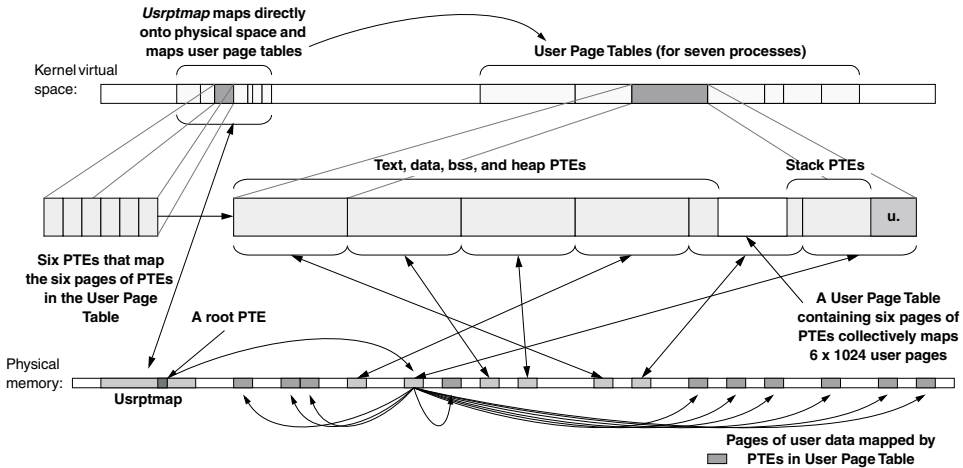

FIGURE 5.29 User-process page tables in 4.3BSD Unix.

containing data initialized as zero at process start-up; the *heap* segment, containing uninitialized data and the process's heap; and the *stack*. Beyond the stack is a region holding the kernel's stack (used when executing system calls on behalf of this process, for example) and the *user struct*, a kernel data structure holding a large quantity of process-specific information. Figure 5.28 illustrates the layout of these segments in a process's address space: The initialized data segment begins immediately after the text segment, the bss segment begins immediately after the initialized data segment, and the heap segment begins immediately after the bss segment. This is possible because the text, initialized data, and bss regions by definition cannot change size during the execution of a process. The heap segment can grow larger, as can the stack. Therefore, these two begin at opposite ends of the address space and grow towards each other. Beyond the 2 GB point, the address space belongs to the kernel; a user reference causes an exception.

This design makes sense for a number of reasons. When the operating system was designed, memory was at a premium. The choice was made to wire down the page tables. Given this, it makes most sense to restrict an address space to be composed of a minimal number of contiguous regions; this would ensure a compact page table (contiguous pages imply densely packed PTEs). The process model includes a single thread of execution per address space; 4.3BSD did not have multiple threads within an address space, nor did it use dynamically loaded libraries. Therefore, there was no need to support sparsely populated address spaces.

Figure 5.29 depicts the layout of process address spaces and the associated process page tables. The page tables are kept in the kernel's virtual address space and are relocatable even if wired down. As shown in the figure, each user-process page table mirrors the process's address space; the PTEs that map the text, data, bss, and heap segments are at the bottom end of a contiguous range of PTEs (which are held in the kernel's virtual pages), and the PTEs that map the user's stack are near the top of the range of PTEs. A user page table is therefore as compact as it can be, with no more than a page of wasted space; the empty space between the ranges of PTEs allows for expansion of the heap and stack segments.

When a process needs to expand its address space beyond the confines of its user page table, the operating system adds an additional page to the page table and shifts all following process page tables up by one virtual page. This is the advantage of placing the user page tables in virtual space; the displaced data need

not be recopied. The disadvantage is that there needs to be another level of mapping to determine where in the physical memory the pages that comprise a process's user page table are located. The *Usrptmap* is a structure that mirrors the entire set of user page tables, and for every page in a process's user page table, there is one PTE in the *Usrptmap*.

When a user reference requires a lookup in the page table, the operating system first determines which process caused the fault; this identifies the appropriate page table within the region of user page tables. The operating system then determines whether the access was to the user's stack or one of the text, bss, or data segments. If the access is to the user's stack, the operating system indexes backward from the top of the appropriate user page table to find the PTE; if the access is to the text, data, bss, or heap segment, the operating system indexes forward from the bottom of the user page table.

The *usrptmap* begins at a known location in physical memory; therefore, any process address space can be mapped. The appropriate root PTE within the *usrptmap* can always be found, given a process ID, and each root PTE points to a page of PTEs in physical memory, each of which then points to a page in the user address space.

### Translation Lookaside Buffers: Caching the Page Table

There is an obvious question of performance to consider: If every memory access by a user program requires a lookup to the page table, how does anything ever get done? The answer is a familiar one: we cache things. Rather than perform a page-table lookup on every memory reference (which returns a PTE that gives us mapping information), we cache the most frequently used PTEs in hardware. The hardware structure is called a *translation lookaside buffer (TLB)*, and because it holds mapping information, the hardware can perform the address translations of those PTEs that are currently cached in the TLB without having to access the page table (see Fig. 5.30). If the appropriate PTEs are stored in hardware, a memory reference completes at the speed of hardware, rather than being limited by the speed of looking up PTEs in the page table.

Most architectures provide a TLB to support memory management; the TLB is a special-purpose cache that holds only virtual-physical mappings. When a process attempts to load from or store to a virtual address, the hardware searches the TLB for the virtual address's mapping. If the mapping exists in the TLB, the hardware can translate the reference to a physical address without the aid of the page table. If the mapping does not exist in the TLB (an event called a *TLB miss*), the process cannot continue until the correct mapping information is loaded into the TLB.

Translation lookaside buffers are fairly large; they usually have in the order of 100 entries, making them several times larger than a register file. They are typically fully associative, and they are often accessed every clock cycle. In that clock cycle they must translate both the I-stream and the D-stream. Thus, they are often split into two halves, each devoted to translating either instruction or data references. They can constrain the chip's clock cycle as they tend to be fairly slow, and they are also power hungry (both are a function of the TLB's high degree of associativity).

**FIGURE 5.30** Address translation with and without a TLB. Address translation without a TLB is shown on the left; translation with a TLB is shown on the right. The only difference is that the TLB caches the most recently used entries in the page table, and the page table is only referenced when a lookup misses the TLB.

In general, if the necessary translation information is on-chip in the TLB, the system can translate a virtual address to a physical address without requiring an access to the page table. In the event that the translation information is not found in the TLB, one must search the page table for the translation and insert it into the TLB before processing can continue. This activity can be performed by the operating system or by the hardware directly; a system is said to have a *software-managed TLB* if the OS is responsible, or a *hardware-managed TLB* if the hardware is responsible. The classic hardware-managed design, as seen in the DEC VAX, GE 645, PowerPC, and Intel x86 architectures [Clark & Emer 1985, Organick 1972, IBM & Motorola 1993, Intel 1993], provides a hardware state machine to perform this activity; in the event of a TLB miss, the state machine would walk the page table, locate the translation information, insert it into the TLB, and restart the computation. Software-managed designs are seen in the Compaq Alpha, the SGI MIPS processors, and the Sun SPARC architecture [Digital 1994, Kane & Heinrich 1992, Weaver & Germand 1994].

The performance difference between the two is due to the page table lookup and the method of operation. In a hardware-managed TLB a hardware state machine walks the page table; there is no interaction with the instruction cache. By contrast, the software-managed design uses the general interrupt mechanism to invoke a software TLB miss-handler—a primitive in the operating system usually 10–100 instructions long. If this miss-handler is not in the instruction cache at the time of the TLB miss-exception, the time to handle the miss can be much longer than in the hardware-walked scheme. In addition, the use of the general-purpose interrupt mechanism adds a number of cycles to the cost by draining the pipeline and flushing a possibly large number of instructions from the reorder buffer; this can add up to something on the order of 100 cycles. This is an overhead that the hardware-managed TLB does not incur; when hardware walks the page table, the pipeline is not flushed, and in some designs (notably the Pentium Pro [Upton 1997]), the pipeline keeps processing, in parallel with the TLB miss-handler, those instructions that are not dependent on the one that caused the TLB miss. The benefit of the software-managed TLB design is that it allows the operating system to choose any organization for the page table, while the hardware-managed scheme defines an organization for the operating system. If TLB misses are infrequent, the flexibility afforded by the software-managed scheme can outweigh the potentially higher per-miss cost of the design. For the interested reader, a survey of hardware mechanisms is provided in [Jacob & Mudge 1998b], and a performance comparison of different hardware/operating system combinations is provided in [Jacob & Mudge 1998c].

Lastly, to put modern implementations in perspective, note that TLBs are not a necessary component for virtual memory, though they are used in every contemporary general-purpose processor. Virtually addressed caches would suffice because they are indexed by the virtual address directly, requiring address translation only on the (hopefully) infrequent cache miss. Such a scheme is detailed and evaluated in [Jacob & Mudge 2001].

## 6.1 Superscalar Processors

*Mark Smotherman*

### Introduction

A superscalar processor is a computer designed to fetch, decode, and execute multiple instructions each clock cycle. The rationale for such a design can be illustrated by considering the basic computer performance equation, that is, execution time is a function of the path length (measured in number of instructions) multiplied by the cycles per instruction (CPI) multiplied by the clock cycle time. The goal of a pipelined processor is to strive towards a minimum CPI of 1.0, while simultaneously reducing or at least limiting any expansion of the path length or clock cycle time, and thus reduce the execution time. The goal of a superscalar design is to attain a fractional CPI, or, stated as the reciprocal, the goal is to attain instructions per cycle (IPC) greater than 1.0. With similar reductions or at least limits over the expansion of the path length and clock cycle time, the result is an even larger reduction in the execution time than for pipelining alone.

A VLIW (Very Long Instruction Word) processor is also designed for fetching, decoding, and executing multiple operations each clock cycle. The difference between a superscalar processor and a VLIW processor is one of implementation and architecture. Superscalar design can be applied as an implementation technique to an existing sequential instruction set, while VLIW design requires that the instruction set

architecture, the implementation, and the compilers be specifically designed to support the packaging of multiple independent operations into long instruction words.

Proponents of the VLIW approach rightly contend that VLIW design reduces the control complexity within a processor; however, the corresponding drawbacks are a loss of program portability at the binary level and a lack of flexibility. With regard to portability, the control logic added by a superscalar processor is used to dynamically determine opportunities for parallel execution within a conventional instruction stream. Thus, superscalar processors dynamically schedule parallel execution of the instructions of existing executable program files, whereas recompilation into a static representation of parallel execution is a requirement for programs to run on VLIW processors. With regard to flexibility, superscalar processors can easily respond to dynamic events, such as cache misses. Dynamic events present a difficulty for VLIW designs. For example, early VLIW designs avoided data caches so that memory access time would be a known quantity for use in compiler scheduling.

The recent introduction of EPIC (Explicitly Parallel Instruction Computing) architectures, such as the IA-64 architecture of Intel and Hewlett-Packard, is an attempt to gain the best of both approaches. Explicit dependence information is incorporated into the instruction formats to reduce the control logic complexity, and some scheduling of dynamic behavior is incorporated to provide flexibility.

## **Instruction-Level Parallelism**

Superscalar processors attempt to identify and exploit parallelism in the instruction stream. That is, instructions that are independent should be executed in parallel. We briefly review the concept of dependencies. More details can be found in Mike Johnson's text on superscalar microprocessor design [1].

### **Dependencies**

Dependencies limit the parallelism between instructions because they must be enforced so that the results of program execution will be correct. Indeed, much of the control logic in a superscalar processor is devoted to identifying dependencies, so that execution will produce the same results as if the instruction stream was being executed on a purely sequential computer. Dependencies can be categorized in three ways.

#### ***Data Dependencies***

Data dependencies exist between two instructions when the order between the two instructions must be maintained for execution to be correct. The most obvious data dependency is the true data dependency (or RAW: read-after-write dependency) in which the result of one instruction is used as an input operand for the second instruction. To preserve correctness, the first instruction must be executed prior to the second. The storage that is used first as a result and then as a source can be either a memory location or a CPU register.

Two other cases arise when the second instruction writes to a storage location. An output dependency (or WAW: write-after-write dependency) occurs when both instructions write to the same storage. To preserve correctness, the result of the second instruction must be the final value of the storage. An anti-dependency (or WAR: write-after-read dependency) occurs when the first instruction reads an input operand from the storage location that will be written with the result of the second instruction. To preserve correctness, the first instruction must obtain its input operand before that value is overwritten by a new value from the second instruction. Both of these cases are called false data dependencies because they arise from the reuse of storage locations.

#### ***Control Dependencies***

A control dependency occurs when an instruction depends on a conditional branch instruction. It is not known whether the instruction is to be executed or not until the branch is resolved. Thus, the branch must be executed prior to the instruction.

#### ***Structural Dependencies***

A structural dependency occurs when two instructions need the same resource. If the resource is not duplicated, the instructions must execute sequentially, one after the other, rather than in parallel. The resource for which the instructions contend might be an adder, a bus, a register file port, or some other component.

## Studies of Instruction-Level Parallelism

In the early 1970s, two studies on decoding and executing multiple instructions per cycle were published—one by Gary Tjaden and Mike Flynn on a design of a multiple-issue IBM 7094 [2] and the other by Ed Riseman and Caxton Foster on the effect of branches in CDC 3600 programs [3]. The conclusion in both papers was that only a small amount of instruction-level parallelism existed in sequential programs—1.86 and 1.72 instructions per cycle determined by the respective studies. Thus, these studies clearly demonstrated the limiting effect of data and control dependencies on instruction-level parallelism, and the result was to encourage researchers to look for parallelism in other arenas, such as vector processors and multiprocessors. However, the Riseman and Foster study did examine the effect of relaxing the control dependencies and found increasing levels of parallelism, up to 51 instructions per cycle, as the number of branches were eliminated (albeit in an impractical way). Later studies, in which false data dependencies were eliminated as well as control dependencies, found much more available parallelism, with the highest published estimate being 90 instructions per cycle by Alexandru Nicolau and Josh Fisher as part of their VLIW research [4].

## Techniques to Increase Instruction-Level Parallelism

Just as the limit studies indicated, performance can be increased if dependencies can be eliminated or reduced. Let us address the dependencies in the reverse order from their enumeration above. First, many structural dependencies can be avoided by providing duplicate copies of necessary resources. Even scalar pipelines provide two paths for memory access (i.e., separate instruction and data caches) and multiple adders (i.e., branch target adder and main ALU). Superscalar processors have even more resource requirements, and it is not unusual to find duplicated function units and even multiple ports to the data cache (e.g., true multiporting, multiple banks, or accessing a single-ported cache multiple times per cycle).

Control dependencies are eliminated by compiler techniques of unrolling loops and performing optimizations such as “if conversion” (i.e., using conditional or predicated execution of instructions so that a control-dependent instruction is transformed into a data-dependent instruction). However, the main approach to reducing the impact of control dependencies is the use of sophisticated branch prediction. For example, the Pentium 4 keeps the history of over 4000 branches [5]. Branch prediction techniques allow instructions from the predicted path to begin before the branch is resolved and execute in a speculative manner. Of course, if a prediction is incorrect, there must be a way to recover and restart execution along the correct path.

False data dependencies can be eliminated or reduced by better compiler techniques (e.g., register and memory allocation algorithms that avoid reuse) or by the use of register and memory renaming hardware on the processor. Register renaming can be accomplished in the hardware by incorporating a larger set of physical registers than are available in the instruction set architecture. Thus, as each instruction is decoded, that instruction’s architectural destination register is mapped to a new physical register, and future uses of that architectural register will be mapped to the assigned physical register. Hardware renaming is especially important for older instruction sets that have few architectural registers and for legacy codes that for one reason or another will not be recompiled.

True data dependencies have been viewed as the fundamental limit for program execution; however, value prediction has been proposed in the past few years as somewhat of an analog of branch prediction, in which paths within the instruction stream, which depend on easily predicted source values, can be started earlier. As with branch prediction, there must be a way to recover from mispredictions. Another method that is currently being proposed to reduce the impact of true data dependencies is the use of simultaneous multithreading in which instructions from multiple threads are interleaved on a single processor; of course, instructions from different threads are independent by definition.

## Out-of-Order Completion

All processors that attempt to execute instructions in parallel must deal with variations in instruction execution times. That is, some instructions, such as those involving simple integer arithmetic or logic operations, will need only one cycle for execution, while others, such as floating-point instructions, will need multiple cycles for execution. If these different instructions are started at the same time, as in a

superscalar processor, or even in adjacent cycles, as in a scalar pipelined processor, a simple instruction can complete earlier than a longer running instruction that appears earlier in the instruction stream. If we allow the simple instruction to write its result to storage before the longer running instruction completes, we may violate a data dependency. Dependency checking hardware can eliminate this problem; however, dependency checking will not solve the problem of an inconsistent state of storage (registers or memory) if the longer running instruction causes an exception. To handle this exception and to be able to resume the program we must know the precise state of the storage, that is, we must know which instructions, prior to the one causing the exception, have not completed and which instructions, after the one causing the exception, have completed. To resume the processor must restore the state and any uncompleted instructions. Two specific methods can accomplish this. The first is to not allow out-of-order completion and force all instructions to complete in-order. The second is to provide a form of buffering, usually called a reorder buffer, in which the instructions completing out-of-order can place their results and then retire the results out of this buffer in program order. If an exception (or for that matter, a branch or value misprediction) occurs, instructions prior to the one causing the exception (or misprediction) are allowed to complete and then the contents of the reorder buffer beyond that instruction are flushed. Execution can then be resumed with a consistent state of storage. See Johnson for more details [1].

## **In-Order vs. Out-of-Order Issue**

A superscalar processor can fetch multiple instructions and then issue (i.e., assign and route) as many instructions as are independent to the various function units, up to the width of the decoding logic and the issue pathways. If the decoding logic stops processing at the first dependent instruction, the instruction issue is said to be done in program order (or in-order). An alternative is to provide a buffer for decoded instructions and dynamically issue (or schedule) any of the buffered instructions that are ready to execute. The selected instructions may not be in program order (thus, out-of-order). The buffer for the instructions can take the form of a centralized “instruction window” or a decentralized set of “reservation stations,” in which a subset of buffers are located at each function unit.

## **Example Machines**

### **Historical Designs**

The idea of a superscalar computer originated with John Cocke at IBM in the 1960s. Gene Amdahl, architect of the IBM 704 and one of the architects of the IBM S/360, postulated a bound on computer performance that included an assumption of a maximum decoding rate of one instruction per cycle on a single processor. John Cocke felt that this was not an inherent limit for a single processor. His ideas about multiple decoding became an important part of the IBM ACS-1 supercomputer design, which was started in 1965 but ultimately cancelled in 1969. In this design, up to 16 instructions would be decoded and checked for dependencies each cycle and up to seven instructions would be issued to function units [6].

After the ACS cancellation and the publication of [2] and [3], the idea of superscalar processing lay dormant until the early 1980s when further research at IBM revived the notion of multiple decoding and multiple issue. John Cocke teamed with Tilak Agerwala at IBM and worked on a series of designs that finally led to the IBM POWER (Performance Optimized With Enhanced RISC) instruction set architecture and the IBM RS/6000 workstation, which was announced in late 1989 and delivered in 1990. Agerwala is credited with coining the term superscalar during a series of talks in 1983–1984 in an effort to compare the performance available in these designs as compared to vector processors. These talks and the related IBM technical report [7] were influential in kindling interest in the approach. In 1989, Intel introduced the first single-chip superscalar microprocessor, the i960CA. Also around this time, LIW efforts, such as the Intel i860, the Apollo DN10000, and the National Semiconductor Swordfish, and VLIW efforts, such as those by Multiflow and Cydrome, were underway.

## Modern Designs

Most high-performance processors now incorporate some form of superscalar processing. Even many simple processors can decode and execute one integer instruction along with one floating-point instruction per cycle. We briefly survey three representative processors in the following subsections. Other notable superscalar designs include the Compaq Alpha 21264, HP 8000, and MIPS R10000. It should be noted that designers of IBM mainframes developed a superscalar implementation, the IBM ES/9000 Model 520, in 1992, but more recent implementations have reverted to scalar pipelines.

### *UltraSPARC, 1995, [8]*

The UltraSPARC is an example of an in-order superscalar processor. It provides four-way instruction issue to nine functional units. The design team extensively simulated many alternatives and concluded that an out-of-order approach would have required a 20% penalty in clock cycle time and increased the time to market by up to half a year. The final design involves a nine-stage pipeline. This includes a decoupled front-end pipeline (fetch and decode stages) that performs branch prediction and places decoded instructions in a 12-entry buffer. A grouping stage then selects up to four instructions in-order from the buffer to be issued in the next cycle. Precise exceptions are provided by padding out most function unit pipelines to four stages each (i.e., the required length for the floating-point pipelines) so that most four-instruction groups complete in-order. The final two stages resolve any exceptions in the groups and write back the results.

### *PowerPC 750, 1997, [9]*

The PowerPC 750 is an example of an out-of-order processor with distributed reservation stations and a reorder buffer (called the completion buffer in the 750). The 750 has six function units, including two integer units. Each unit has one reservation station, except the load/store unit, which has two. Instructions can issue, when ready, from these reservation stations. (This limited form of out-of-order execution is sometimes called “function unit slip.”) The 750 also includes six rename registers for renaming the 32 integer registers and six rename registers for renaming the 32 floating-point registers.

The overall pipeline works as follows. A decoding stage is not needed since instructions are predecoded into a wider representation as they are filled into the instruction cache. Up to four instructions are fetched per cycle into a six-entry instruction buffer. Logic associated with the instruction buffer removes any nops or predict-untaken branches and overwrites predict-taken branches with target-path instructions so that no instruction buffer entries are required for nops or branches. (However, predicted branches are kept in the branch unit until resolution to provide for misprediction recovery.) Up to two instructions can be dispatched per cycle to the reservation stations and can be allocated entries in the six-entry completion buffer. The integer units require a single cycle for execution, while the load/store unit and the floating-point unit require two and three cycles, respectively. After execution, results are placed into the assigned entries in the completion buffer. Up to two entries per cycle can be written back from the completion buffer to the register files.

### *Pentium 4, 2000, [5]*

The Pentium 4 is the most recent 32-bit processor from Intel and is an example of a very aggressive out-of-order processor with a centralized instruction window and a reorder buffer. The original Pentium combines two integer pipelines, each similar in design to the pipeline of the 486, and can thus decode and execute up to two instructions in-order per cycle. Intel then developed the P6 core microarchitecture, which serves as the basis for the Pentium Pro, Pentium II, and Pentium III. After branch prediction and instruction fetch, the P6 core decodes up to three variable-length Intel IA-32 instructions each cycle and translates them into up to six fixed-length uops (microoperations). Up to three uops are processed by register renaming logic each cycle, and these are placed into the 20-entry centralized instruction window along with being allocated entries in the 40-entry reorder buffer. The window is scanned each cycle in a pseudo-FIFO manner in an attempt to issue up to four uops. Preference is given to back-to-back uops to reduce the amount of operand forwarding among the execution units. The actual scanning and issue requires two cycles, while most instructions require single-cycle execution. At maximum, the reorder

buffer can receive up to three results per cycle and can start retirement of up to three uops per cycle. Retirement requires three cycles. Thus the overall pipeline has some 14 stages; but, because some of these stages can overlap, the effect is a minimum latency of 12 cycles per instruction.

The Pentium 4 is a redesign of the core microarchitecture. The translation of IA-32 instructions into uops is retained, but instead of repeatedly fetching, decoding, and translating recurring IA-32 instruction sequences, the uops are stored in a trace cache for repeated access. The trace cache can hold up to 12 K uops, and in a manner somewhat similar to the PowerPC 750 branch elimination logic, the trace cache stores frequently-traversed sequences (i.e., “traces”) of uops with any predict-taken branches followed by instructions from the predicted path. The trace cache can provide up to three uops per cycle, which are then routed through reorder-buffer allocation logic, register-renaming logic, and then into uop queues for scheduling. Up to six uops can be issued per cycle, and up to three uops can be retired per cycle. Part of the aggressiveness of the design can be seen by the increase in the reorder buffer size from 40 entries in the P6 core to 126 entries for the Pentium 4. The clock rate can also be aggressively increased on the Pentium 4, since there are approximately double the number of pipeline stages in it as compared to the P6 core. By cascading ALUs, two dependent addition or subtraction operations can be performed in each cycle.

## 6.2 Register Renaming Techniques<sup>1</sup>

---

*Dezső Sima*

### Introduction

Register renaming (or “renaming” for short) is a widely used technique in instruction level processors (ILP) to remove false data dependencies between register operands of subsequent instructions in a straight line code sequence.<sup>1-3</sup> As false data dependencies we designate read-after-write (RAW) and write-after-write (WAW) dependencies. If false data dependencies are removed, no related precedence requirements constrain the execution sequence of the instructions involved. Thus, on an average, more instructions are available for parallel execution per cycle, which increases processor performance.

---

<sup>1</sup>Portions of this chapter reprinted with permission from Sima, D., The design space of register renaming techniques, *IEEE Micro*, 20 Sept./Oct., 70, 2000. © 2000 IEEE

The *principle of register renaming* is straightforward. The processor removes false data dependencies by writing the results of the instructions first into dynamically allocated rename buffers, rather than into the specified destination registers. For instance, in the case of the following WAR dependency

$$i_1: \text{ add } \dots, r_2, \dots; \quad [\dots \leftarrow (r_2) + (\dots)]$$

$$i_2: \text{ mul } r_2, \dots, \dots; \quad [r_2 \leftarrow (\dots) * (\dots)]$$

the processor renames the destination register of  $i_2$  ( $r_2$ ), say to  $r_{33}$ . Then after the renaming of  $r_2$ , instruction  $i_2$  becomes

$$i'_2: \text{ mul } r_{33}, \dots, \dots; \quad [33 \leftarrow (\dots) * (\dots)]$$

and the processor writes the result of  $i'_2$  into  $r_{33}$  instead of into  $r_2$ . This resolves the previous WAR dependency between  $i_1$  and  $i_2$ . In subsequent instructions, however, references to the source register  $r_2$  must be redirected to the rename buffer  $r_{33}$  as long as the renaming remains valid. In the next section we give a detailed description of the whole rename process.

A precursor to register renaming was introduced in 1967 by Tomasulo in the IBM 360/91,<sup>4</sup> a scalar supercomputer of that time, which pioneered both pipelining and shelving. The 360/91 renamed floating point registers in order to preserve the logical consistency of the program execution, rather than to increase processor performance by removing false data dependencies.

Tjaden and Flynn<sup>5</sup> were the first to suggest the use of register renaming for removing false data dependencies. They proposed the renaming of load type instructions, but they did not yet use the term “*register renaming*.” This specific term was introduced a few years later, in 1975, by Keller<sup>6</sup> who extended renaming to cover all instructions including a destination register. He also described a possible hardware implementation of this technique. Because of the complexity of its implementation, however, about two decades passed until register renaming came into widespread use in superscalars in the beginning of the 1990s.

Early superscalar models of significant processor lines, such as the PA 7100, SuperSparc, Alpha 21064, R8000, and the Pentium, typically did not yet use renaming as indicated in Fig. 6.1. Renaming appeared gradually, first in a restricted form, called *partial renaming*, in the beginning of the 1990s, in the IBM RS/6000 (Power1), Power2, PowerPC 601, and in NextGen’s Nx586 processors, as depicted in Fig. 6.1. Partial renaming restricts renaming to one or to a few data types, such as floating point loads or floating point instructions, as detailed in the section “Scope of Register Renaming.” *Full renaming* emerged later, beginning in 1992, first in the high-end models of the IBM mainframe family ES/9000, then in the PowerPC 603. Subsequently, renaming spread into virtually all superscalar processors with the notable exception of Sun’s UltraSparc line. At present register renaming is considered to be a standard feature of performance oriented superscalar processors.

## Overview of the Rename Process

The rename process itself is considerably complex. It consists of a number of rename specific tasks—such as renaming the destination and the source registers, fetching renamed source operands, updating the rename buffers, releasing allocated rename buffers, recovery of the rename process from faultily executed speculative execution, etc. In addition, each of the rename specific tasks may be implemented in a number of different ways. Furthermore, the kind of the underlying microarchitecture affects how the rename process is carried out. Therefore, each concrete description of the rename process is related to a particular kind of the renaming technique employed and the underlying microarchitecture. Thus, before describing the rename process we need to be specific about both the renaming technique and the microarchitecture assumed.

As far as the *renaming technique* is concerned, in a subsequent section, we will show that eight *basic alternatives for renaming* are available. In our description of the rename process, we need to presume one

**FIGURE 6.1** Chronology of the introduction of renaming in commercial superscalar processors. As date of introduction, we indicate the first year of volume production. Following the model designation, we also show the issue rate of the processors (in brackets). Concerning the issue rate of CISC processors we note that one x86 instruction can be considered to be equivalent of 1.3–1.9 RISC instructions.<sup>38</sup> In this figure, we give references to the processors that make use of renaming.

of them. Our choice is the one where (i) renaming is implemented by using *rename register files (RRF)*, and (ii) architectural registers are mapped to rename registers by means of *mapping tables*. Although both terms are explained later in the subsequent section, beforehand we note that rename register files, split to separate fixed-point (FX) and floating-point (FP) RRFs, store the instruction results produced by the execution units temporarily, while the FX- and FP-mapping tables hold the actual mappings of the FX- and FP-architectural registers to the associated rename registers, as indicated in the section on “Methods of Register Mapping.”

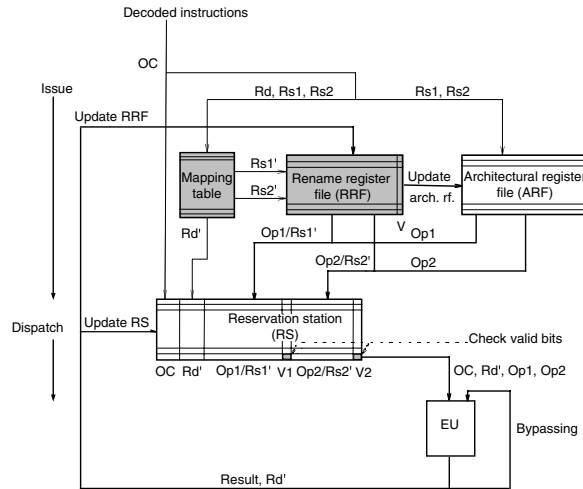

Concerning the *underlying microarchitecture* there are two design aspects, which affect the implementation of the rename process: (i) whether or not the processor uses shelving (dynamic instruction issue, queued issue; see related box) and (ii) assuming the use of shelving, what kind of operand fetch policy is employed (see related box). As recent superscalars predominantly make use of *shelving*, we take this design option for granted throughout this chapter section. Regarding the *operand fetch policy*, which is one design aspect of shelving, we take into account both alternatives, since superscalar processors make use of both policies. Thus, while we describe the rename process in the subsequent two sections, we do it in two scenarios, first assuming the *issue bound fetch policy* and then the *dispatch bound fetch policy*. In both the scenarios mentioned, we describe the rename process by focusing only on a small part of the microarchitecture, which is just enough to highlight the implementation of specific tasks of the rename process.

### The Process of Renaming, Assuming Issue-Bound Operand Fetching

The considered part of the microarchitecture executes FX-instructions and consists of an architectural register file (ARF) and of an execution unit (EU), as shown in Fig. 6.2.

We take for granted that shelving is implemented by providing dedicated buffers, called *reservation stations (RS)*, in front of the EU, and we assume that instructions are forwarded (dispatched) from the RS to the EU in an in-order manner.

Our subsequent description of the rename process is embedded into the general framework of instruction processing. Here, we distinguish the following four processing phases: (i) decoded instructions are

**FIGURE 6.2** The processor core providing shelving with issue bound operand fetching and renaming.

issued into the RS, (ii) executable instructions are dispatched from the RS to the EU, (iii) the EU performs the prescribed operation and generates its result. At this time the instruction is said to be *finished*, and finally, (iv) the processor *completes* (commits, retires) instructions in an in-order fashion, irreversibly updating the program state with the results of the EU.

Assuming the processor core as shown in Fig. 6.2 and issue bound operand fetching, the rename process is carried out as follows:

(i) *During instruction issue*, three rename-related tasks must be performed: (1) the destination registers of issued instructions ( $R_d$ ) need to be renamed, (2) the source registers ( $R_{s1}$  and  $R_{s2}$ ) should be renamed in order to redirect the source references to the associated rename registers, and (3) the required source operands need to be fetched.

(a) In order to *rename the destination register* of an issued instruction, first a free rename register needs to be allocated to the issued instruction. This task is accomplished by means of the mapping table. The mapping table keeps track of the actual mappings of the architectural registers to the rename registers. Renaming of the destination register results in writing the identifier of the allocated rename register ( $R_{d'}$ ) into the corresponding mapping table entry and forwarding this identifier also into the corresponding field of the RS. Typically, the processor uses the index of the allocated rename register as  $R_{d'}$ .

(b) *Source registers*, for which a valid renaming exists, *also need to be renamed*. This is carried out by accessing the mapping table with the source register identifiers ( $R_{s1}$ ,  $R_{s2}$ ) as indices, and fetching the identifiers of the allocated rename registers (designated as  $R_{s1'}$ ,  $R_{s2'}$ ). If for a particular source identifier there is no valid renaming, the required source operand will be accessed from the ARF by using the original source register identifier ( $R_{s1}$  or  $R_{s2}$ ).

(c) Finally, the *referenced source operands need to be fetched*. However, with renaming, requested source operands may be in one of two possible locations. If there is a valid renaming, the requested operand needs to be fetched from the RRF, else from the ARF. To fetch a requested operand, usually the processor accesses both the RRF and the ARF simultaneously. If only the ARF hits, the referenced source register is actually not renamed and the accessed value is the required one. If, however, for a particular source register a valid renaming exists, both register files hit and the processor will give preference to the response of the RRF. In this case, the RRF deliver either a valid operand value ( $Op_1/Op_2$ ), if it has already been produced by a preceding instruction, or the index of that rename register, which will hold the requested value after its generation ( $R_{s1'}/R_{s2'}$ ), if the required result has not yet been calculated. Thus, for each referenced source register either the requested operand value ( $Op_1/Op_2$ ) or the appropriate rename register identifier ( $R_{s1'}/R_{s2'}$ ) will be written into the RS. The valid bits associated with the source

operand fields ( $V_1/V_2$ ) indicate whether the related operand field holds a valid source operand value ( $Op_1/Op_2$ ) or a rename register identifier ( $Rs'_1/Rs'_2$ ).

(ii) *Dispatching* is not at all rename specific. Assuming in-order dispatching, the processor inspects the valid bits of the source operands ( $V_1$  and  $V_2$ ) of the oldest instruction kept in the RS. If both valid bits of this instruction are set and the EU is also free, the instruction is forwarded to the EU for execution.

(iii) *After the EU has finished the execution of an instruction*, both the RS and the RRF need to be updated with the generated result. To *update the RS*, the generated results and their identifiers ( $Rd'$ ) are broadcasted to all the source register entries held in the RS. Through an associative search, all source register identifiers ( $Rs'_1, Rs'_2$ ) are located, which are waiting for the new result. The processor substitutes matching identifiers with the result value and sets the associated valid bits ( $V_1$  or  $V_2$ ) to indicate availability. We note that this task is performed basically in the same way with and without renaming. There is, however, a slight difference, with renaming the search key is the renamed destination register identifier ( $Rd'$ ) rather than the original destination register identifier ( $Rd$ ) that is used without renaming. The second task is to *update the rename register file*. This is done simply by writing the new result value into the RRF using the identifier accompanying the result produced ( $Rd'$ ) and setting the associated valid bit ( $V$ ) to signal availability.

(iv) *While an instruction completes, the processor permanently updates the ARF*, and thus the *program state*, with the content of the associated rename register. This is done by writing the result of the completed instruction from the associated rename register to the addressed destination register. At this stage of the instruction execution the established renaming becomes obsolete. Therefore, the related entry in the mapping table needs to be deleted and the rename register involved can be *reclaimed* for further use. This is so since (1) after completion, the result of the instruction, that is, the content of the rename register, has already been written into the addressed destination register, and (2) after finishing the instruction, the generated result has already been transferred to all instructions waiting for this operand in the RS.

During renaming, rename registers take on a sequence of states, as indicated in Fig. 6.3.

During initialization the processor sets all rename registers into the “available” state. When the processor allocates a rename register to an issued instruction, the state of the allocated register will be changed to “allocated, not valid” and its valid bit will be reset. When this instruction becomes finished, the newly produced result is written into the associated rename register, and its state is set to “allocated, valid.” Finally, while the instruction completes, the result held temporarily in the rename register is written into the specified architectural register. Thus, the allocated rename register can be reclaimed. Its state is then changed to “available.” Nevertheless, it can happen that an exception or faulty speculative execution gives rise to flush not yet completed instructions. In this case, a recovery procedure is needed, and the state of

the concerned rename registers will be changed from the “*allocated, not valid*” or “*allocated, valid*” state to the “*available*” state and the corresponding mappings between architectural and rename registers will be deleted.

### The Process of Renaming, Assuming Dispatch-Bound Operand Fetching

Assuming basically the same processor core as before, but using the *dispatch-bound operand fetching*, the *rename process* is carried out as follows (see Fig. 6.4).

(i) During instruction issue, both the destination register ( $R_d$ ) and the source registers ( $R_{s_1}$  and  $R_{s_2}$ ) are renamed in the same way as described for issue bound operand fetching. But now, beyond the operation code (OC) and the renamed destination register identifier ( $R_d'$ ), the renamed source register identifiers ( $R_{s_1}'$  and  $R_{s_2}'$ ) are written into the RS rather than the operand values ( $Op_1$ ,  $Op_2$ , if available) as with issue bound operand fetching.

(ii) During dispatching two tasks need to be performed: (a) the instruction held in the last entry of the RS needs to be checked to see whether it is executable. If so and if the EU is also free, this instruction needs to be forwarded for execution to the EU. (b) During forwarding of the instruction, its operands need to be fetched either from the RRF or from the ARF in the same way as described in connection with the issue-bound operation.

(iii) When the EU finishes its operation, the generated result is used to update the RRF. Updating is performed by writing the result into the allocated rename register using the supplemented register identifier ( $R_d'$ ) as an index into the RRF and setting the associated valid bit (V-bit).

(iv) Finally, while the processor completes an instruction, the temporary result held in the associated rename register is written into the architectural register, which is specified in the destination field of the instruction. The only tasks remaining are to delete the corresponding entry in the mapping table and to reclaim the rename register associated with the completed instruction. Reclaiming of the rename register is, however, a far more complex task than with issue bound operand fetching. Notice that if operands are fetched issue bound, (a) issued instructions immediately access their operands and (b) missing operands are, after their generation, immediately forwarded from the EU to the instructions waiting for these operands in the RS. In this case, after completion of an instruction, the allocated rename register can immediately be reclaimed. However, if operands are fetched during dispatching, the RS is not automatically updated with the produced results. As a consequence, after an instruction completes, the RS may still contain instructions, which will require the contents of the rename register, which is allocated to the just completed instruction. Thus, while instructions complete, their allocated rename registers cannot be reclaimed immediately as in the case of the issue bound operand fetching. To resolve this problem one possible solution is to maintain a counter for each rename register, which keeps track of the number of references made to this register. The counter will be incremented each time if one of the source operands of an issued instruction addresses this particular rename register, and will be decremented during dispatching of the instructions each time when a source operand is fetched from this register. After all outstanding fetch requests for a particular rename register are satisfied, as indicated by the counter score of zero, and the associated instruction has been completed, the related register becomes eligible for reclaiming. At the first sight it may seem that this intricate reclaim process can be avoided if during completion the RS would have been searched for all renamed source operand identifiers ( $Rs'_1$ ,  $Rs'_2$ ), which refer to the rename buffer, allocated to the completing instruction ( $Rd'$ ), and matching renamed source register identifiers would have been remapped to the associated architectural register ( $Rd$ ). Unfortunately, this idea is not applicable, since there is no guarantee that the addressed architectural register would not be rewritten until instructions needing its content are dispatched.

During the rename process rename registers will take the same states and the same state transitions will also occur as described earlier in connection with Fig. 6.3. The only difference is that now rename registers are reclaimed according to modified conditions, as discussed previously.

We emphasize that other basic alternatives of register renaming differ mainly in two aspects: (1) the processor can hold renamed values in other structures than rename register files and (2) the processor can use a different scheme for mapping the architectural registers to rename registers as assumed above. In addition, the processor should be able to rename not just one instruction per cycle but all issued instructions. Nevertheless, despite these differences, the previous descriptions in the two characteristic scenarios give a good background about how the rename process is carried out in any of the possible implementation schemes.

## The Design Space of Register Renaming Techniques

### Overview

The *design space of register renaming* has four main dimensions: the scope of register renaming, the layout of the rename registers, the implementation technique of register mapping, and the rename rate, as indicated in Fig. 6.5. These aspects are discussed in the subsequent sections. For the presentation of the design space we make use of DS trees.<sup>3,36</sup>

FIGURE 6.5 Design space of register renaming.

**FIGURE 6.6** Scope of register renaming.

## Scope of Register Renaming

The *scope of register renaming* indicates how extensively the processor makes use of renaming. In this respect we distinguish between partial and full renaming. *Partial renaming* is restricted to one or to only a few instruction types, for instance only to FP-instructions. This incomplete form of implementation was typical for the introductory phase of renaming, at the beginning of the 1990s (see Fig. 6.1). Examples of processors using partial renaming are the Power1 (RS/6000), Power2, PowerPC 601, and the Nx586, as shown in Fig. 6.6. Of these, the Power1 (RS/6000) renames only FP-loads. As the Power1 has only a single FP-unit, it executes FP-instructions in sequence, so there is no need for renaming floating point register instructions. Power2 introduces multiple FP-units, consequently it extends renaming to all FP-instructions, whereas the PowerPC 601 renames only the Link and count register. In the Nx586, which includes an integer core, renaming is restricted obviously only to FX-instructions.

*Full renaming covers* all instructions including a destination register. As Fig. 6.6 demonstrates, virtually all recent superscalar processors employ full renaming. Noteworthy exceptions are Sun's UltraSparc line and Alpha processors preceding the Alpha 21264.

## Layout of the Rename Buffers

### Overview

Rename buffers establish the actual framework for renaming. From their layout we point out three essential design aspects—the type and the number of the rename buffers provided as well as the number of the read and write ports, as shown in Fig. 6.7.

### Types of Rename Buffers

The choice of which type of rename buffers to use in a processor has far reaching impact on the implementation of the rename process. Given its importance, we will outline the various design options. To simplify our presentation, we initially assume a common architectural register file for all data types processed. We later extend our discussion to the split register scenario that is commonly employed.

FIGURE 6.7 Layout of the rename buffers.

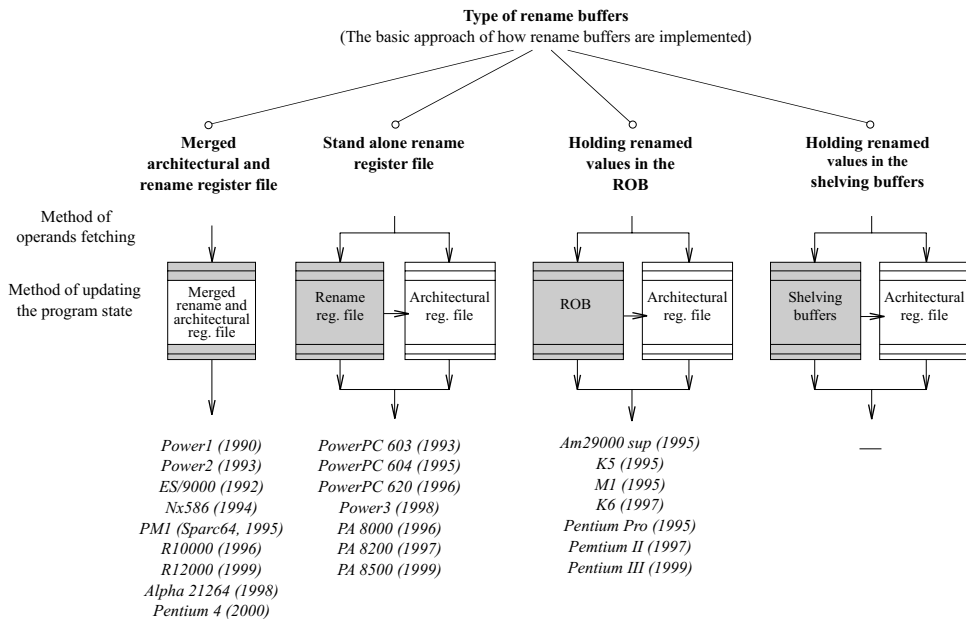

FIGURE 6.8 Generic types of rename buffers (rename buffers are indicated by shaded boxes).

As Fig. 6.8 illustrates, there are four fundamentally different ways to implement rename buffers. The range of choices include: (i) using a merged architectural and rename register file, (ii) employing a stand alone rename register file, (iii) keeping renamed values either in the reorder buffer (ROB), or (iv) in the shelving buffers.

(i) In the first approach, rename buffers are implemented along with the architectural registers in the same physical register file, called the *merged architectural and rename register file* or *the merged register file* for short. Here, both architectural and rename registers are dynamically allocated to particular registers of the same physical file.

Each physical register of the merged architectural and rename register file is at any time in one of four possible states.<sup>28</sup> These states reflect the actual use of a physical register as follows:

- not committed (“available” state),
- used as an architectural register (“architectural register” state),
- used as a rename buffer, but this register does not yet contain the result of the associated instruction (“rename buffer, not valid” state), and finally
- used as a rename buffer, and this register already contains the result of the associated instruction (“rename buffer, valid” state).

As part of the instruction processing, the states of the physical registers are changed as described below and indicated in the state transition diagram in Fig. 6.9.

**FIGURE 6.9** State transition diagram of a particular register of the merged architectural and rename register file<sup>28</sup> (AR: architectural register, RB: rename buffer).

During initialization the first  $n$  physical registers are assigned to the architectural registers, where  $n$  is the number of the registers declared by the instruction set architecture. These registers are set to be in the “architectural register (AR)” state while the remaining physical registers take on the “available” state. When an issued instruction needs a new rename buffer, one physical register is selected from the pool of the available registers and is allocated to the destination register concerned. Accordingly, its state is set to the “rename buffer, not valid” state and its valid bit is reset. After the associated instruction finishes its execution, the produced result is written into the allocated rename buffer. Its valid bit is then set and its state is changed to “rename buffer, valid.” Later, when the associated instruction completes, the rename buffer, which is allocated to it will be declared to be the architectural register, which implements the destination register specified in the just completed instruction. Its state then changes to the “architectural register” state to reflect this. Finally, when an “old” architectural register is reclaimed, its state becomes again “available.” Possible schemes for reclaiming “old” architectural registers are described for both issue bound and dispatch bound operand fetching in a previous section (“Overview of the Rename Process”). It can also happen that not yet completed instructions should be canceled due to exceptions or faultily executed speculative instructions. In this case allocated rename buffers in the states “rename buffer, not valid” or “rename buffer, valid,” are deallocated and their state are changed to “available.” In addition, the corresponding mappings, kept either in the mapping table or in the rename buffer (as discussed later), need to be canceled.

Note that merged architectural and rename register files do not require a physical data transfer to update architectural registers. All that is needed for updating is to change the status of the related registers. By contrast, separate rename register implementations need, for updating the architectural registers, a physical data transfer from the rename buffer file to the architectural register file. This requires additional read and write ports on the rename register file and on the architectural register file, respectively, as well as a dedicated data path. For this reason recent processors make increasing use of merged architectural and rename register files, e.g., the Alpha 21264, Pentium 4, or the K7 (for renaming floating point instructions).

Merged architectural and rename register files are employed furthermore, in the high end models (520-based models) of the IBM ES/9000 mainframe family, the Power and R1x000 lines of processors.

All other alternatives separate rename buffers from architectural registers. Their respective state transition diagram is depicted in Fig. 6.3 and has already been discussed in connection with the overview of the rename process.

(ii) In the first “separated” variant, a *stand alone rename register file (or rename register file for short)* is used exclusively to implement rename buffers. The PowerPC 603–PowerPC 620 and the PA8x00 line of processors are examples for using rename register files.

(iii) Alternatively, renaming can also be based on the *reorder buffer (ROB)*; see related box. The ROB has recently been widely used to preserve the sequential consistency of the instruction execution. When using a ROB, an entry is assigned to each issued instruction for the duration of its execution. Therefore, it is quite natural to use this entry for renaming as well, basically by extending it with a new field, which will hold the result of that instruction. Examples of processors, which use the ROB for renaming, are the Am 29000 superscalar, the K5, K6, the PentiumPro, PentiumII, and PentiumIII.

The ROB can even be extended further to serve as a central shelving buffer. In this case, the ROB is also occasionally designated as the DRIS (*Deferred Scheduling Register Renaming Instruction Shelf*). The Lightning processor proposal<sup>37</sup> and the K6 made use of this solution. As the Lightning proposal, which dates back to the beginning of the 1990s, was too ambitious in the light of the technology available at that time, it could not be economically implemented and never reached the market.

(iv) The last conceivable implementation alternative of rename buffers is to use the *shelving buffers* for renaming. In this case, each shelving buffer needs to be extended functionally to perform the task of a rename buffer as well. But this alternative has a drawback resulting from the different deallocation mechanisms of the shelving and rename buffers. While shelving buffers can be reclaimed as soon as the instruction has been dispatched, rename buffers can be deallocated only at a later time, not earlier than the instruction has been completed. Thus, a deeper analysis is needed to reveal the appropriateness of the use of shelving buffers for renaming. To date, no processor has chosen this alternative.

For simplicity's sake, we have so far assumed that all data types are stored in a common architectural register file. But usually, processors provide *distinct architectural register files* for FX- and FP-data, consequently they typically employ *distinct rename register files*, as shown in Fig. 6.10.

As depicted in this figure, when the processor employs the split register principle, distinct FX- and FP-register files are needed for both the merged files and the stand alone rename register files. In these cases separate data paths are also needed to access the FX- and the FP-registers. Recent processors typically incorporate split rename registers with one exception. When renaming takes place *within the ROB*, usually a *single mechanism* is maintained for the preservation of the sequential consistency of instruction execution. Then all renamed instructions are kept in the same ROB queue, despite using split architectural register files for FX- and FP-data. In this case, clearly, each ROB entry is expected to be long enough to hold either FX- or FP-data.

**Number of Rename Buffers**

Rename buffers keep register results temporarily until instructions complete. As not every instruction produces a register result, in a processor up to as many rename buffers are needed as the maximum number of instructions that have been issued but not yet completed. Issued but not yet completed instructions are either (i) held in shelving buffers waiting for execution (if shelving is employed), or (ii) are just in processing in any of the execution units, or (iii) are in the load queue waiting for cash access (if there is a load queue), or finally (iv) are in the store queue waiting for completion and afterwards for forwarding them into the cache to execute the required store operation (if there is a store queue).

**FIGURE 6.10** Using split registers in the case of (a) merged register files, and (b) stand alone rename register files.

Thus, the maximal number of instructions that may have been issued but have not yet completed in the processor ( $n_{pmax}$ ) is

$$n_{pmax} = w_{dw} + n_{EU} + n_{Lq} + n_{Sq} \quad (6.1)$$

where  $w_{dw}$  is the width of the dispatch window (total number of shelving buffers),  $n_{EU}$  is the number of the execution units, which may operate in parallel,  $n_{Lq}$  is the number of the entries in the load queue, and finally  $n_{Sq}$  is the number of the entries in the store queue.

Assuming a worst case design approach, from Eq. (6.1) we can determine that the total number of rename buffers required ( $n_{rmax}$ ) is

$$n_{rmax} = w_{dw} + n_{EU} + n_{Lq} \quad (6.2)$$

as instructions held in the store queue do not require rename buffers.

Furthermore, if the processor includes an ROB, the ROB needs to maintain an entry for every issued but not yet completed instruction. So, based on Eq. (6.1) the total number of ROB entries required ( $n_{ROBmax}$ ) is

$$n_{ROBmax} = n_{pmax} \quad (6.3)$$

Nevertheless, if the processor has fewer rename buffers or fewer ROB entries than expected to have according to the worst case approach (as given by Eqs. (6.2) and (6.3), respectively), missing free rename buffers or ROB entries can cause issue blockages. With a decreasing number of entries provided we expect a smooth and a slight performance degradation. Hence, a stochastic design approach is also feasible, where the required number of entries is derived from the tolerated level of performance degradation.

Based on Eqs. (6.1)–(6.3), the following relations are typically valid concerning the width of the processor's dispatch window ( $w_{dw}$ ), the total number of the rename buffers ( $n_r$ ), and the reorder width ( $n_{ROB}$ ), which equals the total number of ROB entries available:

$$w_{dw} < n_r \leq n_{ROB} \quad (6.4)$$

In [Table 6.1](#), we summarize the type and the number of rename buffers provided in recent RISC and x86 superscalar processors. In addition, we give four key parameters of the enlisted processors, (i) the issue rate, (ii) the width of the dispatch window ( $w_{dw}$ ), (iii) the total number of rename buffers provided ( $n_r$ ), and (iv) the reorder width ( $n_{ROB}$ ).

As the data in [Table 6.1](#) shows, the interrelations Eq. (6.4) have been taken into account in the design of most processors; however, two obvious exceptions arise. First, the PowerPC 604 provides 20 rename buffers, four more buffers than the reorder width of the processor, which is 16. In the subsequent PowerPC 620, Intel corrected this by decreasing the number of rename buffers to 16. Second, the R10000 provides only 32 ROB entries. This number is far too low compared to the dispatch width (48) and to the number of available rename buffers (64). MIPS addressed this disproportion in its following model, the R12000, by increasing the reorder width of the processor to 48.

### **Number of Read and Write Ports**

By taking into account current practice, in our subsequent discussion we assume split register files.

First, let us focus on the *required number of read ports* (output ports). Clearly, as many read ports are required in the rename buffers as there are data items that the rename buffers may need to supply in any one cycle. In this respect, we should take into account that rename buffers supply required operands for the instructions to be executed and also forward the results of the completed instructions to the addressed architectural registers.

The number of operands, which need to be delivered in the same cycle, depends first of all on whether the processor fetches operands during instruction issue or during instruction dispatch.

? Designates questionable data.

If operands are fetched *issue bound*, the rename buffers need to supply the operands for all instructions, which are issued in the same cycle into the shelving buffers. If there are no issue restrictions, both the FX- and the FP-rename buffers are expected to deliver in each cycle all required operands for up to as many instructions as the issue rate. This means that in a recent four way superscalar processor the FX- and the FP-rename buffers typically need to supply eight and twelve operands respectively, assuming up to two FX- and three FP-operands in each FX- and FP-instruction, respectively. If, however, there are some issue restrictions, the required number of read ports is decreased accordingly.

By contrast, if the processor employs the *dispatch bound* fetch policy, the rename buffers should provide the operands for all instructions, which are forwarded from the dispatch window (instruction window) for execution in the same cycle. In this case, the FX-rename buffers need to supply the required FX-operands for the integer units and for the loadstore units (including register operands for the specified address calculations and FX-data for the FX-store instructions). As far as the FP-rename buffers are concerned, they need to deliver operands for the FP-units (FP-register data) and also for the load store units (FP-operands for the FP-store instructions). In the Power3, for instance, this implies the following read port requirements. The FX-rename buffers need to have 12 read ports (up to  $3 \times 2$  operands for the three integer units as well as  $2 \times 2$  address operands and  $2 \times 1$  data operands for the two load store units). On the other hand, the FP-rename registers need to have eight read ports (up to  $2 \times 3$  operands for the two FP-units and  $2 \times 1$  operands for the two load store units).

In addition, if rename buffers are implemented separately from the architectural registers, the rename buffers need to be able to forward in each cycle as many result values to the architectural registers as the completion rate (retire rate) of the processor. As recent processors usually complete up to four instructions per cycle, this task increases the required number of read ports in the rename buffers typically by four.

We note here that too many read ports in a register file may unduly increase the physical size of the datapath and as a result the cycle time. To avoid this problem, a few high performance processors (such as the Power2, Power3, and the Alpha 21264) implement two copies of particular register files. The Power2 duplicates the FX-architectural register file, the Power3 doubles both the FX-rename and the FX-architectural files, and the Alpha 21264 has two copies of the FX-merged architectural and rename register file. As a result fewer read ports are needed in each of the copies. For example, with two copies of the FX-merged register file, the Power3 needs only ten read ports in each file, instead of 16 read ports in one FX-register file. A drawback of this approach is, however, that a scheme is also required to keep both copies coherent.

Now let us turn to the *required number of write ports* (input ports). Since rename buffers need to accept in each cycle all results produced by the execution units, they need to provide as many write ports as many results the execution units may produce per cycle. The FX-rename buffers receive results from the available integer-execution units and from the load/store units (fetched FX-data), whereas the FP-rename buffers hold the results of the FP-execution units and of the load/store units (fetched FP-data). Most results are single data items requiring one write port. However, there are a few exceptions. When execution units generate two data items they require two write ports as well; like the load/store units of PowerPC processors. After execution of the LOAD-WITH-UPDATE instruction, these units return both the fetched data value and the updated address value.

**Layout of the Register Mapping**

**Overview**

Register mapping includes three tasks, as depicted in Fig. 6.11: (1) The processor needs to allocate rename buffers to the destination registers of the issued instructions; (2) it also must keep track of the actually valid mappings; and (3) it needs to deallocate no longer used rename buffers.

**Allocation Scheme of Rename Buffers**

As far as the *allocation scheme of rename buffers* is considered, processors usually allocate rename buffers to every issued instruction rather than only to those including a destination register in order to simplify logic. Although rename buffers are not needed until the results become available in the last execution cycle, rename buffers are typically allocated to the instructions as early as during instruction issue. This kind of register allocation leads to wasted rename register space. Delaying the allocation of rename buffers to the instructions until instructions finish<sup>39</sup> saves rename register space. Various schemes have been proposed for this, such as virtual renaming<sup>39-42</sup> and others.<sup>43</sup> In fact, a virtual allocation scheme has already been introduced into the Power3.<sup>39</sup>

**Method of Keeping Track of Actual Mapping**

Two possibilities are available for *keeping track of the actual mapping* of particular architectural registers to allocated rename buffers. The processor can use a mapping table for this or can track the actual register

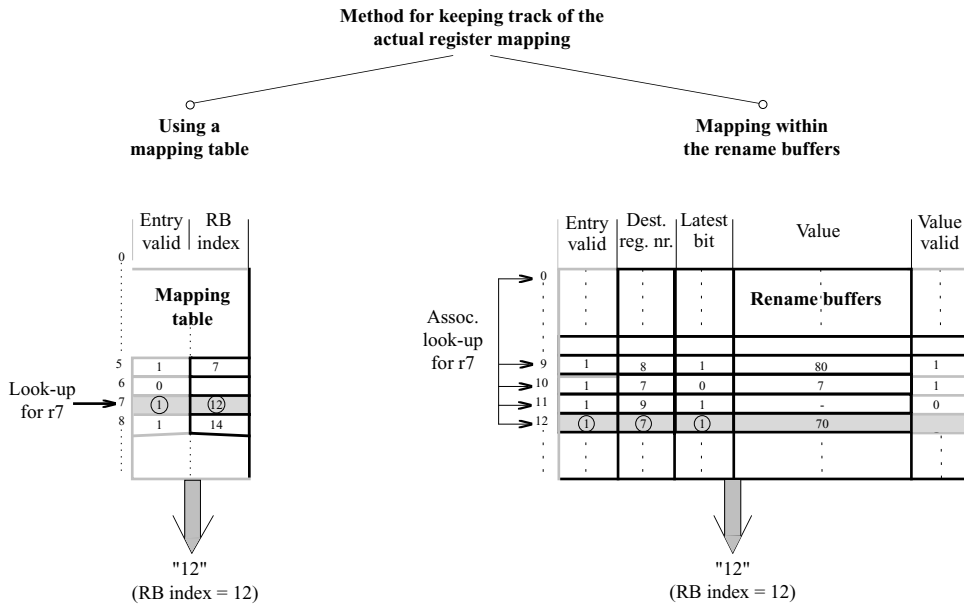

FIGURE 6.11 Layout of the register mapping.

**FIGURE 6.12** Methods for keeping track of the actual mapping of architectural registers to rename buffers. (RB designates rename buffer.)

mapping within the rename buffers themselves. In the following section we outline these methods, illustrated in Fig. 6.12.

A *mapping table* has as many entries as there are architectural registers in the instruction set architecture (ISA), usually 32. Each entry holds a status bit (called the entry valid bit in the figure), which indicates whether the associated architectural register is renamed. Each valid entry supplies the index of the rename buffer, which is allocated to the architectural register belonging to that entry (called the RB-index). For instance, the left side of Fig. 6.12 shows that the mapping table holds a valid entry for architectural register r<sub>7</sub>, which contains the RB-index of 12, indicating that the architectural register r<sub>7</sub> is actually renamed to rename buffer number 12. As already indicated, usually each entry is set up during instruction issue while new rename buffers are allocated to the issued instructions. A valid mapping is updated when the architectural register belonging to that entry is renamed again, and it will be invalidated when the instruction associated with the actual renaming completes. In this way, the mapping table continuously holds the latest allocations. Source registers of issued instructions are renamed by accessing the mapping table with the register numbers as indices and fetching the associated rename buffer identifiers (RB-indices), as shown in Fig. 6.12.

We note that for split architectural register files obviously separate FX- and FP-mapping tables are needed.

Mapping tables should provide one read port for each source operand that may be fetched in any one cycle, and one write port for each rename buffer that may be allocated in any one cycle (as discussed earlier in the section on “Number of Read and Write Ports”).

The other fundamentally different alternative for keeping track of the actual register mappings relies on an *associative mechanism* (see the right side of Fig. 6.12). In this case no mapping table exists but each rename buffer holds the identifier of the associated architectural register (usually the register number of the renamed destination register) and additional status bits as well. These entries are set up usually during instruction issue when a particular rename buffer is allocated to a specified destination register. As Fig. 6.12 shows, in this case each rename buffer holds five pieces of information: (1) a status bit, which indicates that this rename buffer is actually allocated (called the entry valid bit in the figure), (2) the identifier of the associated architectural register (Dest. reg. no.), (3) a further status bit, called the latest

bit, whose role will be explained subsequently, (4) another status bit, called the value valid bit, which shows whether the actual value of the associated architectural register has already been generated, and finally (5) the value itself (value), provided that the “value valid” bit signifies an already produced result. The latest bit is needed to mark the last allocation of a given architectural register if it has more than one valid allocation due to repeated renaming. For instance, in our example, architectural register  $r_7$  has two subsequent allocations. From these, entry number 12 is the latest one as its latest bit has been set. Thus, in our figure, renaming of the source register  $r_7$  would yield the RB-index of 12. We point out that in this method source registers are renamed by an associative lookup for the latest allocation of the given source register.

If operands are fetched issue bound, source registers are both renamed and accessed during the issue process. Then processors usually integrate renaming and operand accessing, and therefore maintain register mapping within the rename buffers. For dispatch bound operand fetching, however, these tasks are separated. Source registers are usually renamed during instruction issue, whereas the source operands are accessed while the processor dispatches the instructions to the execution units. Therefore, in this case, processors typically use mapping tables.

### **Deallocation Scheme of Rename Buffers**

If rename buffers are no longer needed, they should be reclaimed (deallocated). The actual *scheme of reclaiming* depends on key aspects of the overall rename process. In particular, it depends on the allocation scheme of the rename buffers, the type of rename buffers used, the method of keeping track of actual allocations, and even whether operands are fetched issue bound or dispatch bound. Here, we do not go into details, but refer to the section on “Implementation of the Rename Process” for a few examples on how processors reclaim rename registers.

### **Rename Rate**

As its name suggests, the *rename rate* stands for the maximum number of renames that a processor is able to perform in a cycle. Basically, the processor should be able to rename all instructions issued in the same cycle in order to avoid performance degradation. Thus, the rename rate should equal the issue rate. This is easier said than done because it is not at all an easy task to implement a high rename rate (four or higher). This is true for two reasons. First, for higher rename rates the detection and handling of inter-instruction dependencies during renaming (as discussed later in the section on “Implementation of the Rename Process”) becomes a more complex task. Second, higher rename rates require a larger number of read and write ports on register files and on mapping tables. For instance, the 4-way superscalar R10000 can issue any combination of 4 FX- and FP-instructions. Accordingly, its FX-mapping table needs 12 read ports and 4 write ports, and its FP-table requires 16 read and 4 write ports. This number of ports are needed since FX-instructions can refer up to three and FP-instructions up to four source operands in this processor.

Another example worth looking at is the PM1, also called Sparc64. This 4-way superscalar processor can issue any combination of 4 FX- and 2 FP-instructions, up to a maximum of 4 instructions. In this case, both the FX-mapping table and the merged register file have 10 read and 4 write ports while its FP-counterpart has 6 read and 3 write ports. According to Asato et al.,<sup>44</sup> this 14-port 116 word 64-bit merged register file needs 371 K transistors, far more than the entire Intel 8086 processor (about 30 K transistors) or slightly more than the i386 (about 275 K transistors).<sup>45</sup>

## **Basic Alternatives and Possible Implementation Schemes of Register Renaming**

In the design space of register renaming, theoretically each possible combination of the available design choices yields one possible implementation alternative. Instead of considering all possible implementation alternatives, it makes sense to focus only on those, which differ in relevant qualitative aspects from each other. We designate these alternatives the basic alternatives. Possible *basic alternatives* can be derived from the design space in two steps—first by identifying the relevant qualitative design aspects and then by

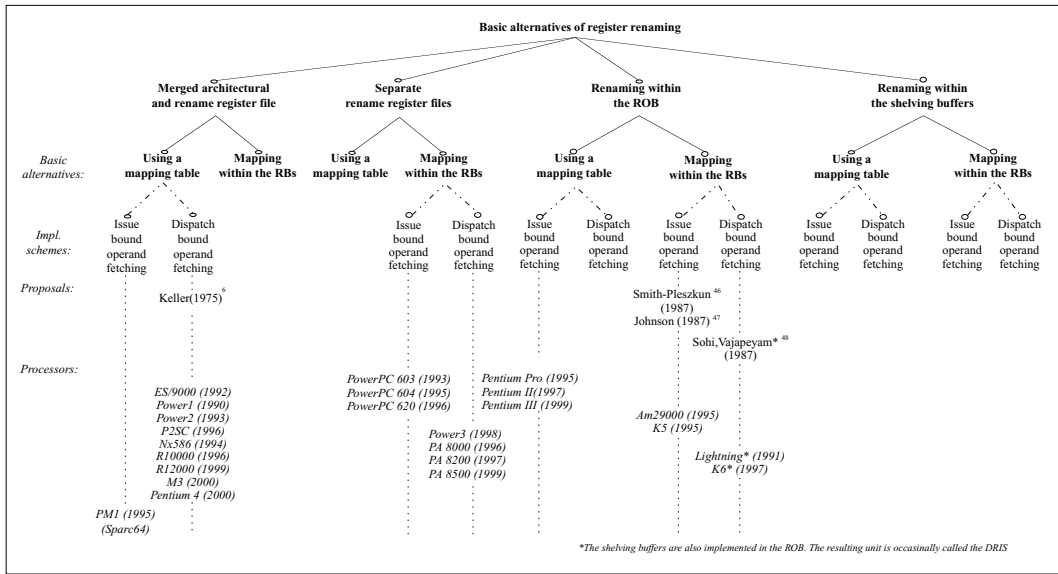

FIGURE 6.13 Basic implementation alternatives of register renaming.

composing their possible combinations. Concerning the selection of the *relevant qualitative design aspects*, we recall the design space of renaming, shown in Fig. 6.5. First, we can ignore two main aspects, the scope of register renaming, as recent processors typically implement full renaming, and the rename rate, because of its quantitative character. Thus, two main design aspects remain, the layout of the rename buffers and the implementation of register mapping. Furthermore, as Fig. 6.7 indicates, the layout of the rename buffers itself covers three design aspects: the type and the number of rename buffers, and the number of the read and write ports. Of these only the type of the rename buffers is of qualitative character. From the design aspect layout of the register mapping (Fig. 6.11) we consider the method of keeping track of actual mappings the only relevant aspect. It follows that the design space of register renaming includes only two relevant qualitative aspects: the type of the rename buffers and the method of keeping track of actual mappings.

The design choices available for these two relevant design aspects result in eight possible *combinations*, called the *basic alternatives* for register renaming, as shown in Fig. 6.13. In addition, as the operand fetch policy of the processor, which is a design aspect of shelving, significantly affects how the rename process is carried out, in this figure we also take into account this aspect. This splits the eight basic renaming alternatives into 16 feasible *implementation schemes*. In this figure we also indicate which implementation schemes are used in relevant superscalar processors, as well as give some hints about their origins.

As Fig. 6.13 indicates, out of the eight possible basic alternatives of renaming, relevant superscalar processors make use only of four. Moreover, we can recognize that the latest processors employ mostly the following three basic alternatives of renaming:

1. Use of merged architectural and rename register files and of mapping tables (R10000, R12000, M3)
2. Use of separate rename register files and mapping registers within the rename registers (PA8x00 line, Power3)
3. Renaming within the ROB and using mapping tables (Pentium Pro, Pentium II, Pentium III)

We note furthermore that it is also conceivable to use different basic alternatives for renaming FX- and FP-instructions, as is done in the K7. This processor uses the ROB for renaming FX-instructions and a merged architectural and rename register file for renaming floating point ones; however, as AMD did not disclose the method of register mapping, we have not included this processor into Fig. 6.13.

As Fig. 6.13 shows, the latest processors fetch operands predominantly dispatch bound due to the comparative advantage of this fetch policy.<sup>49</sup> The move away from the issue bound to the dispatch bound fetch policy is manifested in AMD's subsequent K5 and K6, in Intel's line of P6-based models (Pentium Pro, Pentium II, and Pentium III) compared to the Pentium 4, and by the fact that the PowerPC 620-based Power3 also made this transition.

## Implementation of the Rename Process

With reference to the section "Overview of the Rename Process" we emphasize that the rename process can be broken down into the following subtasks:

- (a) renaming the destination registers
- (b) renaming the source registers
- (c) fetching the renamed source operands
- (d) updating the rename buffers
- (e) updating the architectural registers with the content of the rename buffers
- (f) reclaiming of the rename buffers
- (g) recovery from wrongly performed speculative execution and handling of exceptions

These subtasks are carried out more or less differently in the 16 distinct implementation schemes of renaming.

Of these, in the section on "Overview of the Rename Process," we described the rename process presuming one particular basic alternative (assuming the use of rename register files and mapping tables) in both operand fetch scenarios, that is in two implementation schemes. Below, instead of pointing out all differences in all further implementation schemes of register renaming, we focus only on three particular tasks of renaming and point out significant differences encountered in different implementation schemes. In addition, we briefly discuss how inter-instruction dependencies are dealt with during renaming, how the processor recovers from misspeculation, and how it handles exceptions.

### Remarks on Renaming Destination Registers

The way how the processor allocates new rename buffers depends on the type of rename buffers used. If rename buffers are realized in the ROB, a new ROB entry, and thereby a new rename buffer will automatically be allocated to each issued instruction. Else rename buffers need to be allocated only to those issued instructions, which include a destination register.

### Remarks on Updating the Architectural Registers

As discussed previously, when instructions complete, their results need to be forwarded from the associated rename buffers into the originally addressed architectural registers. In cases where rename buffers are implemented separately from the architectural register file (as a stand alone rename register file, or they are in the ROB or in the shelving buffer file), this task instructs the processor to physically transfer the contents of the related rename buffers into the referenced architectural registers. By contrast, if the processor uses a merged architectural and rename file, no physical data transfer is required, instead only the status of the related registers needs to be changed, as indicated before and shown in Fig. 6.10.

### Remarks on Reclaiming Rename Buffers

The conditions for reclaiming no longer used rename buffers vary with the rename scheme employed. Thus, when operands are fetched issue bound, associated rename buffers may immediately be reclaimed after an instruction has been completed. On the other hand, if the processor fetches operands dispatch bound, associated rename buffers may only be reclaimed after the related instruction has been completed and, in addition, if it is also sure that no outstanding operand fetch requests are available to that rename buffer. The latter condition can be checked in different ways. One possibility is to use a counter for each rename buffer for checking outstanding fetch requests, as described in the section on "Overview of the Rename Process." Another option is applicable with merged architectural and rename register files.

In this case, however, during instruction execution a rename buffer becomes an architectural register and reclaiming is related to no longer used architectural registers, as discussed in the section on “Types of Rename Buffers.” This method relies on keeping track of the most recent prior instance of the same architectural register, and on reclaiming it when the instruction giving rise to the new instance completes.<sup>28</sup>

### Renaming of Destination and Source Registers if Inter-Instruction Dependencies Exist between the Instructions Issued in the Same Cycle

As we know, shelving relieves the processor of the need to check for data- and control dependencies as well as for busy EUs during instruction issue. Nevertheless, despite shelving, instructions issued in the same cycle must still be checked for inter-instruction dependencies, and, in the case of dependencies, the rename logic must be modified accordingly. Let us assume, for instance, that there are RAW dependencies between two subsequent instructions issued in the same cycle, as in the following example:

```
i1:  mul  r2, ..., ...
i2:  add  ..., r2, ...
```

Here,  $i_2$  needs the result of  $i_1$  as  $r_2$  is one of its source operands. We will also assume that the destination register of  $i_1$  ( $r_2$ ) will be renamed to  $r_{33}$  as follows:

```
i'1:  mul  r33, ..., ...
```

In this case the RAW-dependent source operand of  $i_2$  ( $r_2$ ) has to be renamed to  $r_{33}$  rather than to the rename buffer allocated before renaming of  $i_1$  to  $r_2$ .

Similarly, if WAW dependencies exist among the instructions issued in the same cycle, as for instance, between the instructions

```
i1:  mul  r2, ..., ...
i2:  add  r2, ..., ...
```

obviously, different rename buffers need to be allocated to the destination registers of  $i_1$  and  $i_2$ , as shown below:

```
i'1:  mul  r34, ..., ...
i'2:  add  r35, ..., ...
```

### Recovery of the Rename Process from Wrongly Executed Speculation and Handling of Exceptions

If the processor performs speculative execution, for instance due to branch prediction, it may happen that the speculation turns out to be wrong. In this case the processor needs to recover from the misspeculation. This involves essentially two tasks: (i) to undo all register mappings set up, and (ii) to reclaim rename buffers allocated, as already discussed. *To invalidate established mappings* there are two basic methods to choose from, independently of the actual implementation of renaming. The first option is to *roll back* all register mappings made during speculative execution, by using the identifiers of the faulty instructions, supplied by the ROB. While using this alternative, the recovery process lasts several cycles, since the processor can cancel only a small number of instructions (two to four) per cycle. A second alternative is based on *checkpointing*. In this method, before the processor begins with speculative execution, it saves the relevant machine state, including also the actual mapping, in shadow registers. If the speculative execution turns out to be wrong, the processor restores the machine state in a single cycle by reloading the saved state. For instance, both the PM1 (Sparc64) and the R10000 use checkpointing

for recovery. Both processors incorporate mapping tables for register mapping, while the R10000 provides four sets of shadow registers and the PM1 16 for subsequent speculations.

We note that beyond the two basic methods discussed above, there is also a third option in the case when the processor uses mapping tables and dispatch bound operand fetching. This method relies upon *shadow mapping tables*, which keep track of the actual mappings of the completed instructions. The entries of the shadow tables are set up when instructions complete and are deleted when allocated rename buffers are reclaimed. In the case of misspeculation, the correct state of the mapping table can be restored by loading the content of the shadow table. For example, Cyrix's M3 makes use of this recovery mechanism.

The second task to be done during misspeculation is *to reclaim rename buffers*, which are allocated to the faulty instructions. This task can easily be performed by changing the state of the rename buffers involved to "available," as indicated in Figs. 6.3 and 6.9.

A similar situation to the above described misspeculation arises when *exceptions* occur. In this case the exception request must wait until the associated instruction comes to completion to provide precise exceptions.<sup>46</sup> At this time, the processor accepts the exception and cancels all instructions, which have been issued after the failing one. For cancellation of the rename process the same methods can be used as discussed above. For example, in the event of an exception the R10000 rolls back all younger register mappings made, whereas the PM1 first restores the mapping state to the first checkpoint after the failing instruction in one cycle, and then rolls back the remaining mappings until the failing instruction is reached.

### Appendix A: Types of Data Dependencies<sup>1-3</sup>

Data dependencies are precedence requirements between operands of subsequent instructions. Data dependencies may occur in two different situations: either in straight line code segments, called *inter instruction dependencies*, or between operands of instructions occurring in subsequent loop iterations, designated as *recurrences* (see Fig. A). In both situations *either register operands or memory operands* may be involved.

Inter-instruction dependencies may be broken down into read-after-write (RAW), write-after-read (WAR), and write-after-write (WAW) dependencies, as depicted in Fig. B. In the following overview of these types of dependencies we confine ourselves to register operands, but the given interpretation can be applied to memory operands as well.

*RAW dependencies*, designated also as *flow dependencies*, are producer-consumer relations between operands, which can be bisected into load-use and define-use dependencies (see Fig. B). *Load-use dependencies*

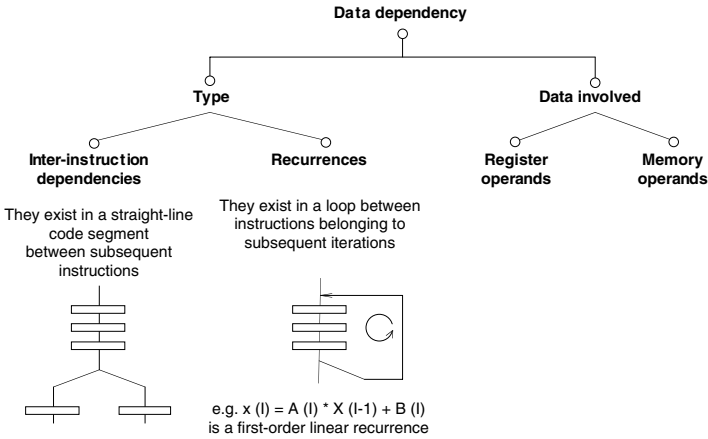

FIGURE A. Main aspects of data dependencies. (In this and in subsequent figures, relevant aspects and possible alternatives are illustrated by using DS-trees.<sup>3,36</sup>)

FIGURE B. Terms relating to data dependencies occurring in straight line code (Instruction semantics is  $r_1 \leftarrow r_2 * r_3$  etc.).

arise in scenarios when an instruction uses a register operand, which needs to have been loaded by a preceding load instruction from the memory, as shown in the example in Fig. B. If, however, the requested operand is produced by a preceding operational instruction, the arising dependency is called *define-use dependency*, as illustrated in Fig. B.

WAR dependencies or *anti-dependencies* arise between instructions if a given instruction reads an operand from a particular register and a subsequent instruction writes the same register, as depicted in Fig. B. If, for any reason, the subsequent instruction ( $i_2$ ) would have written this register before it is read by the previous one ( $i_1$ ), then the subsequent instruction would pick up an erroneous operand value.

Finally, two instructions are said to be *WAW dependent*, or *output dependent*, if they both write the same destination.

WAR and WAW dependencies are designated as *false dependencies*, since they can be removed by appropriate techniques (that is register renaming in the case of register operands). By contrast, RAW dependencies are *true dependencies*, since they cannot be eliminated.

Data dependencies may also occur in loops. This is the case if an instruction of the loop body is dependent on an instruction belonging to a previous loop iteration, as exemplified in Fig. A. This type of dependency is called *recurrence*, designated also as inter-iteration data dependency or loop carried dependency. In the above example the value of  $X(I)$  depends on the value that is computed in the previous iteration. The recurrence shown is a first-order linear one.

## Appendix B: The Principle of Instruction Shelving

*Instruction shelving* (also known as indirect issue or dynamic instruction scheduling)<sup>1-3,49</sup> removes the issue bottleneck caused by control and data dependencies and by busy execution units. Its main idea is to “shelve” issued instructions and defer dependency checking until a subsequent processing step, designated as dispatching.

*Without shelving* (see Fig. C) the processor issues instructions from the so called *issue window* (instruction window), to the execution units (EU). Actually, the issue window comprises the last  $n$  entries of the instruction buffer (I-buffer), where  $n$  is the *issue rate*. The processor decodes the instructions kept in the window and checks for dependencies between the instructions in the window and those in execution, and also among the instructions held in the window. Dependent instructions are not issued, moreover, depending on the issue policy of the processor,<sup>36</sup> they can even block the issue of subsequent not dependent instructions. Occurring blockages heavily restrict the average number of instructions issued per cycle and thus also processor performance.

FIGURE C. The principle of direct issue.

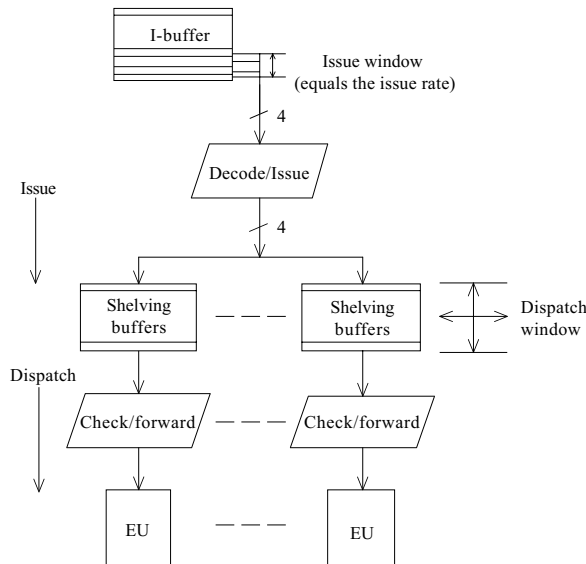

FIGURE D. The principle of shelving (indirect issue).

*Shelving* removes the issue bottleneck by decoupling instruction issue and dependency checking through buffering issued instructions, as indicated in Fig. D. There are various possibilities as to how shelving buffers can be implemented.<sup>49</sup> Of these in Fig. D we show shelving buffers provided in front of each execution unit (EU), also called individual reservation stations or simply reservation stations. With shelving, instructions are *issued* first to the shelving buffers, with no checks for data dependencies or busy execution units. In the second step, instructions held in the shelving buffers are *dispatched* for execution. During dispatching instructions are checked for dependencies and not dependent instructions are forwarded to free execution units. Concerning terminology we note that at the time being there is no consensus on the use of the terms instruction issue and instruction dispatch. Both terms are used in both possible interpretations.

Shelving not only removes the issue bottleneck but substitutes the *issue window* with the much wider *dispatch window* (instruction window), which is made up of all shelving buffers. Because the total number of the shelving buffers is usually an order of magnitude higher than the issue rate, with shelving the processor will find in each clock cycle on the average far more executable instructions than without shelving.

Thus, shelving substantially raises the sustained instruction throughput rate of the processor. Although conceived as early as in the middle of the 1960s for the first instruction level parallel (ILP) processors (the CDC6600<sup>50</sup> and the IBM 360/91),<sup>4</sup> because of the complexity of its implementation, shelving only came into widespread use more than two decades later in superscalars.

### Appendix C: Operand Fetch Policies<sup>3</sup>

If the processor uses the *issue bound fetch policy* it fetches referenced register operands during instruction issue, that is while it forwards decoded instructions into the shelving buffers.<sup>3,36</sup> In contrast, *the dispatch bound fetch policy* defers operand fetching until executable instructions are forwarded from the shelving buffers to the execution units. When the processor fetches operands issue bound, shelving buffers hold the source operand values. In contrast, in the case of dispatch bound operand fetching, shelving buffers have much shorter entries, as they contain only the register identifiers.

### Appendix D: The Principle of the Reorder Buffer (ROB)

It is implemented basically as a circular buffer whose entries are allocated and deallocated by means of two revolving pointers.<sup>46</sup> The ROB operates as follows. When instructions are issued, an ROB entry is allocated to each instruction strictly in program order. Each ROB entry keeps track of the execution status of the associated instruction. The ROB allows instructions to complete (commit, retire) only in program order by permitting an instruction to complete only if it has finished its execution and all preceding instructions are already completed. In this way, instructions update the program state in exactly the same way as a sequential processor would have done. After an instruction has completed, the associated ROB entry is deallocated and becomes eligible for reuse.

## 6.3 Predicting Branches in Computer Programs

*Kevin Skadron*

### What Is Branch Prediction and Why Is it Needed?

#### What Is Branch Prediction?

*Branch* instructions permit a program to control the flow of instruction execution within a program. Examples of high-level program constructs that translate into branches are “if-then” statements and “for” loops. They test some condition, and depending on the outcome, execution proceeds down one of two possible paths. In almost all instruction sets, branch instructions have exactly two possible outcomes: *not-taken*, the sequential or fall-through case, in which the condition is false and the program continues executing the instructions that immediately follow the branch; and *taken*, the nonsequential case, in which the condition is true and execution jumps to a target specified in the branch instruction. In the case of an “if” statement, the two outcomes are the “then” clause and the fall-through case, which may correspond to an “else” clause. In the case of a “for” loop, the two outcomes are an iteration of the loop body or the fall-through case, which corresponds to exiting the loop. For example, a typical loop structure in assembly code might look like this (“bnez” means “branch if the condition is not equal to zero”):

```
L: (loop body)
    ...
    sub r1, #1, r1      ; r1 is the loop counter
    bnez r1, L         ; if the loop count is not yet zero, branch back
                        ; to the top of the loop (label “L”) and iterate
    (fall-through code) ; this code gets executed after the loop exits
```

Note that in all the assembly-language examples in this chapter, destination registers are listed last.

Branches create a problem because the identity of the proper path can only be known after the branch has finished testing its condition, a process that takes time. Due to the pipelined nature of almost all modern processors, this resolution latency necessitates branch prediction. [Figure 6.14](#) shows the flow of a branch through a generic pipeline. Resolving the branch requires waiting until it proceeds through several stages and finally executes. If the fetching of subsequent instructions must wait until the proper path is known with confidence, stall time or a “bubble” results [1].

If branch outcomes are instead predicted and subsequent instructions are speculatively fetched and executed, this bubble is eliminated whenever the prediction is correct. This is shown in [Fig. 6.15](#). If the prediction is incorrect, these speculative instructions must be squashed—removed from the pipeline—and no time has been wasted compared to the alternative of no prediction. Squashing can be accomplished simply by preventing the mis-speculated instructions from modifying any processor state. These squashed instructions, however, represent an opportunity cost: had the branch been correctly predicted, those instructions would have been correct, and would have performed useful work. This wasted time is called the *misprediction penalty* and is equal to the branch resolution time.

Other control-flow instructions exist that transfer execution to some other program location but are not conditional and do not branch. These *jump* instructions either jump to the target specified in the instruction (*direct* jumps), or jump to a target that has been computed and whose address is found in a register (*indirect* jumps). A procedure call is an example of the former, and a procedure return is an

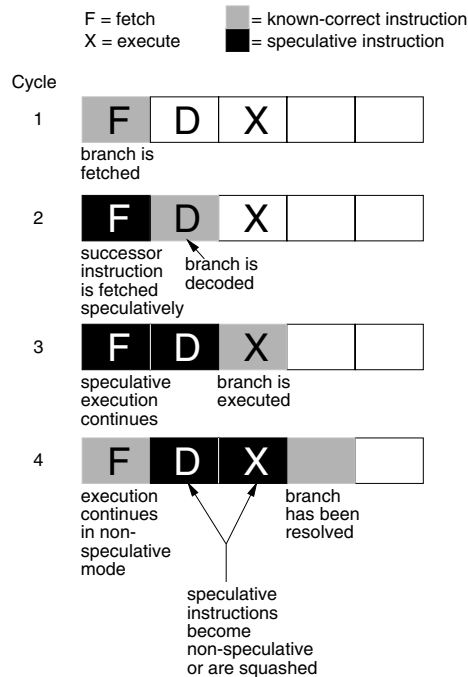

**FIGURE 6.14** A branch flowing through a generic pipeline with no prediction. The branch, the first gray box, flows from left to right. After being fetched, one or more cycles elapse (one cycle in this diagram) while the instruction is decoded and perhaps other manipulation takes place. Once the branch finally completes executing (i.e., testing its condition), the next instruction (the next gray box) can be identified and fetched. This figure shows that the resolution time introduces a delay during which the pipeline stalls. The corresponding “bubble” here is two cycles long. (From Skadron, K., “Characterizing and removing branch mispredictions.” PhD thesis, Princeton Univ., June 1999. With permission.)

example of the latter. Jumps are also frequently used to jump around the else clause of an if-then-else construct. For example, the following C code on the left would be translated into the pseudo-assembly code on the right (bz: “branch if zero”):

		; r1 holds cond
if (cond)	bz    r1, L1	; if cond == 0, do else clause
procedure1();	call  procedure 1	; cond != 0
else /* cond == 0 */	jump  L2	; skip else clause
procedure2();	L1: call  procedure2	; cond == 0
x = x + 1;	L2: add  r20, #1, r20	; r20 holds x

As with branches, some time is required to determine jump targets. Direct jumps can be resolved early with proper hardware in the fetch stage to extract the jump target from the instruction, or the targets can be predicted (e.g., using a branch target address cache—see section on “Branch Target Address Caches”). Indirect jumps generally cannot be resolved early, and instead must proceed through the pipeline in order to read their target from the register file, just like any other instruction. Fortunately, their targets can also be predicted. Prediction of indirect jumps is an active research topic [2–5], but is beyond the scope of this treatment of branch prediction. Return instructions are a special case of indirect jumps, and are easily predicted using a simple structure known as a return-address stack [6,7].

The term “branch” is often used to refer to any type of control-flow instruction, giving us not only conditional branches but also direct and indirect (unconditional) *branches* instead of *jumps*. But the term *branch* is best reserved for conditional branches, because control truly “branches” at such instructions, and unconditional control-flow instructions are best called *jumps*.

**FIGURE 6.15** Pipeline behavior with branch prediction. In this diagram, the branch’s outcome is predicted. Immediately in the next cycle, subsequent instructions are fetched and executed speculatively (black boxes). If the prediction is correct, the speculative instructions do useful work and the bubble has been eliminated. If the prediction is incorrect, the speculative instructions are squashed. (From Skadron, K., “Characterizing and removing branch mispredictions.” PhD thesis, Princeton Univ., June 1999. With permission.)

### Why Is It Needed?

Branch prediction is necessary because branches are frequent, 15–25% of instructions in a typical program. Without prediction, the pipeline would stall for each branch’s resolution (refer again to Fig. 6.14) and impose a substantial performance penalty. Even if the processor could issue only one instruction per cycle, and branch resolution stalled the pipeline for only one cycle, this would impose a performance penalty of 15–25%. But today’s pipelines are substantially longer (to permit faster clock speeds) and wider (to exploit instruction-level parallelism or ILP), making the penalties much more severe in terms of wasted instruction-issue opportunities. Every additional stage in the pipeline between fetch and execute adds a cycle to the branch resolution delay. In addition, in today’s wide-issue “superscalar” pipelines, the penalty is equal to the resolution delay times the issue width. The minimum resolution delay in the Compaq<sup>1</sup> Alpha 21264—a four-wide superscalar processor—is seven cycles [8], and the minimum resolution delay in the Intel Pentium<sup>2</sup> Pro—a three-wide superscalar organization—and its successors is eleven cycles [9]. The corresponding penalties are 28 and 33 instruction-issue slots. Of course, programs often do not exhibit enough ILP to use the full issue width all the time, so the actual penalties are not quite so severe. On the other hand, the resolution delays just specified are only the minimum delays. The out-of-order nature of many high-performance processors’ execution engines means that instructions may spend an arbitrary amount of time in decoupling buffers, and this makes the pipeline seem longer and exacerbates the branch resolution delays. A correct branch prediction eliminates these stall cycles. A further problem

is that mispredictions limit the processor's ability to build up a large window of instructions over which to expose ILP.

With the misprediction penalty so high in terms of wasted instruction-issue opportunities, not only is branch prediction necessary, but the highest possible prediction accuracy is necessary in order to minimize stall cycles and maximize the processor's ability to exploit ILP.

## Software Techniques

Branches can be predicted or otherwise managed by both software and hardware techniques. This section focuses on software techniques, and the section on "Hardware Techniques" focuses on hardware techniques.

### Branch Delay Slots

One early software technique that was able to eliminate the need for prediction in early processors is the *branch delay slot*. Instead of predicting the branch's outcome, the instruction-set architecture can be defined so that some number of instructions following a branch execute regardless of the branch's outcome. These instruction positions are called delay slot(s) and must be filled with instructions that are safe to execute regardless of the outcome of the branch, or with *nops* (but nops do no useful work). Instructions to fill the delay slot might come from positions that preceded the branch in the original code schedule but can safely be reordered, for example. Consider the sequence of code:

1. `add r1, r2, r3`
2. `add r4, r5, r6`
3. `bnez r6`
4. (delay slot)

Instruction 1 can safely be moved into the delay slot, because doing so violates no data dependencies. Instruction 2, of course, cannot be moved into the delay slot, because it computes the value of `r6` that the branch then examines. More aggressive techniques can analyze instructions from after the branch, identify a safe instruction, and hoist it into the delay slot. A more thorough treatment of branch delay slots and associated techniques can be found in [10].

Unfortunately, delay slots have drawbacks. Even the most aggressive techniques still leave some delay slots unfilled, wasting instruction-issue opportunities. Delay slots also have the problem that they expose processor implementation details that might change. Current instruction sets that use delay slots were defined when processors issued instructions in order, one at a time, and pipelines were short. The branch resolution delay was hence just one cycle and the corresponding penalty was only one instruction issue slot, so these instruction sets defined branches to have a single delay slot. Examples include the MIPS<sup>3</sup> [11] and SPARC<sup>4</sup> [12] instruction sets. Yet, later implementations made the pipeline longer and issued multiple instructions per cycle. This meant that the resolution delay corresponded to many issue slots, even though the number of delay slots was still fixed by the instruction set at one instruction. In addition, with multiple issue, a bundle of instructions being considered for issue in any particular cycle might consist of several instructions following a branch. Exactly one of these—the delay slot—must be issued unconditionally, while the others are control-dependent on the branch and their execution depends on the branch outcome. For these reasons, later instruction sets like Alpha AXP [13] do not include delay slots.

### Profiling and Compiler Annotation

An alternative software technique is to *profile* the program's behavior by gathering data about how individual branches behave. This involves gathering data while the program is running about its branches' behavior. This data can then be fed to a second compilation pass, which annotates the branches to indicate

<sup>4</sup>SPARC International, Inc., Santa Clara, California.

the predominant direction. The hardware then predicts each branch according to the annotation. So for example, a branch that is taken 80% of the time and not taken 20% of the time would be annotated *predict-taken*. More sophisticated profiling and compiler analysis can even make multiple copies of segments of code so that the branches therein have more consistent behavior, or uncover branches whose behavior is correlated and thus capture some of the same behavior as global-history prediction. This is described by Young and Smith in [14].

## Predication

A third technique is *predication* or *if-conversion*, in which the branch is removed and instructions from both the taken and not-taken paths can be executed simultaneously. This eliminates the need to predict the branch, and converts code that was control-dependent into code that is data-dependent on the branch condition. This defers the dependence to the execution core and permits fetching to continue without risk of rollback due to mispredictions. If done judiciously and execution from the two paths is properly balanced, if-conversion can be done without any performance penalties. Correctness is ensured by modifying the instructions that were once controlled or “guarded” by the if-converted branch so that they can only commit if the branch condition would have permitted it.

If-conversion is accomplished in one of two ways. In *full* predication, each individual instruction is guarded by a condition. This *predicate value* is specified as a third operand register, usually from a dedicated register file. Clearly, this requires instruction-set support in every instruction. In *partial* predication, on the other hand, there is no support for guarding predicates. Instead, predication is accomplished using *conditional move* instructions (CMOVs), which can simply be added to retrofit to existing instruction sets. One branch path is executed UNCONDITIONALLY. The results for the other path are computed into temporary registers and then moved into their final destination with CMOVs. The CMOV only completes if the specified condition (the branch condition) holds true. The following code sequence gives an example:

<u>Original code</u>	<u>Full predication</u>	<u>Partial predication</u>
if (cond)	pdef cond, p	add a, b, x
x = a + b;	add a, b, x(p)	cmov a, x (cond)
else	mov a, x (!p)	mul x, x, y
x = a;	mul x, x, y	
y = x * x;		

The “pdef” instruction defines a predicate; the condition is evaluated and the result placed in p. In all cases, “y = x \* x” gets the correct value of x because y is data-dependent on x and can only use x once its final value is assigned. The final value of x, in turn, is either control-dependent (original code) or data-dependent (predicated code) on cond. Although in this example, the partially-predicated sequence is shorter, partial predication has two drawbacks. It requires a CMOV instruction for each destination register on the path being predicated, and each destination register requires a temporary register [15].

Research by Mahlke et al. [16] has shown that predication substantially reduces both the number of branches executed as well as the branch misprediction rate. Nevertheless, resource constraints mean that not all branches can be predicated, and so predication still requires the presence of branch prediction. This brings us to the hardware techniques, which can be used alone or in conjunction with the software techniques just described.

## Hardware Techniques

### Static Techniques

The simplest hardware technique is to simply stall after every branch until its outcome is known. As described above, the consequent delays lead to untenable performance penalties. A better yet still simple technique is to statically predict all branches to be either taken or not taken. A static not-taken policy is the easier of the two, because it corresponds to sequential execution. This eliminates the need for the

fetch engine to identify which instructions are branches or to compute branch targets. Unfortunately, in most programs more than half of branches are taken [17], making the performance of static-not-taken usually quite poor. On the other hand, a static taken policy either requires the fetch engine to identify which instructions are branches and immediately identify their taken targets, or requires some delay while instructions are decoded and the target is computed.

A third policy takes advantage of the fact that backward conditional branches almost always correspond to loops, which tend to iterate multiple times, so these branches are likely to be taken. Non-backward branches, on the other hand, are less biased. Hennessy and Patterson [10] found that 85% of backward branches are taken while only 60% of forward branches are taken. This suggests a static policy of *backwards-taken*, *forwards-not-taken*, or BTFNT. The problem of computing branch targets remains.

These policies were described by Smith [17] along with the core, bimodal dynamic prediction technique described in the section on “Bimodal Prediction.” Another seminal paper from this era is the exploration of branch predictor and branch target address cache design choices by Lee and Smith [18]. Both papers also survey the earliest literature on branch handling.

### Branch Target Address Caches

Not only static techniques, but in fact all branch-prediction techniques have the problem that on a predicted-taken branch, the branch’s target must be computed. This requires extracting the offset field from the branch instruction and adding it to the PC; tasks which typically cannot be performed until the instruction-decode stage. If this is the case, some stall cycles result, called a “branch-taken bubble.” A second type of predictor—a branch target predictor—can eliminate this problem. In its simplest form, this is simply a small on-chip memory in the fetch stage that serves as a table of recently seen branches, a *branch target address cache* or BTAC [19,20]. (The BTAC is also often referred to as a *branch target buffer* or BTB, but this latter term is too heavily overloaded.) The BTAC is indexed with the branch’s address (in other words, the PC—program counter—used to fetch the branch). It may be direct-mapped or associative, and tagged or not tagged. Omitting tags reduces cost, but then a BTAC miss cannot be identified, the predicted-taken branch will use the wrong target, and this will not be discovered until the branch resolves. For this reason, BTACs are best tagged.

The dynamic hardware schemes described later in this section maintain tables in which they track state about conditional branch directions. These direction-prediction tables are often indexed using the branch address. Because the BTAC table is also indexed by branch address, it may be convenient with these dynamic schemes to store the direction-prediction information in the BTAC along with each branch’s target. Aside from the convenience of integrating these different sources of information into one table, this confers the advantage that if the BTAC is tagged, any branch prediction state stored in the BTAC is also tagged. While some processors use this organization, Calder and Grunwald [21] point out that many branches are not taken and hence do not require the BTAC to store a target. Decoupling the direction-prediction state from the target-prediction state therefore permits a smaller BTAC. It also improves flexibility, as some predictors, such as global-history predictors (see the section on “Two-level Prediction”) do not keep a one-to-one mapping between branch addresses and direction-prediction entries.

Instead of a BTAC, the processor might employ a *branch target instruction cache*, which stores some actual instructions from the branch target rather than merely the target address. This replicates quite a bit of state from the instruction cache, so this organization is rarely seen, although it does appear in the Motorola<sup>5</sup> PowerPC<sup>6</sup> G4 [22], for example.

The BTAC can also be integrated with the instruction cache. Each cache line can simply store the target address of one or more of its branches in case that branch is predicted taken. Alternatively, the I-cache can implement a *next-line* predictor [23]. Each cache line now stores the index of the next cache line to be fetched (and also the set if the cache is associative) [24]. If no branches are taken in the current line, the next-line address will be the next sequential address. If there is a taken branch, the next-line address

will be the appropriate target address. As branches change their taken/not-taken behavior, this next-line address is updated accordingly. The next-line predictor is, therefore, a combination of the functionality of a BTB and a bimodal predictor (see the section on “Bimodal Prediction”). If a more sophisticated direction predictor is present, it overrides the next-line predictor. One motivation for using such an organization is to permit a larger, slower, but more accurate direction predictor that may not be able to be accessed in a single cycle. The Alpha 21264 takes such an approach [25], using as its slower but more accurate direction predictor the hybrid predictor described in the section on “Hybrid Prediction.”

### Pipeline Issues

In the most efficient organization, both the BTAC and the branch direction predictor are consulted during the fetch stage as shown in Fig. 6.16. In this way, the PC can be updated immediately and the processor can fetch from the appropriate location (taken or not-taken) in the next cycle. This avoids introducing pipeline bubbles unless there is a BTAC miss or a branch misprediction.

Unfortunately, some problems occur with probing the branch-prediction hardware in the fetch stage. One concern is the branch-predictor and BTAC lookup times. These tables must be fast enough, and hence small enough, to permit the lookup to complete and the PC to be updated within a single cycle. Otherwise the fetch stage falls behind. Current processors use predictors as big as 32 kbits, but Jiménez et al. [26] argue that the feasible predictor size for single-cycle access will *shrink* in the coming years. The reason for this is that even though the feature size on a processor die continues to shrink with Moore’s law [27], electrical RC delays are not shrinking accordingly, and hence wire delays are not shrinking as fast as logic delays. As feature size shrinks, large structures therefore seem to be getting relatively *slower*.

Another problem is that in a typical organization, the fetch stage cannot determine whether the instructions being fetched from the instruction cache contain any branches; that information must wait until the instructions are decoded. Several solutions are available. The first technique is for the instructions to be “pre-decoded” before they are installed into the instruction cache to indicate which instructions are branches. The predictor structures can then be indexed using the actual addresses of the branches. Note that this means either that the predictor must be multi-ported to cope with fetch blocks that contain more than one branch, or the predictor can only predict one branch at a time. This is not necessarily a major restriction, since if the predicted result is not-taken, the remaining instructions in

**FIGURE 6.17** A schematic for a bimodal predictor. “Baddr” is the branch address or PC, which is used to index the PHT (pattern history table), select the corresponding two-bit counter, and make a prediction of taken or not-taken.

the fetch block after the branch are still valid and can still be passed on to decode. The second solution is for the branch predictor to just predict fetch-block successors instead of specific branches. In this case, the predictor simply predicts whether the next fetch block will be sequential (not-taken) or non-sequential (taken, in which case the target supplied by the BTAC is used). This is slightly better than the first choice, because it eliminates the need for pre-decode bits and can fetch past more than one not-taken branch in a fetch block. It does require the decode stage to identify how each branch in a fetch block was implicitly predicted. The third solution is for the BTAC and branch predictor to be indexed with the address of every instruction in the fetch block. Hits in the BTAC indicate which instructions are branches, and only the corresponding direction predictions are then used. The problem with this approach is that it requires as many ports into the BTAC and branch-prediction structures as there are instructions in the fetch block. These are the basic choices, although many variations and improvements have been proposed, e.g., [24,28–30].

### Bimodal Prediction

The simplest dynamic technique, introduced by Smith [17], is to maintain a small, on-chip memory with a table of saturating counters that is indexed by branch address. The saturating counters—typically two bits each—simply remember the predominant direction of previous outcomes for that branch. A schematic for a bimodal predictor appears in Fig. 6.17. As mentioned, the table—usually called the *pattern history table* or PHT—although logically a distinct entity, might actually be implemented as a unified structure with the BTAC. This prediction scheme goes by different names, often simply “two-bit prediction,” but recent literature has often referred to it as “bimodal” prediction to distinguish it from other more sophisticated schemes that also use two-bit saturating counters.

Each time a branch resolves, its corresponding counter is incremented if the branch was taken, and decremented if not. Incrementing or decrementing has no effect if the counter is already at its maximum or minimum value, hence the term “saturating” counter and the name “bimodal.” In the simplest case of a one-bit counter, the only possibilities are values of 0 and 1 and the predictor simply remembers the last outcome for each branch. In the case of two-bit counters, values of 00 and 01 correspond to strongly not-taken and weakly not-taken, and values of 10 and 11 corresponding to weakly taken and strongly taken. Two-bit counters give better performance because they exhibit some hysteresis that makes them less sensitive to infrequent occurrences of outcomes in the non-dominant direction. A state-transition diagram for the most common two-bit counter configuration appears in Fig. 6.18. Other configurations [18,31] are possible, however, for example, regardless of its current state, the counter might reset to 00 on a not-taken branch.

As an example of how two-bit counters improve over one-bit counters, recall that a loop branch will normally be taken. When the loop exits, a one-bit counter will only remember that most recent direction (not taken), even though the predominant direction is “taken.” When this same loop is encountered again, and the loop branch will once again be taken until the loop exits, the first prediction with a one-bit counter will be “not taken.” A two-bit counter, on the other hand, only changes its state from 11 to 10 upon loop exit, and still predicts taken when it returns to the loop, thus eliminating a misprediction compared to the one-bit counter.

FIGURE 6.18 The state-transition diagram for a saturating two-bit counter.

FIGURE 6.19 A schematic for a PAg local-history predictor. The branch address is used to index the table of per-branch histories (the BHT), select the appropriate history, and then this history is used to index the PHT.

Wider counters have been considered [17] but confer little benefit and take longer to adjust to a change in a branch’s behavior.

The size of the PHT is of course not infinite, so the ideal of one entry per branch may not be realized. The table is indexed by the branch address modulo the table size, so some branches may collide. If these branches are biased in the same direction this is harmless, but if not, they will interfere with each others’ attempts to update the counter, and these *destructive PHT conflicts* will lead to mispredictions. Sources of mispredictions are discussed in the section on “Sources of Misprediction.”

## Two-Level Prediction

Bimodal prediction can be improved in two ways, both of which explicitly track prior branch outcomes and were introduced by Yeh and Patt. *Local-history* prediction [32] maintains a table of per-branch histories. Instead of tracking each branch’s predominant direction, this *branch history table* or BHT tracks explicit history in order to detect patterns. For example, a local history can detect patterns like TNTN... that confound simple saturating counters. The predictor still keeps a PHT of two-bit counters, but these are now indexed using the local history pattern, and the counters now learn outcomes for each history pattern. A schematic of a local history predictor appears in Fig. 6.19. One apparent problem with local-history prediction is that it would seem to require two serial lookups: first the BHT to obtain the history pattern, then the PHT to obtain the actual prediction. This problem is solved by caching the most recent PHT value for a given BHT entry as an extra field in the BHT. The next time that BHT entry is indexed, it provides both the current history and the cached prediction. Fetching proceeds with that cached prediction while the PHT is probed with the history pattern. The PHT result overrides the cached result, so if the PHT disagrees with the cached prediction, the pipeline is flushed from the point of the “mispredicted” branch.

*Global-history* prediction [33] on the other hand, keeps a single history register—the global branch history register or GBHR—into which all branch outcomes are shifted, as seen in Fig. 6.20. It might seem that intermingling outcomes from different branches simply produces noise, but instead global-history

**FIGURE 6.20** A schematic for a GAg global-history predictor. The global history of recent branch outcomes, contained in the global branch history register (GBHR) is used to index the PHT.

prediction is extremely effective. The reason is that global history exposes correlation among branches (and hence these predictors are also called *correlating* predictors). Consider the following sequence of code.

```

B1:  if (x)
      ...
B2:  if (y)
      ...
      z = x && y;
B3:  if (z)
      ...

```

Even if B1 and B2 are entirely unpredictable because  $x$  and  $y$  have very random behavior, B3 can be predicted with *100% accuracy* if the outcomes of B1 and B2 are known, because the outcome of B3 is entirely correlated with the outcomes of B1 and B2. Global history is an admittedly crude way to expose this sort of correlation, because the GBHR also contains outcomes from other branches that provide no useful information. Yet as the section on “Comparison of Hardware Prediction Strategies” shows, global history is quite effective, and Evers et al. [34] have shown that many programs contain substantial degrees of correlated branch behavior. Unfortunately, no one has come up with a practical hardware technique for exposing correlation while avoiding the noise that unrelated branches introduce into the GBHR.

Both the local-history and global-history predictors described above have the problem that different branches may see the same prior history. All branches that see the same history will map to the same PHT entry. Especially with global prediction, equivalent history does not always mean the branches will behave the same way. To reduce the consequent destructive PHT conflicts, Pan, So, and Rahmeh [35] point out that bits from the branch address can be combined with the history bits in order to provide some degree of anti-aliasing—see Fig. 6.21, for example. The simplest technique is to concatenate the two bit sources. For  $N$  bits of history and  $M$  bits of branch address, this creates a configuration where each  $M$ -bit address pattern has its own  $2^N$ -entry PHT.

For a fixed table size and hence a fixed number of bits in the index, this necessitates a reduction in the number of history bits, so a balance must be found between the added prediction capability provided by history bits and the anti-aliasing capability provided by address bits. This balance is sensitive to the table size. In a study of the SPECint95 benchmarks [36], Skadron, Martonosi, and Clark [37] find that as a general rule of thumb, both global- and local-history predictors should use at least 6–7 bits of branch address, regardless of predictor size. Predictors with more aggressive anti-aliasing techniques, e.g., the bi-mode predictor of Lee, Chen, and Mudge [38], will need fewer address bits.

To classify the different possible two-level predictor organizations, Yeh and Patt [33,39] developed a naming scheme that uses three letters to characterize the different organizational choices. The first letter, G, P, or S, indicates the type of history, global, per branch (i.e., local), or per branch set. The last choice

**FIGURE 6.21** A schematic for a GAs global-history predictor.  $N$  global history bits are concatenated with  $M$  bits from the branch address to form the PHT index.

refers to a predictor that explicitly allocates groups of branches to particular BHT entries, and is only feasible with extensive profiling or compiler support and hence has received little study. Skadron, Martonosi, and Clark [37] added a fourth type, M, to this naming scheme to describe predictors that track a combination of global and local history. The second letter, A or S, indicates whether the PHT is adaptive, using a finite state machine based on saturating counters, or fixed, using statically assigned directions (a profiling pass might determine the best PHT value for each entry); almost all predictors proposed or under study, however, are A—adaptive. The third letter, g, s, or p, indicates the PHT organization. The PHT might be indexed purely by history (g); or indexed using some concatenated branch address bits, making it set-associative (s); or the predictor might have a separate PHT for each branch (p, for per-branch). This last choice eliminates aliasing among branches but is prohibitively large for all but small history sizes, and is therefore mainly of theoretical interest. A pure global-history predictor like that in Fig. 6.20 is, therefore, a GAg predictor and a pure local-history predictor like that in Fig. 6.19 is a PAg predictor. If either of these concatenate some address bits into the index, like the global-history predictor in Fig. 6.21, they become GAs or PAs predictors. Note that the GAs predictor has also sometimes been referred to as *gselect* [40]. Finally, a predictor that uses both global and per-branch history, such as the bi-mode predictor, would be an MAg or MAs predictor [37]. As for specifying the specific configuration of a predictor—how many bits, how many entries, etc.—so many notations are involved that it is better to just be explicit.

An alternative anti-aliasing approach is to XOR the history string and address string together; this approach, introduced by McFarling [40], is called *gshare*. This avoids the need to use a shorter history string—both strings can be as long as the index. Recent data by Sechrest, Lee, and Mudge [41], however, suggest that *gshare* confers little benefit over GAs.

Two-level prediction can seem like magic, especially global-history prediction. But it operates on the same principle as compression; a predictable sequence is also compressible. Indeed, two-level prediction is a simplified version of a Markov model, the same principle that underlies the *prediction by partial matching* (PPM) compression scheme [42].

### Hybrid Prediction

Because some branches do benefit from global history and others do not, McFarling [40] proposed *hybrid* branch prediction. Several different organizations have been proposed [43–45], but the common idea is to operate two different predictors in parallel, and for each branch select which predictor’s output to actually use in making the prediction. The selector is itself a predictor and can be any of the structures described above, but the selector tracks predictor successes rather than branch outcomes. For each branch, the selector attempts to learn which predictor component is more effective. Figure 6.22 shows a high-level schematic of a hybrid predictor’s organization. Note that both predictor components and the selector can all be accessed in parallel to minimize lookup time.

The Compaq Alpha 21264 [25] uses a hybrid predictor comprised of 12-bit GAg and 10-bit PAg predictors. The PAg component has a 1 K-entry BHT and, because it uses only history bits in indexing

**FIGURE 6.22** A schematic for a hybrid predictor. “Pred1” and “pred2” are configured as regular, standalone branch predictors (they might be a global-history and a local-history component, for example), but both components make a prediction and the selector then chooses one component prediction (via the multiplexor or “mux”) to use as its final prediction. The selector is a predictor too, but tracks component outcomes rather than branch direction outcomes.

the PHT, the PHT is also 1 K entries. An unusual aspect of the PAg component is that it uses three-bit instead of two-bit saturating counters in order to achieve a stronger bias once the predictor has trained. The selector is also a 12-bit GAg predictor, but its PHT tracks which component has been more successful for each branch, rather than which direction the branch should take.

Hybrid prediction has also been called “tournament,” “competitive,” and “combining” branch prediction.

### Other Issues in Predictor Organization

The preceding sections have described the basic predictor organizations. Because prediction accuracy so strongly underpins processor performance, branch prediction remains an active area of research and a wealth of additional organizations have been proposed, primarily focusing on reducing mispredictions due to destructive aliasing. Interested readers should consult recent proceedings of the symposia and conferences in the list of works cited.

It is worth noting, however, that researchers have also considered how to adapt branch prediction to wider-issue machines. Such a machine must fetch past multiple, possibly-taken branches in order to exploit the wider fetch width. Otherwise the processor becomes fetch-bottlenecked and its effective width is restricted by the average basic block size.

Yeh, Marr, and Patt [29] describe a different branch address cache that learns segments of the control-flow graph and, in conjunction with a banked instruction cache, can fetch several blocks from non-contiguous cache lines in a single cycle. Conte et al. [28] describe a *collapsing buffer* that can also fetch past branches that are taken but whose target is in the same fetch block. Reinman, Austin, and Calder [46] decouple branch prediction from fetch, allowing the branch predictor to run ahead of fetch when possible, and they predict the length of fetch blocks so that not-taken branches do not unnecessarily limit fetching. The most aggressive proposal is the *trace cache* [30] of Rotenberg, Bennett, and Smith, which dynamically collapses noncontiguous fetch streams into contiguous *traces* that are stored in the trace cache and, which appears in the Intel Pentium® 4 [47] and the HAL Sparc64 V [48].

### Sources of Mispredictions

To better understand the behavior of branch predictors, it is helpful to examine some of the reasons a misprediction might occur. These reasons can be broken down into two broad categories: behavioral and structural. Behavioral mispredictions stem from the intrinsic behavior of a branch and are independent of the predictor’s organization. Any irregular or random behavior by a branch will inhibit its predictability.

Structural mispredictions, on the other hand, stem from properties of the predictor's hardware organization. The major structural sources of mispredictions are described below and come from [37].

### **Destructive PHT and BHT Conflicts**

All predictors that track state can suffer when unrelated branches map to the same predictor entry and interfere with each others' state. In the predictor's PHT or in a hybrid predictor's selector PHT, destructive conflicts arise when branches map to the same 2-bit PHT counter and these branches go in opposite directions. In the BHT of a local-history predictor, destructive conflicts arise when branches map to the same history entry and hence the history of one branch displaces that of another branch. Note that *constructive* conflicts can also occur in all these structures when—for reasons of either luck or correlated behavior—the state of one branch causes a correct prediction by other branches. This means the expected gain from eliminating conflicts would eliminate both destructive and constructive conflicts, but the destructive behavior usually outweighs the constructive behavior.

### **Training Time**

Because dynamic predictors work by recognizing patterns of branch behavior, they take time to train. The training time comes from two sources. First, the predictor must see enough branches to observe any patterns that exist. Second, the predictor must reach steady state. Consider the simple pattern TN,TN... in a 6-bit history. After this branch has been seen twice, the history will contain xxxxTN, where "x" signifies that these history bits contain a random value. Unless by sheer luck the bits in the "xxxx" portion happen to be TNTN, this pattern is a transient that will not be seen again. This branch must therefore be seen four more times before the history is fully initialized. In addition, for both types of training, a pattern must be seen often enough not only to initialize the branch history, but also to put the corresponding counters in the PHT into the proper state. In the TN,TN... example and assuming two-bit counters in the PHT, this means that the history TNTNTN must be seen twice in order to ensure that the two-bit counter has crossed the threshold. (The counter's initial value might have been 00, but the correct prediction is T.) The larger the saturating counters, the longer this component of the training time.

The predictor must train not only when a program first starts executing, but must also retrain after every context switch and also when the program's behavior changes, either because it enters a new phase, or the nature of its input changes, etc.

### **"Wrong" Type of History**

Mispredictions can also occur because the predictor does not track the most useful type of history—global or local—for the branch in question. This has been called *wrong* history, even though it does not imply that the actual history bits contain any invalid information. Unfortunately, most programs have some branches that do well with global history *and* some branches that do well with local history. A predictor that only tracks one or the other type of history therefore penalizes some branches in each program. Evers et al. showed this to be important in [34]. Skadron, Martonosi, and Clark [37] found wrong-history mispredictions are especially severe in global-history predictors, comprising 35–50% of the total misprediction rate.

### **History Length**

Mispredictions might also arise even if the predictor tracks the correct type of history but it uses too short a history. For example, a history length of only two bits may not capture the full behavior of a pattern longer than 2 bits. Consider the pattern TNNN,TNNN.... A two-bit local history will learn that TN → N and this is always correct. But the problem arises for the pattern NN. The predictor will first learn NN → N, but on the fifth occurrence of the branch, this will cause a misprediction. On the other hand, there exist longer patterns for which short history is still sufficient. Consider two bits of history and the pattern TNNTT,TNNTT.... Although the overall pattern is longer than 2 bits, none of the distinct sub-patterns (TN, NT, and TT) are longer than two bits.

Alternatively, the history can also be too *long*. The problem here is that the history may contain many bits that are entirely uncorrelated with the behavior of the branch to be predicted. This means that every

time this branch is seen, those bits may have a different value, and the predictor may potentially have to train on all possible combinations of those unrelated bits. This has the effect of smearing a particular branch's predictor state across a large portion of the PHT. In the absence of conflicts, this should, however, only be a problem for global history. This problem might also be called a training-time misprediction and was discussed by Evers et al. in [34].

### Update Timing

Depending on how the predictor is updated, mispredictions can also arise because the predictor contains *stale* state. If the predictor is not updated until a branch exits the pipeline, information about that branch's behavior does not appear in the predictor while the branch is in flight. Yet later branches that are fetched and predicted before the first branch retires may depend on that first branch's outcome [49]. Consider again the sequence of correlated branches:

```
B1:  if (x)
      ...
B2:  if (y)
      ...
      z = x && y;
B3:  if (z)
      ...
```

In a global-history predictor, if B1 or B2 has not yet resolved, the predictor will use state and hence possibly incorrect global history when looking up the prediction for B3. A similar problem arises in a local-history predictor for branches with repeating patterns.

The solution is to speculatively update the branch history immediately after the branch has been predicted, using the just-predicted value. If the prediction is correct, all subsequent branches see the correct history. If not, the history must be repaired, or the predictor will accumulate bogus history. Fortunately, because all instructions after a misprediction are squashed and re-fetched, subsequent branches still see the correct history. This speculative-update-with-repair scheme therefore gives the illusion of omniscient history update. These mechanisms were first described by Jourdan et al. [50], who also found that in two-level predictors, it is only early update of the branch history that matters. Barring destructive conflicts, the prediction for a particular PHT index is fairly stable over time, so the two-bit saturating counters can be updated after the branch resolves.

### Comparison of Hardware Prediction Strategies

Figures 6.23 and 6.24 present the prediction accuracies of conditional-branch directions for static-not-taken, static-taken, BTFNT, bimodal, GAs, PAs, and hybrid predictors for the SPECint95 benchmarks [36] and for two different sizes: a small predictor configuration of 8 kbits, and a large configuration of 64 kbits. The specific configurations are presented in Table 6.2 and 6.3. Of course, static predictors have no size, so the data for these is simply replicated in both graphs. The configurations for GAs, PAs, and the hybrid predictor are taken from Skadron, Martonosi, and Clark [37], which explored the different possible combinations of history bits, address bits, and, for the hybrid predictor, different possible sizes of the three structures.

The data was gathered using a modified version of the simple, instruction-level branch-predictor simulator from SimpleScalar version 2.0 [51]. All the benchmarks were compiled using gcc version 2.6.3 for the SimpleScalar research instruction set (PISA), and with optimization set at `-O3`—funroll-loops (note that `-O3` includes inlining). Simulation captures all user-level behavior, including libraries, but cannot capture any behavior in the kernel due to system calls. Data was gathered using the SPEC reference inputs. Some benchmarks come with multiple inputs, in which case one has been chosen. Go uses a playing level of 50 and a  $21 \times 21$  board with the 9 stone 21 input. M88ksim uses the dhrystone input, gcc the `cccp.i` input, xliip the 9-queens problem, ijpeg the `vigo.ppm` input, and perl the scrabble game.

*Note:* All benchmarks are run for one billion instructions in statistics-gathering mode after the fast-forward interval.

The reference inputs produce very long simulation times—on the order of days even for simpler instruction-level simulations—so the results here are taken for only a representative, 1-billion-instruction segment of each program’s execution. A representative segment is reached by fast-forwarding past unrepresentative initial program behavior using a fast-simulation mode that updates the branch predictor state (so that the predictor state is accurate when the full-detail simulation starts) but does not gather branch-prediction statistics [52]. The fast-forward intervals are taken from [37] and are presented in [Table 6.4](#), along with the observed number of static branch sites and the number of dynamic branches executed for each benchmark.

As can be seen from the data in [Figs. 6.23](#) and [6.24](#), the static schemes all perform terribly, and different schemes are better for different benchmarks, usually by a significant margin. BTFNT is the best static scheme

FIGURE 6.23 Branch prediction accuracies for 8-kbit predictors for the SPECint95 benchmarks. “Bim” is the bimodal predictor, and “Hyb” is the hybrid predictor. Specific configurations appear in Table 6.3.

for five of the eight benchmarks, but performs terribly for m88ksim. (But keep in mind that BTFNT would look better for floating-point codes, which are heavily loop-oriented.) Always-taken is the best static scheme for m88ksim and jpeg, but is the worst for three other benchmarks. This variability of the best scheme among different benchmarks makes it difficult to choose one static scheme to implement.

Among dynamic schemes, bimodal is worse than the more sophisticated dynamic schemes for all except go and vortex. Unlike the other schemes, however, bimodal is less sensitive to predictor size, with a mean difference between the 8-kbit and 64-kbit bimodal predictors of only 0.55%. The reason for this is that the bimodal predictor allocates only one entry to each branch site (i.e., a static branch location in the program), no matter how often that branch executes or how varied its behavior. Most of the programs have a fairly small number of branch sites, and of course the property of locality means that only a subset of these are active at any one time. A 4 K-entry (8 kbit) table is, therefore, sufficient to capture most of the static branch locations, and making the table larger has little effect.

Among two-level predictors, GAS is better than PAs about as often as PAs is better than GAS. As with the static schemes, this variability of the best scheme among benchmarks makes it difficult to choose which scheme to implement. This is strong motivation for use of the hybrid predictor, especially given the observation [34,37] that many programs have some branches that are much better predicted using global history, while other branches are much better predicted using local history. GAS, PAs, and hybrid, however, are all the more sensitive to predictor size than bimodal is. Go and gcc are particularly sensitive

to predictor size, and so are x86 and perl to some extent. The hybrid predictor is the most sensitive to size, because it must allocate the available hardware budget across four tables: the selector's PHT, the global-history component's PHT, and the local-history component's BHT and PHT. Each of these tables is therefore substantially smaller than in a single two-level predictor and therefore suffers more destructive interference. This especially affects the programs with large static branch footprints, like `go` and `gcc`. Yet a hybrid predictor also has an important advantage: in order to better control destructive conflicts, it can dynamically shift which component it uses to make a prediction for each branch.

Note that these results do not include the effects of predication, context switching, operating system behavior, or any profile-guided feedback. All of these effects might change the results.

## Summary

Branch prediction is important because otherwise every branch stalls the fetch engine. Some alternatives exist, like delay slots and predication, but delay slots are not compatible with modern, wide-issue superscalar processors, and predication cannot remove all branches. Static prediction techniques that require no hardware support are also possible, but they are either very simple, or in the case of compiler directives, require instruction-set support. Static techniques also have the drawback that they cannot adapt to changing run-time conditions.

Dynamic branch-prediction techniques have evolved from the simple bimodal predictor to more sophisticated two-level and hybrid predictors that exploit patterns in branch behavior and correlation among branches. Refinements to these techniques, as well as new fetch organizations that permit fetching past multiple branches, continue to be active areas of research.

The massive effort to find better branch-handling techniques is motivated by the severe penalty imposed by mispredictions. Especially with the long and wide pipelines of modern processors, a very small misprediction rate can severely harm performance. Indeed, the fetch bottleneck remains one of the most severe limitations on faster processing, and Jouppi and Ranganathan [53] argue that it may become the most severe bottleneck in future processors, even more severe than memory latency or memory bandwidth.

## 6.4 Network Processor Architecture

*Tzi-cker Chiueh*

### Introduction

The explosive traffic growth on the Internet comes with an ever more demanding requirement on the available bandwidth and thus on the performance of the network devices that move network packets from sources to destinations. In the most general sense, network processors are those that are specifically designed to transport, order, and manipulate network packets as they move through the network. As network protocols are typically structured as a stack of layers, network processors can be classified into *physical-layer*, *link-layer*, and *network-layer* processors, depending on the protocol layer at which they operate. Physical-layer processors are responsible for electrical or optical signal generation and interpretation for

transporting digital bits, whereas link-layer network processors deal with framing, bit error detection/correction and arbitration of concurrent accesses to shared media. Network-layer processors operate on individual packets and determine how to route packets from their senders to receivers in a particular order, and modify their headers or even payloads along the way if necessary. Because the Internet is largely based on the IP protocol, almost all state-of-the-art network-layer processors are designed to process IP packets only. The conspicuous exception is network-layer processors designed for ATM networks. The focus of this paper, however, is exclusively on network-layer processors, which can operate at from Layer 3 to Layer 7 in the ISO/OSI protocol stack model.

In general, three approaches are used for network processor design, which correspond to different design points in the programmability/performance spectrum. The *ASIC* approach takes a full customization route by dedicating specially-made hardware logic to specific network packet processing functionalities. Although this approach gives the highest performance, it is typically not programmable and therefore not sufficiently flexible to support a wide variety of network devices. Consequently, such processors are more expensive and tend to be outdated sooner because they cannot exploit economies of scale to keep up with technology advances. The *general-purpose CPU* approach either takes an existing processor for PCs or embedded systems as it is, or augments it with a small set of instructions specifically included to improve network packet processing. While this approach admits the most programming flexibility, the throughput of these processors is substantially lower than what modern network devices require. The main reason for this lackluster performance is that network device workloads are data movement-intensive, whereas traditional processors are designed to support computation-intensive tasks. The last approach to network processor design, *programmable network processor*, attempts to strike a balance between programmability and performance and achieves the best of both worlds. Instead of using general-purpose instruction set, a programmable network processor defines the set of instruction set primitives for network packet processing from scratch, and exposes these primitives to system designers so that they can tailor the processor to the requirement of different network devices. In the rest of this paper, we will concentrate only on programmable network processors, as they represent the most promising and commercially popular approach to network processor design.

In addition to the basic network processing function such as packet routing and forwarding, modern network processors are tasked with additional capabilities that support advanced network functionalities, such as differentiated quality of service (QoS), encryption/decryption, etc. For network processors that are to be used in *edge* network devices, they may need to perform even higher-level tasks such as firewalling, virtual private network (VPN) support, load balancing, etc. Given an increasing variety of features that network devices have to support, it is crucial for a network processor architecture to be sufficiently general that system designers can build newer functionalities on these processors without causing serious performance degradation. The challenge for network processor design is thus to identify the set of packet processing primitives that is elastic enough to support as many different types of network devices as possible, and at the same time is sufficiently customized so that the performance overhead due to “impedance mismatch” is minimized.

In the rest of this chapter section, we first discuss fundamental design issues related to network processor architecture in the “Design Issues” section, and then describe specific network processor architectural features that have been proposed in the “Architectural Support for Network Packet Processing” section. In the section on “Example Network Processors,” we review the design of several commercially available network processors to contrast their underlying approaches. Finally, we outline future network processor research directions in the “Conclusion” section.

## Design Issues

To understand the network processor architecture, let us first look at what a programmable network processor is supposed to do. After receiving an IP packet from an input interface, the network processor first determines the output interface via which the packet should be forwarded toward its destination. In the case that multiple input packets are destined to the same output interface, the network processor

also decides the order in which these packets should be sent out on the associated output link, presumably according to certain quality of service (QoS) policy. Finally, before the packet is forwarded to the next-hop router, the network processor modifies the packet's header or even payload according to standard network protocols or application-specific semantics. For IP packets, at least the TTL (time-to-live) field in the header must be decremented at each hop and as a result the IP packet header checksum needs to be re-computed. Other IP header fields such as TOS (type-of-service) may also need to be modified for QoS reasons. In some cases, even the packet body need to be manipulated, e.g., transcoding of a video packet in the presence of congestion. In summary, given an input packet, the network processor needs to identify its output interface, schedule its transmission on the associated output link, and make necessary modifications to its header or payload to satisfy general protocol or application-specific requirements.

Fundamentally, a network processor performs three types of tasks: *packet classification*, *packet scheduling*, and *packet forwarding*. Given an input IP packet, the packet classification module in the network processor decides how to process this packet, based on the packet's header and sometimes even payload fields. In the simplest case, the result of packet classification is the output interface through which the input packet should be forwarded. To support differentiated QoS, the result of packet classification becomes a specific output connection queue into which the input packet should be buffered. In the most general case, the result of packet classification points to the software routine that is to be invoked to process the input packet; possible processing ranges from forwarding the input packet into an output interface and a buffer queue, to arbitrarily complex packet manipulation. The design challenge of packet classification is that the number of bits used in packet classification is increasing due to IPv6 and/or multiple header fields, and varying because of application-level protocols such as URL in the HTTP protocol.

The packet forwarding module of a network processor physically moves an input packet from an incoming interface to its corresponding outgoing interface. The key design issues on packet forwarding are the topology of the switch fabric and the switch scheduling policy to resolve output contention, i.e., when multiple incoming packets need to be forwarded to the same output interface. State-of-the-art network devices are based on crossbar fabrics, which are more expensive but greatly reduce the implementation complexity of the switch scheduler. Given a crossbar fabric, the switch scheduler finds a match between the incoming packets and the output interfaces so that the switch fabric is utilized with maximum efficiency and the resulting matching is consistent with the output link's scheduling policy, which in turn depends on the QoS requirement. Algorithmically, this is a constrained bipartite graph matching problem, which is known to be NP-complete. The design challenge of switch scheduling is to find a solution that approximates the optimal solution as closely as possible and that is simple enough for efficient hardware implementation. One such algorithm is iterative random matching [1] and its optimized variant [2].

Traditionally, a FIFO queue is associated with each output link of a network device to buffer all outgoing packets through that link. To support fine-grained QoS, such as per-network-connection bandwidth guarantee, one buffer queue is required for each network connection whose QoS is to be protected from the rest of the traffic. After classification, packets that belong to a specific connection are buffered in the connection's corresponding queue. A link scheduler then schedules the packets in the per-connection queues that share the same output link in an order that is consistent with each connection's QoS requirement. A general framework of link scheduling is packetized fair queuing (PFQ) [3], which performs the following two operations for each incoming packet, *virtual finish time computation*, which is  $O(N)$  computation, and *priority queue sorting*, which is  $O(\log N)$  computation, where  $N$  is the number of active connections associated with an output interface. Intuitively, a packet's virtual finish time corresponds to the logical time at which that packet should be sent if the output link is scheduled according to the fluid fair queuing model. After the virtual finish time for each packet is computed, packets are sent out in an ascending order of their virtual finish time. A nice property of virtual finish time is that an earlier packet's virtual finish time is unaffected by the arrival of subsequent packets. With per-connection queuing and output link scheduling, traffic shaping is automatic if packets are dropped when they reach a queue that is full. As the complexity of both operations in link scheduling depends

FIGURE 6.25 The system architecture of a generic network device such as an IP packet router.

on  $N$ , they cannot readily scale to a large number of QoS-sensitive connections. Although there are various attempts to simplify PFQ, most hardware link schedulers use a much simpler weighted round-robin algorithm, which multiplexes connections on an output link according to weights that are proportional to the connections' QoS requirements.

In addition to the above three types of tasks, a network processor may need to support such higher-level functionalities as security, multicast, congestion control, etc., because more and more intelligence is moved from end hosts to the network. It is not clear what common primitives these high-level functions can share, as comprehensive workload characterization along this line is almost nonexistent. The entire *active network* field [4] is about the development of operating system and network protocols support for *programmable* network devices so that they can perform application-specific operations on an application's packets as they go through the network; however, until now the research on architectural support for active networking is almost nonexistent in the literature.

Figure 6.25 shows the generic architecture of an Internet router, which serves as an instance of a network device that is built on network processor. The line cards are input/output interfaces and are connected to external network links. Line cards typically include hardware for physical-layer and link-layer protocol processing, and a network processor that performs packet classification, queuing and output-link scheduling. The switch fabric controller determines when input packets should be forwarded to their corresponding output interface. The control processor is typically a standard RISC processor and is responsible for non-time-critical tasks such as routing table maintenance and traffic statistics collection and reporting.

## Architectural Support for Network Packet Processing

Given the network device system architecture in Fig. 6.25, in this section we present architectural features that were proposed previously to improve the performance of network processors. But first let's consider the performance requirements of a very high-speed router. Assuming the worst-case scenario, i.e., each packet is 64-byte long, an OC-768 or 40 Gbps network processor needs to handle 80 million packets per second, or one packet every 12.5 ns. Assume further that a packet is processed in a pipeline fashion, i.e., packet classification, packet forwarding, and packet scheduling. Therefore, this 12.5 ns corresponds to the pipeline cycle time, rather than the total packet latency within the network device. In packet classification, multiple memory accesses to the routing/classification table data structure are needed. For a static RAM with 2-ns cycle time, a 12.5-ns cycle time means that the network processor cannot access more than six memory words if the memory system is 32-bit wide. In packet forwarding, the output buffer queue memory should run at 1,250 MHz using a 128-bit-wide interface, because the rule of the thumb is that packet buffers need to operate at four times as fast the line rate. In packet scheduling, even assuming a modest number of active connections, say 1,000, the link scheduler logic needs to perform each primitive operation in virtual finish time calculation within 12.5 ps, or about one CMOS transistor delay.

The above analysis demonstrates that in all three cases, new architecture-level and circuit-level innovations are required to develop a network processor that meets the OC-768 performance goal.

Two basic approaches to speeding up network packet processing inside a network processor are pipelining and parallelization. A deeper pipeline reduces the cycle time of the pipeline and, therefore, improves the system throughput. However, because packet classification, packet forwarding, and packet scheduling each exhibit complicated internal dependencies and sometimes iterative structures, it is difficult to pipeline these functions effectively. Parallelization can be applied at different granularities. Finer granularity parallelism is more difficult to exploit but potentially leads to higher performance gain. In the case of network packet processing, because processing of one packet is independent of processing of another packet, packet-level parallelism appears to be the right granularity that strikes a good balance between performance gain and implementation complexity. Typically, a thread is dedicated to the processing of one packet, and different threads can run in parallel on distinct hardware engines. To reap further performance improvement by exploiting instruction-level parallelism, researchers and companies have proposed to run concurrent packet-processing threads on a simultaneous multi-threading processor [5,11] to mask as many pipeline stalls as possible. Such multithreading processors require the support of multiple hardware contexts and fast context switching.

Compared with generic CPU workloads, network packet processing requires much more frequent bit-level manipulation, such as header field extraction and header checksum computation. In a standard RISC processor, extracting an arbitrary range of bits from a 32-bit word requires at least three instructions, and performing a byte-wide summing of the four bytes within a word takes at least 13 instructions. Therefore, commercial network processors [6] include special bit-level manipulation and 1's complement instructions to speed up header field extraction and replacement, as well as packet checksumming computation.

Caching is arguably the most effective and most often used technique in modern computer system design. One place in network processor design to which caching can be effectively applied is packet classification. Since multiple packets travel on a network connection in its lifetime, in theory each intermediate network device only needs to perform packet classification once for the first packet and reuses the resulting classification decision for all subsequent packets. This corresponds to temporal locality if one treats the set of all possible values of the header fields used in packet classification as an address space. Empirical studies [7,8] show that network packet streams indeed exhibit substantial temporal locality but very little spatial locality. In addition, unlike CPU cache, the classification results for neighboring points in this address space tend to be identical. Therefore, network processor cache can be designed to cache address ranges rather than just address space points, as in standard cache. Chiueh and Pradhan [8] showed that caching ranges of classification address space can increase the effective coverage of a network processor cache by several orders of magnitude as compared to conventional caches that cache individual addresses.

Another alternative to speed up packet classification is through special content-addressable memory (CAM) [13]. Commercial CAMs support ternary comparison logic (0, 1, and X or don't-care). Classification rules are pre-stored in the CAMs. Given an input packet, the selective portion of its packet header is compared against all the stored classification patterns in parallel, and a priority decoder picks the highest priority among the matched rules if there are multiple of them. Although CAM can identify relevant packet classification rules at wire speed, two problems are associated with applying CAM to the packet classification problem. First, to support range match, e.g., source port number 130–202, one has to break a range rule to multiple range rules, each covering a range whose size is a multiple of 2. This is because CAMs only support don't-care match but not arbitrary arithmetic comparison. For example, the range 129–200 needs to be broken down into eight ranges: 130–130, 131–132, 133–136, 137–144, 145–160, 161–192, 193–200, and 201–202. For classification rules with multiple range fields, the need for range decomposition can significantly increase the number of CAM entries required. Second, because CAMs are hardwired memory with built-in width, it cannot easily support matching of variable-length fields such as URL, or accommodate changing packet classification rules after network devices are put into field use.

Finally, because the main task of network devices is to move packets from one interface to another, efficient data movement is of paramount importance. Because most packet buffer memory is implemented in DRAM, it is essential to exploit the fast access mode in modern DRAM chips to keep up with the line rate. In addition, it should support multiple DMA channels to allow multiple data transfer transactions to proceed in parallel without the attention of network processors.

## Example Network Processors

Intel's Internet exchange architecture (IXA) [6] includes an IXE component as the switching fabric, an IXF component for framing and formatting, an LXT component for physical-layer processing, and an Internet exchange processor (IXP) for packet processing. The IXP consists of a StrongARM core, six microengines and interfaces with the SRAM, SDRAM, the PCI bus, and a proprietary bus, the IX bus. The StrongARM core performs such supervisory processing as maintaining the routing table. Each of six microengines is a RISC core augmented with special instructions optimized for network processing such as bit extraction, table lookup, and single-cycle shifting, and with support for hardware multithreading. Each microengine has four program counters that allow four parallel threads to time-share a microengine's data path. There are two banks of single-ported general-purpose registers for ALU operations, and four single-ported transfer registers to read/write SRAM and SDRAM. The IX bus allows the IXPs to interface with IXFs and IXEs, and supports 5 Gbps at 80 MHz.

Agere's PayloadPlus architecture [9] includes a fast pattern processor (FPP), a routing switch processing (RSP), an agere system interface (ASI), and a functional programming language (FPL) for programming the FPP and RSP. The FPP sits between the physical interface and the RSP, and performs packet re-assembly, protocol recognition and associated computation, and calculation of checksums and CRC. The FPP is based on a pipelined and multithreaded architecture. It allocates a thread and a context to process each incoming packet, and operates on one 64-byte block at a time, each in the associated packet's context. To program the FPP, system designers use a declarative programming language, FPL, to specify the set of protocols to recognize and the set of actions to take for each specified protocol. Programs for the FPP are represented as trees, where nodes correspond to pattern recognition functions and leaves as actions. The RSP sits between the FPP and the switch fabric controller, and consists of three VLIW engines: Traffic Management Compute engine that enforces packet discarding policies and maintains queue statistics, Traffic Shaper Compute engine that ensures QoS and CoS for each connection queue, and Stream Editor Compute engine that performs necessary packet modifications. These three engines work on each packet together as a linear pipeline. The ASI interfaces with the host processor for configuration and program download, and in addition coordinates the data movement between the FPP and RSP.

C-Port's digital communications processor (DCP) [10] includes 16 channel processors (CP), five specialized processors, and a 160 Gbps internal bus. Each CP interfaces with the physical link interface, and consists of a RISC core and two serial data processors (SDP). SDPs perform low-level bit manipulation task whereas the RISC core performs such high-level task as packet scheduling and traffic statistics collection. The five specialized processors perform classification table access, packet buffering, routing table look-up, interfacing with the switch fabric, and supervisory processing. C-Port supports a special communications programming interface called C-Ware to simplify system designers' task of programming DCP.

## Conclusion

In this chapter section, we present the set of tasks that a modern network processor needs to perform, describe a set of architectural features specifically designed for network packet processing, and survey several commercial network processor architectures as examples. Most of existing network processors include special instructions to speed up packet processing, and use a parallel multithreaded architecture to exploit multiple levels of parallelism; however, these architectures cannot scale to OC768 link rate and

beyond, and, therefore, further research into network processor architecture is warranted. Here are several research directions that we believe are worth exploring:

- Scalable packet classification mechanism that supports variable-length application-level classification patterns
- Integrated packet scheduling for both switch fabric and output links to achieve per-connection QoS in an input queuing network device architecture
- Novel memory management scheme that exploits the abundant internal bandwidth of intelligent RAM architecture [12] to cost-effectively satisfy the memory bandwidth requirements of terabit links
- Architectural support for active networking and other high-level network functionalities

### 7.1 Introduction

---

Power dissipation limits have emerged as a key constraint in the design of microprocessors, even for those targeted for the high end server product space. At the low end of the performance spectrum, power has always dominated over performance as the primary design constraint; however, although battery life expectancies have shown modest increases, the larger demand for increased functionality and speed has increased the severity of the power constraint in the world of handheld and mobile systems. At the high end, where performance was always the primary driver, we are witnessing a trend where energy and power limits are increasingly dictating the high-level processing paradigms, as well as the lower-level issues related to clocking and circuit design.

Figure 7.1 shows the expected maximum chip power (for high performance processors) through the year 2014. The data plotted is based on the updated 2000 projections made by the International Technology Roadmap for Semiconductors [<http://public.itrs.net>]. The projection indicates that beyond the linear growth period (through the year 2005) there will be a saturation in the maximum chip power. This is ostensibly due to thermal/packaging and die size limits that are expected to kick in during that time frame. Beyond a certain power regime, air cooling is not sufficient to dissipate the heat generated; and, use of liquid cooling and refrigeration causes a sharp increase of the cost-performance ratio. Thus, power-aware design techniques, methodologies, and tools are of the essence at all levels of design.

FIGURE 7.1 Maximum chip power projection (ITRS roadmap).

In this chapter, we first present a survey of some of the most promising ideas in power-aware design at the (micro)architecture level. We base this review on the currently available literature, with special emphasis on relevant work presented at recent architecture conferences and workshops. Where useful, we also refer to prior papers that deal with fundamental issues related to the performance, cost, and scalability of concurrent machine architectures. We show how the fundamentals of machine performance relate to the modern problem of architecting processors in a way that allows them to scale well (over time) in terms of joint power-performance metrics. In this context, we comment on and compare the viability and future promise of several microarchitectural paradigms that seem to be catching on in industry: e.g., clustered super scalars, various flavors of multithreading (e.g., SMT), and chip multiprocessors (CMP).

In Section 7.2, we review the fundamentals of pipelined and vector/parallel computation as they relate to performance and energy characteristics. We also touch briefly on the topic of defining a suitable set of metrics to measure power-performance efficiency at the microarchitecture level. In Section 7.3, we provide a survey of the most promising ideas and approaches in power-aware design at the microarchitecture level, with references to circuit design and clocking issues that are relevant in that discussion. This review is presented in the context of workloads and benchmarks that represent different markets. In Section 7.4, we compare the power-performance outlook of three emerging microarchitectural paradigms in the general purpose processor space: multicluster superscalars, multithreaded processors, and chip multiprocessors. We conclude, in Section 7.5, by summarizing the main issues addressed in this survey paper. We also point to a list of future research items that the architecture community needs to pursue in collaboration with the circuit design community in order to achieve the targets dictated by future cost and performance pressures. In passing, we refer briefly to LPX: a research processor prototype being designed at IBM Watson, to validate some key ideas in power-aware design.

## 7.2 Fundamentals of Performance and Power: An Architect's View

### Performance Fundamentals [1,2]

The most straightforward metric for measuring performance is the execution time of a given program mix on the target processor. The execution time can be written as:

$$T = PL \times CPI \times CT = PL \times CPI \times (1/f) \quad (7.1)$$

where PL is the dynamic path length of the program mix, measured as the number of machine instructions executed; CPI is the average processor cycles per instruction incurred in executing the program mix; and CT is the processor cycle time (measured in seconds per cycle) whose inverse determines the clock

frequency  $f$ . Since performance increases with decreasing  $T$ , one may formulate performance, Perf as:

$$\text{Perf}_{\text{chip}} \sim K_{\text{pf}} \cdot f \sim K_{\text{pv}} \cdot V \quad (7.2)$$

where the  $K$ 's are constants for a given microarchitecture-compiler implementation and for a specific workload mix. The  $K_{\text{pf}}$  value stands for the average number of machine instructions that are executed per cycle on the machine being measured; this is usually referred to as IPC, the inverse of CPI. Performance,  $\text{Perf}_{\text{chip}}$ , in this case is measured in units such as (millions of) instructions per second, or mips. In Eq. (7.2),  $V$  is the chip supply voltage (often written as  $V_{\text{dd}}$ ). As stated below, and in [2,3], the operating frequency is often assumed to be roughly proportional to the supply voltage.

Selecting a suite of publicly available benchmark programs that everybody accepts as being “representative” of real-world workloads is difficult to begin with. Adopting a noncontroversial weighted mix is also not easy. For the commonly used SPEC benchmark suite (see <http://www.specbench.org>) the SPECmarks rating (for each class: e.g., integer or floating point) is derived as a geometric mean of execution time ratios for the programs within that class. Each ratio is calculated as the speed up with respect to execution time on a specified reference machine. This method has the advantage that different machines can be ranked unambiguously from a performance viewpoint, if one believes in the particular benchmark suite. That is, the ranking can be shown to be independent of the reference machine used in such a formulation.

Even if one is able to fix the input workload mix to some known average characteristics, there is usually a large variation in workload behavior across different applications in the mix and in some cases, within even a single application. Thus, even though one can compute an average IPC (or  $K_{\text{pf}}$  in Eq. (7.2)), it is possible to exploit the variations in IPC to reduce average power in architectures where the resources are dynamically adapted to match the IPC requirements (see the subsection “Adaptive Microarchitectures” in Section 7.3).

Let us now discuss the basics of power dissipation in a processor chip.

## Power Fundamentals [2–5]

At the elementary transistor gate (e.g., an inverter) level, total power dissipation can be formulated as the sum of three major components: switching loss, leakage, and short-circuit loss.

$$\text{Power}_{\text{device}} = \frac{1}{2} C \cdot V_{\text{dd}} \cdot V_{\text{swing}} a \cdot f + I_{\text{leakage}} \cdot V_{\text{dd}} + I_{\text{sc}} \cdot V_{\text{dd}} \quad (7.3)$$

where  $C$  is the output capacitance,  $V_{\text{dd}}$  is the supply voltage,  $f$  is the chip clock frequency, and  $a$  is the activity factor ( $0 < a \leq 1$ ), which determines the device switching frequency;  $V_{\text{swing}}$  is the maximum voltage swing across the output capacitor, which in general can be less than  $V_{\text{dd}}$ ;  $I_{\text{leakage}}$  is the leakage current; and  $I_{\text{sc}}$  is the short-circuit current. In the literature,  $V_{\text{swing}}$  is often approximated to be equal to  $V_{\text{dd}}$  (or simply  $V$  for short), making the switching loss  $\sim (1/2)CV^2af$ . Also, as discussed in [3], for today’s range of  $V_{\text{dd}}$  (say 1–3 V) switching loss:  $(1/2)CV^2af$  remains the dominant component, assuming the activity factor to be above a reasonable minimum. So, as a first-order approximation, for the whole chip, we may formulate the power dissipation to be

$$\text{Power}_{\text{chip}} = \frac{1}{2} \left[ \sum_i C_i \cdot V_i^2 \cdot a_i \cdot f_i \right] \quad (7.4)$$

where  $C_i$ ,  $V_i$ ,  $a_i$ , and  $f_i$  are unit- or block-specific average values in the most general case; the summation is taken over all blocks or units  $i$ , at the microarchitecture level (e.g., icache, dcache, integer unit, floating point unit, load-store unit, register files and buses [if not included in individual units], etc.). Also, for the voltage range considered, the operating frequency is roughly proportional to the supply voltage; and

the capacitance  $C$  remains roughly the same if we keep the same design but scale the voltage. If a single voltage and clock frequency are used for the whole chip, the above reduces to

$$\text{Power}_{\text{chip}} = V^3 \cdot \left( \sum_i K_i^v \cdot a_i \right) = f^3 \cdot \left( \sum_i K_i^f \cdot a_i \right) \quad (7.5)$$

If we consider the very worst-case activity factor for each unit  $i$ , i.e., if  $a_i = 1$  for all  $i$ , an upper bound on the maximum chip power may be formulated as

$$\text{MaxPower}_{\text{chip}} = K_V \cdot V^3 = K_F \cdot f^3 \quad (7.6)$$

where  $K_V$  and  $K_F$  are design-specific constants. Note that an estimation of peak or maximum power is important, for the purposes of determining the packaging and cooling solution required. The larger the maximum power, the more expensive is the net cooling solution. Note that the formulation in Eq. (7.6) is overly conservative, as stated. In practice, it is possible to estimate the worst-case achievable maximum for the activity factors. This allows the designers to come up with a tighter bound on maximum power before the packaging decision is made.

The last Eq. (7.6) is what leads to the so-called “cube-root” rule [3], where redesigning a chip to operate at 1/2 the voltage (and frequency) results in the power dissipation being lowered to  $(1/2)^3$  or 1/8 of the original. This implies the single-most efficient method for reducing power dissipation for a processor that has already been designed to operate at high frequency: namely, reduce the voltage (and hence the frequency). It is believed that this is the primary mechanism of power control in the Transmeta chip (see <http://www.transmeta.com>). There is a limit, however, of how low  $V_{\text{dd}}$  can be reduced (for a given technology), which has to do with manufacturability and circuit reliability issues. Thus, a combination of microarchitecture and circuit techniques to reduce power consumption, without necessarily employing multiple or variable supply voltages, is of special relevance in the design of robust systems.

The formulation of performance and power, especially the abstractions expressed through Eqs. (7.2) and (7.4–7.6), can actually be improved quite a bit, based on more rigorous mathematics, backed by experimental evidence collected from real circuit-level simulations. This is reported separately for readers who want to delve into these issue in more detail [33].

## Power-Performance Efficiency Metrics

The most common (and perhaps obvious) metric to characterize the power-performance efficiency of a microprocessor is a simple ratio, such as mips/watt. This attempts to quantify the efficiency by projecting the performance achieved or gained (measured in millions of instructions per second) for every watt of power consumed. Clearly, the higher the number, the “better” the machine is. Dimensionally, mips/watt equates to the inverse of the average energy consumed per instruction. This seems a reasonable choice for some domains where battery life is important; however, strong arguments are against it in many cases, especially when it comes to characterizing higher end processors. Performance has typically been the key driver of such server-class designs and cost or efficiency issues have been of secondary importance. Specifically, a design team may well choose a higher frequency design point (which meets maximum power budget constraints) even if it operates at a much lower mips/watt efficiency compared to one that operates at better efficiency but at a lower performance level. As such,  $(\text{mips})^2/\text{watt}$  or even  $(\text{mips})^3/\text{watt}$  may be the metric of choice at the high end. On the other hand, at the lowest end, where battery-life (or energy consumption) is the primary driver, one may want to put an even greater weight on the power aspect than the simplest mips/watt metric, i.e., one may just be interested in minimizing the watts for a given workload run, irrespective of the execution time performance, provided the latter does not exceed some specified upper limit.

The “mips” metric for performance and the “watts” value for power may refer to average or peak values, derived from the chip specifications. For example, for a 1 GHz ( $=10^9$  c/s) processor, which can complete up to 4 instructions per cycle, the theoretical peak performance is 4000 mips). If the average completion rate for a given workload mix is  $p$  instructions per cycle, the average mips would equal 1000 times  $p$ ; however, when it comes to workload-driven evaluation and characterization of processors, metrics are often controversial. Apart from the problem of deciding on a “representative” set of benchmark applications, there are fundamental questions which persist about how to boil down “performance” into a single (“average”) rating that is meaningful in comparing a set of machines. Since power consumption varies, depending on the program being executed, the issue of benchmarking is also relevant in assigning an average power rating. In measuring power and performance together for a given program execution, one may use a fused metric like power-delay product (PDP) or energy-delay product (EDP) [5,6]. In general, the PDP-based formulations are more appropriate for low-power, portable systems, where battery-life is the primary index of energy efficiency. The mips/watt metric is an inverse PDP formulation, where delay refers to average execution time per instruction. The PDP, being dimensionally equal to energy, is the natural metric for such systems. For higher end systems (e.g., workstations) the EDP-based formulations are deemed to be more appropriate, since the extra delay factor ensures a greater emphasis on performance. The (mips)<sup>2</sup>/watt metric is an inverse EDP formulation. For the highest performance, server-class machines, it may be appropriate to weight the “delay” part even more. This would point to the use of (mips)<sup>3</sup>/watt, which is an inverse ED<sup>2</sup>P formulation. Alternatively, one may use (cpi)<sup>3</sup>.watt as a direct ED<sup>2</sup>P metric, applicable on a “per instruction” basis (see [2]).

The energy\*(delay)<sup>2</sup> metric, or perf<sup>3</sup>/power formula is analogous to the cube-root rule [3], which follows from constant voltage scaling arguments (see previous discussion, Eq. (7.6)). Clearly, to formulate a voltage-invariant power-performance characterization metric, we need to think in terms of perf<sup>3</sup>/(power). When we are dealing with the SPEC benchmarks, one may therefore evaluate efficiency as (SPECrating)<sup>x</sup>/watt, or (SPEC)<sup>x</sup>/watt for short; where the exponent value  $x$  ( $=1, 2, \text{ or } 3$ ) may depend on the class of processors being compared.

Brooks et al. [2] discuss the power-performance efficiency data [sources used are: <http://www.bwrc.eecs.berkeley.edu/CIC/>, <http://www.specbench.org>, *Microprocessor Report*, August 2000, and individual vendor Web sites] for a range of commercial processors of approximately the same generation. In each chart, the latest available processor is plotted on the left and the oldest one on the right. We have used SPEC/watt, SPEC<sup>2</sup>/watt, and SPEC<sup>3</sup>/watt as the alternative metrics, where SPEC stands for the processor’s SPEC95 rating (see definition principles, earlier in this section or in [1]). For each category, such as SPEC<sup>2</sup>/watt, the best performer is normalized to 1, and the other processor values are plotted as relative fractions of the normalized maximum. The data validates the assertion that depending on the metric of choice, and the target market (determined by workload class and/or the power/cost) the conclusion drawn about efficiency can be quite different. For performance-optimized, high-end processors, the SPEC<sup>3</sup>/watt metric seems to be fairest, with the very latest Intel Pentium-III and AMD Athlon offerings (at 1 GHz) at the top for integer workloads; and, the older HP-PA 8600 (552 MHz) and IBM Power3 (450 MHz) still dominating in the floating point class. For “power-first” processors targeted toward integer workloads (such as Intel’s mobile Celeron-333) spec/watt seems to be the fairest.

Tables 7.1 and 7.2 below show the explicit ranking of the processors considered in [2] from a power-performance efficiency viewpoint based on specint and specfp benchmarks. The only intent here is to illustrate the point that we tried to make earlier: that depending on the intended market (e.g., general purpose: server-class, workstation or low-power mobile, etc.) and application class (e.g., integer-intensive or floating-point intensive) different efficiency metrics may be suitable. Note that we have relied on published performance and “max power” numbers; and, because of differences in the methodologies used in quoting the maximum power ratings, the derived rankings may not be completely accurate or fair. As an example, the 33 W maximum power rating for the Intel PIII-1000 processor that we computed from the maximum current and nominal voltage ratings specified for this part in the vendor’s Web page [<http://www.intel.com/design/pentiumiii/datashts/245264.htm>] is higher than that reported in the *Microprocessor Report* source cited previously. Actually, this points to the need of standardization of methods

### 7.3 A Review of Key Ideas in Power-Aware Microarchitectures

In this chapter, we limit our attention to dynamic (“switching”) power governed by the  $CV^2af$  formula. Recall that  $C$  refers to the switching capacitance,  $V$  is the supply voltage,  $a$  is the activity factor ( $0 < a < 1$ ), and  $f$  is the operating clock frequency. Power reduction ideas must, therefore, focus on one or more of these basic parameters. In this section, we examine the key ideas that have been proposed in terms of (micro)architectural support for power-efficiency.

The effective (average) value of  $C$  can be reduced by using: (a) area-efficient designs for various macros; (b) adaptive structures, that change in effective size, latency or communication bandwidth depending on the needs of the input workload; (c) selectively “powering off” unused or idle units, based on special “nap/doze” and “sleep” instructions generated by the compiler or detected via hardware mechanisms; (d) reducing or eliminating “speculative waste” resulting from executing instructions in mis-speculated branch paths or prefetching useless instructions and data into caches, based on wrong guesses.

The average value of  $V$  can be reduced via dynamic voltage scaling, i.e., by reducing the voltage as and when required or possible (e.g., see the description of the Transmeta chip: <http://www.transmeta.com>). Microarchitectural support, in this case, is not required, unless the mechanisms to detect “idle” periods or temperature overruns are detected using counter-based “proxies,” specially architected for this purpose.

Hence, in this paper, we do not dwell on dynamic voltage scaling methods. (Note again, however, that since reducing  $V$  also results in reduction of the operating frequency  $f$  net power reduction has a cubic effect; thus, dynamic voltage scaling, though not a microarchitectural technique *per se*, is the most effective way of power reduction).

The average value of the activity factor  $a$  can be reduced by: (a) the use of clock-gating, where the normally free-running synchronous clock is disabled in selected units or sub-units within the system based on information or predictions about current or future activity in those regions; (b) the use of data representations and instruction schedules that result in reduced switching. Microarchitectural support is provided in the form of added mechanisms to: (a) detect, predict, and control the generation of the applied gating signals or (b) aid in power-efficient data and instruction encodings. Compiler support for generating power-efficient instruction scheduling and data partitioning or special instructions for “nap/doze/sleep” control, if applicable, must also be considered under this category.

Lastly, the average value of the frequency can be controlled or reduced by using: (a) variable, multiple, or locally asynchronous (self-timed) clocks; (b) reduced pipeline depths.

We consider power-aware microarchitectural constructs that use  $C$ ,  $a$ , or  $f$  as the primary power-reduction lever. In any such proposed processor architecture, the efficacy of the particular power reduction method that is used must be assessed by understanding the net performance impact. Here, depending on the application domain (or market), a PDP, EDP, or ED<sup>2</sup>P metric for evaluating and comparing power-performance efficiencies must be used (see earlier discussion in Section 7.2).

## Optimal Pipeline Depth

A fundamental question that is asked has to do with pipeline depth. Is a deeply pipelined, high frequency (“speed demon”) design better than an IPC-centric lower frequency (“brainiac”) design? In the context of this chapter, “better” must be judged in terms of power-performance efficiency.

Let us consider, first, a simple, hazard-free, linear pipeline flow process, with  $k$  stages. Let the time for the total logic (without latches) to compute one answer be  $T$ . Assuming that the  $k$  stages into which the logic is partitioned are of equal delay, the time per stage and thus the time per computation becomes (see [7], Chapter 2)

$$t = T/k + D \quad (7.8)$$

where  $D$  is the delay added due to the staging latch. The inverse of  $t$  determines the clocking rate or frequency of operation. Similarly, if the energy spent (per cycle, per second, or over the duration of the program run) in the logic is  $W$  and the corresponding energy spent per level of staging latches is  $L$ , then the total energy equation for the  $k$ -stage pipelined version is, roughly,

$$E = L \cdot k + W \quad (7.9)$$

The energy equation assumes that the clock is free-running, i.e., on every cycle, each level of staging latches is clocked to enable the advancement of operations along the pipeline. (Later, we shall consider the effect of clock-gating.) Equations (7.8) and (7.9), when plotted as a function of  $k$ , are depicted in Figs. 7.2(a,b), respectively.

As the number of stages increases, the energy or power consumed increases linearly; while, the performance also increases, but not as fast. In order to consider the PDP-based power-performance efficiency, we compute the ratio:

$$\frac{\text{Power}}{\text{Performance}} = (L \cdot k + W)(T/k + D) = L \cdot T + W \cdot D + (L \cdot D \cdot k^2 + W \cdot T)/k \quad (7.10)$$

FIGURE 7.2 Power and performance curves for idealized pipeline flow.

FIGURE 7.3 Power-performance ratio curve for idealized pipeline flow.

Figure 7.3 shows the general shape of this curve as a function of  $k$ . Differentiating the right hand side expression in Eq. (7.10) and setting it to zero, one can solve for the optimum value of  $k$  for which the power-performance efficiency is maximized; i.e., the minimum of the curve in Fig. 7.2(b) can be shown to occur when

$$k(\text{opt.}) = \sqrt{(W \cdot T)/(L \cdot D)} \tag{7.11}$$

Larson [8] first published the above analysis, albeit from a cost/performance perspective. This analysis shows that, at least for the simplest, hazard-free pipeline flow, the highest frequency operating point achievable in a given technology may not be the most energy-efficient! Rather, the optimal number of stages (and hence operating frequency) is expected to be at a point which increases for greater  $W$  or  $T$  and decreases for greater  $L$  or  $D$ .

For real super scalar machines, the number of latches in a design tends to go up much more sharply with  $k$  than the linear assumption in the above model. This tends to make  $k(\text{opt.})$  even smaller. Also, in real pipeline flow with hazards, e.g., in the presence of branch-related stalls and disruptions, performance actually peaks at a certain value of  $k$  before decreasing [3,9] (instead of the asymptotically increasing behavior shown in Fig. 7.2(b)). This effect would also lead to decreasing the effective value of  $k(\text{opt.})$ . (However,  $k(\text{opt.})$  increases if we use EDP or ED<sup>2</sup>P metrics instead of the PDP metric used.)

## Vector/SIMD Processing Support

Vector/SIMD modes of parallelism present in current architectures afford a power-efficient method of extending performance for vectorizable codes. Fundamentally, this is because: for doing the work of fetching and processing a single (vector) instruction, a large amount of data is processed in a parallel or pipelined manner. If we consider a SIMD machine, with  $p$   $k$ -stage functional pipelines (see Fig. 7.4) then looking at the pipelines alone, one sees a  $p$ -fold increase of performance, with a  $p$ -fold increase in power, assuming full utilization and hazard-free flow, as before. Thus, a SIMD pipeline unit offers the potential

FIGURE 7.4 Parallel SIMD architecture.

FIGURE 7.5 Execution pipe utilization component stack across workloads.

of scalable growth in performance, with commensurate growth in power, i.e., at constant power-performance efficiency. If, however, one includes the instruction cache and fetch/dispatch unit that are shared across the  $p$  SIMD pipelines, then power-performance efficiency can actually grow with  $p$ . This is because, the energy behavior of the instruction cache (memory) and the fetch/decode path remains essentially invariant with  $p$ , while net performance grows linearly with  $p$ .

In a super scalar machine with a vector/SIMD extension, the overall power-efficiency increase is limited by the fraction of code that runs in SIMD-mode (Amdahl's Law).

### Clock-Gating: Power Reduction Potential and Microarchitectural Support

Clock-gating refers to circuit-level control (e.g., see [10,17]) for disabling the clock to a given set of latches, a macro, a bus or an entire unit, on a particular machine cycle. Microarchitecture-level analysis points to opportunities of power savings in a processor, since idle periods of a particular resource can be identified and quantified. Figure 7.5 depicts the execution pipe utilization of the various functional units (e.g., fixed point or integer unit, floating point unit, load-store unit, branch unit, condition register unit) within a current generation, out-of-order superscalar processor. This data is based on *simulation-based* data of a hypothetical processor, similar in complexity to that of current generation designs such as the Power4™ [11].

**FIGURE 7.6** (a) Instruction frequency mix for a typical commercial workload trace segment. (b) Stall profile in the instruction fetch unit (IFU) for the commercial workload.

We show the results for selected SPEC95 benchmarks and a large sample from a commercial TPC-C trace. The data shows that the pipe utilization attains a maximum of slightly over 50% only for the FXU; in many cases, the utilization is quite low, often 10% or less.

Figures 7.6(a) and (b) show the opportunities available within several units (and in particular, the instruction fetch unit, IFU) of the same example processor in the context of the TPC-C trace segment referred to above. Figure 7.6(a) depicts the instruction frequency mix of the trace segment used. This shows that the floating point unit (FPU) operations are a very tiny fraction of the total number of instructions in the trace. Therefore, with proper detection and control mechanisms architected in hardware, the FPU unit could essentially be “gated off” in terms of the clock delivery for the most part of such an execution. Figure 7.6(b) shows the fraction of total cycles spent in various modes within the instruction fetch unit (IFU). I-fetch was on hold for about 48% of the cycles; and the fraction of useful fetch cycles was only 28%. Again, this points to great opportunities: either in terms of clock-gating or dynamic ifetch throttling (see the subsection on “Dynamic Throttling of Communication Bandwidths below”).

(Micro)architectural support for clock-gating can be provided in at least three ways: (a) dynamic detection of idle modes in various clocked units or regions within a processor or system; (b) static or

dynamic prediction of such idle modes; (c) using “data valid” bits within a pipeline flow path to selectively enable/disable the clock applied to the pipeline stage latches. If static prediction is used, the compiler inserts special “nap/doze/sleep/wake” type instructions where appropriate, to aid the hardware in generating the necessary gating signals. Methods (a) and (b) result in coarse-grain clock-gating, where entire units, macros or regions can be gated off to save power; while, method (c) results in fine-grain clock-gating, where unutilized pipe segments can be gated off during normal execution within a particular unit, such as the FPU. The detailed circuit-level implementation of gated-clocks, the potential performance degradation, inductive noise problems, etc. are not discussed in this chapter; however, these are very important issues that must be dealt with adequately in an actual design.

Referring back to Figs. (7.2) and (7.3), note that since (fine-grain) clock-gating effectively causes a fraction of the latches to be “gated off,” we may model this by assuming that the effective value of  $L$  decreases when such clock-gating is applied. This has the effect of increasing  $k$  (opt.); i.e., the operating frequency for the most power-efficient pipeline operation can be increased in the presence of clock-gating. This is an added benefit.

## Variable Bit-Width Operands

One of the techniques proposed for reducing dynamic power consists of exploiting the behavior of data in programs, which is characterized by the frequent presence of small values. Such values can be represented as and operated upon as short bit-vectors. Thus, by using only a small part of the processing datapath, power can be reduced without loss of performance. Brooks and Martonosi [12] analyzed the potential of this approach in the context of 64-bit processor implementations (e.g., the Compaq Alpha™ architecture). Their results show that roughly 50% of the instructions executed had both operands whose length was less than or equal to 16 bits. Brooks and Martonosi proposed an implementation that exploits this by dynamically detecting the presence of narrow-width operands on a cycle-by-cycle basis. (Subsequent work by Jude Rivers et al. at IBM has documented an approach to exploit this in PowerPC architectures, using a different implementation. This work is still not available for external publication).

## Adaptive Microarchitectures

Another method of reducing power is to adjust the size of various storage resources within a processor or system, with changing needs of the workload. Albonesi [13] proposed a dynamically reconfigurable caching mechanism, that reduces the cache size (and hence power) when the workload is in a phase that exhibits reduced cache footprint. Such downsizing also results in improved latency, which can be exploited (from a performance viewpoint) by increasing the cache cycling frequency on a local clocking or self-timed basis. Maro et al. [14] have suggested the use of adapting the functional unit configuration within a processor in tune with changing workload requirements. Reconfiguration is limited to “shutting down” certain functional pipes or clusters, based on utilization history or IPC performance. In that sense, the work by Maro et al. is not too different from coarse-grain clock-gating support, as discussed earlier. In recent work done at IBM Watson, Buyuktosunoglu et al. [15] designed an adaptive issue queue that can result in (up to) 75% power reduction when the queue is sized down to its minimum size. This is achieved with a very small IPC performance hit. Another example is the idea of adaptive register files (e.g., see [16]) where the size and configuration of the active size of the storage is changed via a banked design, or through hierarchical partitioning techniques.

## Dynamic Thermal Management

Most clock-gating techniques are geared towards the goal of reducing *average* chip power. As such, these methods do not guarantee that the worst-case (maximum) power consumption will not exceed safe limits. The processor’s maximum power consumption dictates the choice of its packaging and cooling solution. In fact, as discussed in [17], the net cooling solution cost increases in a piecewise linear manner with respect to the maximum power; and the cost gradient increases rather sharply in the higher power regimes. This necessitates the use of mechanisms to limit the maximum power to a controllable ceiling,

one defined by the cost profile of the market for which the processor is targeted. Most recently, in the high performance world, Intel's Pentium 4 processor is reported to use an elaborate on-chip thermal management system to ensure reliable operation [17]. At the lower end, the G3 and G4 PowerPC microprocessors [18,19] include a Thermal Assist Unit (TAU) to provide dynamic thermal management. In a recently reported academic work, Brooks and Martonosi [20] discuss and analyze the potential reduction in "maximum power" ratings without significant loss of performance, by the use of specific dynamic thermal management (DTM) schemes. The use of DTM requires the inclusion of on-chip sensors to monitor actual temperature; or proxies of temperature [20] estimated from on-chip counters of various events and rates.

## Dynamic Throttling of Communication Bandwidths

This idea has to do with reducing the width of a communication bus dynamically, in response to reduced needs or in response to temperature overruns. Examples of on-chip buses that can be throttled are: instruction fetch bandwidth, instruction dispatch/issue bandwidths, register renaming bandwidth, instruction completion bandwidths, memory address bandwidth, etc. In the G3 and G4 PowerPC microprocessors [18,19], the TAU invokes a form of instruction cache throttling as a means to lower the temperature when a thermal emergency is encountered.

## Speculation Control

In current generation high performance microprocessors, branch mispredictions and mis-speculative prefetches end up wasting a lot of power. Manne et al. [21,22] have described means of detecting or anticipating an impending mispredict and using that information to prevent mis-speculated instructions from entering the pipeline. These methods have been shown to reduce power by up to 38% with less than a 1% performance loss.

## 7.4 Power-Efficient Microarchitecture Paradigms

---

Now that we have examined specific microarchitectural constructs that aid power-efficient design, let us examine the inherent power-performance scalability and efficiency of selected paradigms that are currently emerging in the high-end processor roadmap. In particular, we consider: (a) wide-issue, speculative super scalar processors; (b) multi-cluster superscalars; (c) chip multiprocessors (CMP)—especially those that use single program speculative multithreading (e.g., multiscalar); (d) simultaneously multithreaded (SMT) processors.

In illustrating the efficiency advantages or deficiencies, we use the following running example. It shows one iteration of a loop trace that we consider in simulating the performance and power characteristics across the above computing platforms.

Let us consider the following floating-point loop kernel, shown below (coded using the PowerPC™ instruction set architecture):

### Example Loop Test Case

```
[P] [A] fadd fp3, fp1, fp0
[Q] [B] lfd  fp5, 8(r1)
[R] [C] lfd  fp4, 8(r3)
[S] [D] fadd fp4, fp5, fp4
[T] [E] fadd fp1, fp4, fp3
[U] [F] stfd fp1, 8(r2)
[V] [G] bc  loop_top
```

The loop body consists of seven instructions, the final one being a conditional branch that causes control to loop back to the top of the loop body. The instructions are labeled A through G. (The labels P through V are used to tag the corresponding instructions for a parallel thread—when we consider SMT

FIGURE 7.7 High-level block-diagram of machine organization modeled in the eliot/elpaso tool.

and CMP). The lfdx/stfdx instructions are load/store instructions with update, where the base address register (e.g., r1, r2, or r3) is updated after execution by holding the newly computed address.

### Single-Core Superscalar Processor Paradigm

One school of thought anticipates a continued progression along the path of wider, aggressively superscalar paradigms. Researchers continue to innovate in an attempt to extract the last “ounce” of IPC-level performance from a single-thread instruction-level parallelism (ILP) model. Value prediction advances (pioneered by Lipasti et al. [23]) promise to break the limits imposed by true data dependencies. Trace caches (Smith et al. [23]) ease the fetch bandwidth bottleneck, which can otherwise impede scalability; however, increasing the superscalar width beyond a certain limit tends to yield diminishing gains in *net* performance (i.e., the inverse of  $CPI \times CT$ ; see Eq. (7.1)). At the same time, the power-performance efficiency metric (e.g., performance per watt or  $(\text{performance})^2/\text{watt}$ , etc.) tends to degrade beyond a certain complexity point in the single-core superscalar design paradigm. This is illustrated below in the context of our example loop test case.

Let us consider a base machine that is a 4-wide superscalar, with two load-store units supporting two floating-point pipes (see Fig. 7.7). The data cache has two load ports and a separate store port. Two load-store unit pipes (LSU0 and LSU1) are fed by a single issue queue, LSQ; similarly, the two floating-point unit pipes (FPU0 and FPU1) are fed by a single issue queue, FPQ. In the context of the loop above, we essentially focus on the LSU-FPU sub-engine of the whole processor.

Let us assume the following high-level parameters (latency and bandwidth) characterizing the base super scalar machine model of width  $W = 4$ .

- Instruction fetch bandwidth,  $\text{fetch\_bw} = 2 \times W = 8$  instructions/cycle.
- Dispatch/decode/rename bandwidth,  $\text{disp\_bw} = W = 4$  instructions/cycle; dispatch is assumed to stall beyond the first branch scanned in the instruction fetch buffer.
- Issue\_bandwidth from LSQ (reservation station),  $\text{lsu\_bw} = W/2 = 2$  instructions/cycle.
- Issue\_bandwidth from FPQ,  $\text{fpu\_bw} = W/2 = 2$  instructions/cycle.
- Completion bandwidth,  $\text{compl\_bw} = W = 4$  instructions/cycle.

- Back-to-back dependent floating point operation issue delay,  $fp\_delay = 1$  cycle.
- The best-case load latency, from fetch to writeback is: 5 cycles.
- The best-case store latency, from fetch to writing in the pending store queue is: 4 cycles; (a store is eligible to complete the cycle after the address-data pair is valid in the store queue).
- The best-case floating point operation latency, from fetch to writeback is: 7 cycles (when the issue queue, FPQ is bypassed, because it is empty).

Loads and floating point operations are eligible for completion (retirement) the cycle after writeback into rename buffers. For simplicity of analysis let us assume that the processor uses in-order issue from the issue queues (LSQ and FPQ). In our simulation model, the superscalar width  $W$  is a ganged parameter, defined as follows:

$$W = (\text{fetch\_bw}/2) = \text{disp\_bw} = \text{compl\_bw}$$

The number of LSU units,  $ls\_units$ , FPU units,  $fp\_units$ , data cache load ports,  $l\_ports$  and data cache store ports are varied as follows as  $W$  is changed:

$$ls\_units = fp\_units = l\_ports = \max[\text{floor}(W/2), 1]$$

$$s\_ports = \max[\text{floor}(l\_ports/2), 1]$$

For illustrative purposes, a simple (and decidedly naive) analytical energy model is assumed, where the power consumed is a function of the following parameters:  $W$ ,  $ls\_units$ ,  $fp\_units$ ,  $l\_ports$ , and  $s\_ports$ . In particular, the power  $PW$ , in watts, is computed as:  $PW = K \times [(W)^\gamma + ls\_units + fp\_units + l\_ports + s\_ports]$ , where  $\gamma$  ( $0 < \gamma < 1$ ) is an exponent that may be varied to see the effect on power-performance efficiency;  $K$  is a constant. Figure 7.8 shows the performance and performance/power ratio variation with superscalar width,  $W$ ; for this graph,  $\gamma$  has been set to 0.5 and the scaling constant  $K$  is 2. The BIPS (billions of instructions per second) values are computed from the IPC (instruction per cycle) values, assuming a clock frequency of 1 GHz.

The graph in Fig. 7.8(a) shows that a maximum issue width of  $W = 4$  could be used to achieve the best (idealized) BIPS performance. This idealized plot is obtained using a tool called eliot [24]. This is a parameterized, PowerPC super scalar model, that can operate either in cycle-by-cycle simulation mode, or, it can generate idealized bounds, based on static analysis of a loop code segment. The eliot model has now been updated to include parameterized, analytical energy models for each unit or storage resource within the processor. This new tool, called elpaso can be used to generate power-performance efficiency data for loop test cases. As shown in Fig. 7.8 (b), from a power-performance efficiency viewpoint

FIGURE 7.8 Loop performance and performance/power variation with issue width.

(measured as a performance over power ratio), the best-case design is achieved for  $W < 4$ . Depending on the sophistication and accuracy of the energy model (i.e., how power varies with microarchitectural complexity), and the exact choice of the power-performance efficiency metric, the inflexion point in the curve in Fig. 7.8(b) changes; however, it should be obvious that beyond a certain superscalar width, the power-performance efficiency diminishes continuously. Fundamentally, this is due to the single-thread ILP limit of the loop trace being considered (as apparent from Fig. 7.8 (a)).

Note, by the way that the resource sizes are assumed to be large enough, so that they are effectively infinite for the purposes of our running example above. Some of the actual sizes assumed for the base case ( $W = 4$ ) are: Completion (reorder) buffer size,  $cbuf\_size = 32$ ; load-store queue size,  $lsq\_size = 6$ ; floating point queue size,  $fpq\_size = 8$ ; pending store queue size,  $psq\_size = 16$ .

The microarchitectural trends beyond the current superscalar regime, are effectively targeted towards the goal of extending the power-performance efficiency factors. That is, the complexity growth must ideally scale at a slower rate than the growth in performance. Power consumption is one index of complexity; it also determines packaging and cooling costs. (Verification cost and effort is another important index). In that sense, a microarchitecture paradigm that ensures that the power-performance efficiency measure of choice is a nondecreasing function of time: is the ideal, complexity-effective design paradigm for the future. Of course, it is hard to keep scaling a given paradigm beyond a few processor generations. Whenever we reach a maximum in the power-performance efficiency curve, it is time to invoke the next paradigm shift.

Next, we examine some of the promising new trends in microarchitecture that can serve as the next platform for designing power-performance scalable machines.

## Multicluster Superscalar Processors

As described in our earlier article [2], Zyuban et al. [25,26] studied the class of multicluster superscalar processors as a means of extending the power-efficient growth of the basic super scalar paradigm. One way to address the energy growth problem at the microarchitectural level is to replace a classical superscalar CPU with a set of clusters, so that all key energy consumers are split among clusters. Then, instead of accessing centralized structures in the traditional superscalar design, instructions scheduled to an individual cluster would access local structures most of the time. The main advantage of accessing a collection of local structures instead of a centralized one is that the number of ports and entries in each local structure is much smaller. This reduces the latency and energy per access. If the non-accessed sub-structures of a resource can be “gated off” (e.g., in terms of the clock), then, the net energy savings can be substantial.

According to the results obtained in Zyuban’s work, the energy dissipated per cycle in every unit or sub-unit within a superscalar processor can be modeled to vary (approximately) as  $IPC_{unit} \times (IW)^g$ , where  $IW$  is the issue width,  $IPC_{unit}$  is the average IPC performance at the level of the unit or structure under consideration; and,  $g$  is the energy growth parameter for that unit. Then, the energy-delay product (EDP) for the particular unit would vary as:

$$EDP_{unit} = \frac{IPC_{unit} \times (IW)^g}{IPC_{overall}} \quad (7.12)$$

Zyuban shows that for real machines, where the overall IPC always increases with issue width in a sub-linear manner, the overall EDP of the processor can be bounded as

$$(IPC)^{2g-1} \leq EDP \leq (IPC)^{2g} \quad (7.13)$$

where  $g$  is the energy-growth factor of a given unit and  $IPC$  refers to the overall IPC of the processor; and,  $IPC$  is assumed to vary as  $(IW)^{0.5}$ . Thus, according to this formulation, superscalar implementations that minimize  $g$  for each unit or structure will result in energy-efficient designs. The eliot/elpaso tool

does not model the effects of multi-clustering in detail yet; however, from Zyuban’s work, we can infer that a carefully designed multicluster architecture has the potential of extending the power-performance efficiency scaling beyond what is possible using the classical superscalar paradigm. Of course, such extended scalability is achieved at the expense of reduced IPC performance for a given superscalar machine width. This IPC degradation is caused by the added inter-cluster communication delays and other power management overhead in a real design. Some of the IPC loss (if not all) can be offset by a clock frequency boost, which may be possible in such a design, due to the reduced resource latencies and bandwidths.

Current high-performance processors (for example, the Compaq Alpha 21264 and the IBM Power4) certainly have elements of multi-clustering, especially in terms of duplicated register files and distributed issue queues. Zyuban proposed and modeled a specific multicluster organization in his work. This simulation-based study determined the optimal number of clusters and their configurations, for the EDP metric.

### Simultaneous Multithreading (SMT)

Let us examine the SMT paradigm [27] to understand how this may affect our notion of power-performance efficiency. The data in Table 7.3 shows the steady-state utilization of some of the resources in our base super scalar machine in response to the input loop test case discussed earlier. Since, due to fundamental ILP limits, the IPC will not increase beyond  $W = 4$ , it is clear why power-performance efficiency will be on a downward trend beyond a certain width of the machine. (Of course, here we assume maximum processor power numbers, without any clock gating or dynamic adaptation to bring down power.)

With SMT, assume that we can fetch from two threads (simultaneously, if the icache is dual-ported, or in alternate cycles if the icache remains single-ported). Suppose two copies of the same loop program (see example at the beginning of this section, i.e., Section 7.4) are executing as two different threads. So, thread-1 instructions A-B-C-D-E-F-G and thread-2 instructions P-Q-R-S-T-U-V are simultaneously available for dispatch and subsequent execution on the machine. This facility allows the utilization factors, and the net throughput performance to go up, without a significant increase in the maximum clocked power. This is because, the issue width  $W$  is not increased, but the execution and resource stages or slots can be filled up simultaneously from both threads. The added complexity in the front-end of maintaining two program counters (fetch streams), and the global register space increase alluded to previously, adds to the power a bit. On the other hand, the core execution complexity can be relaxed a bit without a performance hit. For example, the `fp_delay` parameter can be increased, to reduce core complexity, without any performance degradation. Figure 7.9 shows the expected performance and power-performance variation with  $W$  for the 2-thread SMT processor. The power model assumed for the SMT machine is

the same as that of the underlying superscalar, except that a fixed fraction of the net power is added to account for the SMT overhead. (The fraction added is assumed to be linear in the number of threads, in an  $n$ -thread SMT). Figure 7.9 shows that under the assumed model, the performance-power efficiency scales better with  $W$ , compared with the base superscalar (Fig. 7.8).

Seng and Tullsen [28] presented analysis to show that using a suitably architected SMT processor, the per-thread speculative waste can be reduced, while increasing the utilization of the machine resources by executing simultaneously from multiple threads. This was shown to reduce the average energy per instruction by 22%.

## Chip Multiprocessing

In a multiscalar-like chip-multiprocessor (CMP) machine [29], different iterations of a single loop program could be initiated as separate tasks or threads on different core processors on the same chip. Thus, the threads A-B-C-D-E-F-G and P-Q-R-S-T-U-V, derived from the same user program would be issued in sequence by a global task sequencer to two cores, in a 2-way multiscalar CMP. Register values set in one task are forwarded in sequence to dependent instructions in subsequent tasks. For example, the register value in  $fp1$  set by instruction E in task 1 must be communicated to instruction T in task 2; so instruction T must stall in the second processor until the value communication has occurred from task 1. Execution on each processor proceeds speculatively, assuming the absence of load-store address conflicts between tasks; dynamic memory address disambiguation hardware is required to detect violations and restart task executions as needed. In this paradigm also, if the performance can be shown to scale well with the number of tasks, and if each processor is designed as a limited-issue, limited-speculation (low complexity) core, it is possible to achieve better overall scalability of performance-power efficiency.

Another trend in high-end microprocessors is true chip multiprocessing (CMP), where multiple (distinct) user programs execute separately on different processors on the same chip. A commonly used paradigm in this case is that of (shared memory) symmetric multiprocessing (SMP) on a chip (see Hammond et al. in [23]). Larger SMP server nodes can be built from such chips. Server product groups such as IBM's high-end PowerPC division have relied on such CMP paradigms as the scalable paradigm for the immediate future. The Power4 design [11] is the first example of this trend. Such CMP designs offer the potential of convenient coarse-grain clock-gating and "power-down" modes, where one or more processors on the chip may be "turned off" or "slowed down" to save power when needed.

## 7.5 Conclusions and Future Research

In this chapter, we first discussed issues related to power-performance efficiency and metrics from an architect's viewpoint. We limited the discussion to dynamic power consumption. We showed that depending on the application domain (or market), it may be necessary to adopt one metric over another in comparing processors within that segment. Next, we described some of the promising new ideas in power-aware microarchitecture design. This discussion included circuit-centric solutions like clock-gating, where

microarchitectural support is needed to make the right decisions at run time. Later, we used a simple loop test case to illustrate the limits of power-performance scalability in some popular paradigms that are being developed by various vendors within the high-end processor domain. In particular, we show that scalability of current generation super scalars may be extended effectively through multi-clustering, SMT, and CMP. Our experience in simulating these structures points to the need of keeping a single core (or the uni-threaded core) simple enough to ensure scalability in the power, performance, and verification cost of future systems. Detailed simulation results with benchmarks to support these conclusions were not provided in this tutorial-style paper. Future research papers from our group will present such data for specific microarchitectural paradigms of interest.

We limited our focus to a few key ideas and paradigms of interest in future power-aware processor design. Also, we did not consider methods to reduce static (leakage) power: a component of net processor power that is expected to grow significantly in future technologies. Many new ideas to address various aspects of power reduction have been presented in recent workshops (e.g., [30–32]). All these ideas could not be discussed in this chapter; but the interested reader should certainly refer to the cited references for further detailed study.

At IBM T. J. Watson Research Center, a project on power-aware microprocessor design, led by the author of this article, is currently engaged in designing a research processor prototype, called LPX (low-power issue-execute processor). This processor has many of the elements touched upon in this paper among other new innovations. By incorporating on-chip monitoring hardware, we shall attempt to measure power reduction benefits and performance degradations (if any) resulting from the various ideas that are being tried. This hardware prototype will also enable us to validate our power-performance simulation methodologies, e.g., the *PowerTimer* toolkit referred to in [2]. Details of the LPX design will be described in later publications.

### Introduction

In queuing theory literature, many models describe the dynamic behavior of computer systems. Good sources of such information (e.g. [5,7]) usually include stochastic models based on birth-death formulas, the convolution algorithm [2], load independent and load dependent mean value analysis (MVA) models [10], and BCMP networks [1]. Theoretical queuing models presented in computer literature easily explain phenomena such as bottlenecks, saturation, resource utilization, etc.; however, it is very difficult to find sources that show a second level of modeling, which focuses on the ability of models to also achieve good numerical accuracy when modeling real computer systems running real workloads. Although the phenomenology is important in the classroom, it is the numerical accuracy that counts in engineering practice. The usual task of performance analysts is to measure system performance and then derive models that can describe and predict the behavior of analyzed systems with reasonable accuracy. Those who try to model the dynamic behavior of real computer systems running real workloads frequently find this to be a difficult task.

Our first goal is to develop load dependent models of disk units that have a moderate level of complexity suitable for engineering practice. The presented disk unit models describe disk access times, head movement optimization, and disk caching. These models are then used for creating MVA models of disk subsystems. Our second goal is to investigate and exemplify the limits of numerical accuracy of presented queuing models, and to propose indicators of predictive power of analyzed models. We present case studies of disk subsystem modeling of a VAX under VMS and a PC under Windows NT. They provide a good insight into the level of difficulty encountered in practical disk subsystem modeling and help establish realistic expectations of modeling errors. The relative simplicity of MVA models makes them attractive for practice. They can be easily combined with our disk unit models. However, our experiments with MVA models show that only the load dependent version of MVA generates results with reasonable accuracy.

## Description Errors and Prediction Errors of Disk Subsystem Models

Modeling errors are defined as differences between queuing theory results and experimental measurements. Simple queuing models of disk subsystems (such as load independent MVA) frequently generate modeling errors of 30–50% or more. In the majority of practical cases such low accuracy is not acceptable. Modeling errors below 5% are usually acceptable, but require detailed and more sophisticated models.

The accuracy of models can only be evaluated with respect to measurements performed for a specific system running a specific workload. Our approach to modeling and analysis of disk subsystems includes the following main steps:

- Specification of drive workload that can be used to create various levels of disk subsystem load.
- Measurement of system performance under a strictly increasing disk subsystem load.
- Development of an analytic model with adjustable parameters that describes the dynamics of a disk subsystem.
- Calibration of the analytic model by adjusting all model parameters to minimize the difference between the measured values and the values computed from the analytic model.
- Assessment of the predictive power of the analytic model.
- The use of the calibrated model for performance prediction of systems with different parameters and/or workload.

It is useful to identify two types of modeling errors: *description errors* and *prediction errors*. We define a description error as the mean relative error between the measured performance indicators of a real system and the performance indicators of a calibrated model. The description error is defined only within the range of measurements. By contrast, the prediction error is the error in predicting the values of performance indicators outside the range of measurements, or for different configurations of the analyzed system, or for a different workload. For example, if we measure the response time for the degree of multiprogramming from 1 to 8, then the description error is the mean error between eight measured values and eight computed values. The prediction error is the error between the computed response time for 20 jobs and the actual response time if it were measured. The prediction error is also the error between predicted and actual response times for a system with a different number of disks, processors, or for a different workload.

The basic problem of modeling is that the ratio between prediction errors and description errors can frequently be large, e.g., 2 to 10. Consequently, to provide reasonable prediction power, the description errors of analytic models must be small, typically just a few percent.

### A Simple Acceleration/Deceleration Model of Disk Access Time

The movement of the disk input/output (I/O) mechanism is usually modeled assuming that movement is caused by applying a constant force for both acceleration and deceleration. This is a simple and usually realistic assumption illustrated in Fig. 8.1. If the mass of the I/O mechanism is  $m$ , then force  $f$  causes the acceleration  $a = f/m$ . After acceleration with force  $f$  we apply deceleration with force  $-f$ . The I/O heads travel the total distance  $x$  and the corresponding time  $T$  is called the seek time. After accelerating for time  $T/2$  the I/O heads attain the speed  $v = aT/2$  and travel the distance  $x/2 = a(T/2)^2/2$ . Therefore, the

**FIGURE 8.1** Movement of the disk I/O mechanism (seek). (From Dujmovic, J., Tomasevich, D., and Au-Yeung, M., Proc. CMG, 1999, Reno, NV. With permission.)

seek time as a function of distance is  $T(x) = 2\sqrt{x/a}$ . If the maximum distance is  $x_{\max}$  then the maximum seek time is  $T_{\max}$ , the acceleration is  $a = 4x_{\max}/T_{\max}^2$ , and  $T(x) = T_{\max}\sqrt{x/x_{\max}}$ . The distance  $x$  can be expressed as a physical length, or as a number of cylinders traveled (in this case the dimension of acceleration is cylinder/s<sup>2</sup>). If the head moves from cylinder  $y$  to cylinder  $z$ , the traveled distance is  $x = |y - z|$ . The seek time is  $t(y, z) = T_{\max}\sqrt{|y - z|/x_{\max}}$ . The initial position  $y$  and the final position  $z$  can be anywhere in the interval  $[0, x_{\max}]$ . Assuming the uniform distribution of accesses to all cylinders the average seek time  $T_{\text{seek}}$  can be computed as follows:

$$T_{\text{seek}} = \frac{1}{x_{\max}^2} \int_0^{x_{\max}} \int_0^{x_{\max}} t(y, z) dy dz = \frac{T_{\max}}{x_{\max}^{5/2}} \int_0^{x_{\max}} \int_0^{x_{\max}} \sqrt{|y - z|} dy dz = \frac{8}{15} T_{\max} = \frac{16}{15} \sqrt{\frac{x_{\max}}{a}}$$

Consider the case where each cylinder has a fixed data capacity of  $b$  bytes. For a large contiguous file of size  $F$  the maximum distance the I/O mechanism can travel is  $x_{\max} = F/b$  cylinders. Consequently, the average seek time for this file is  $T_{\text{seek}} = c\sqrt{F}$ , where  $c = 16/(15\sqrt{ab}) = \text{const}$ . If we access data in the range  $0 \leq F \leq F_{\max}$ , the average seek time is the following function of the file size:

$$T_{\text{seek}}(F) = T_{\text{max seek}} \sqrt{F/F_{\max}}, \quad T_{\text{max seek}} = \frac{16}{15} \sqrt{\frac{F_{\max}}{ab}}$$

Now the constant  $T_{\text{max seek}}$  has a suitable interpretation of the maximum value of the average seek time for the file of size  $F_{\max}$ .

When the I/O mechanism reaches a destination cylinder, it is necessary to wait the latency time until the desired sector reaches the read/write head. For a disk that rotates at  $N_{\text{rev}}$  revolutions per minute, the total revolution time is  $60/N_{\text{rev}}$ . The latency time is uniformly distributed between 0 and  $60/N_{\text{rev}}$ . Therefore, the average latency is half of the revolution time, i.e.,  $T_{\text{latency}} = 30/N_{\text{rev}}$ . The disk data transfer time for one sector is  $T_{\text{transfer}} = 60/N_{\text{rev}} N_{\text{sector}} = 2T_{\text{latency}}/N_{\text{sector}}$ . Therefore, the mean time to access and transfer disk data from a file of size  $F$  is

$$\begin{aligned} T_{\text{access}} &= T_{\text{seek}} + T_{\text{latency}} + T_{\text{transfer}} \\ &= T_{\text{max seek}} \sqrt{F/F_{\max}} + 30(1 + 2/N_{\text{sector}})/N_{\text{rev}} \\ &\cong T_{\text{max seek}} \sqrt{F/F_{\max}} + 30/N_{\text{rev}} \end{aligned}$$

This is the simplest and idealized model of the mean disk access time. This model neglects phenomena such as differences between disk acceleration and deceleration, head settle time [15] (dominating short seeks), limited maximum velocity, nonuniformity of rotational latency for nonindependent requests, zoning, bus interface and contention [11], disk command overhead [4], as well as effects of caching and head movement optimization.

## A Fixed Maximum Velocity Model of Seek Time

A more realistic model of seek time can be derived if we assume that the maximum velocity of the I/O heads has a constant maximum value, as shown in Fig. 8.2. For small distances (exemplified by seek times  $t_1, t_2$  and all other seek times  $t \leq T^*$ ) we assume that the heads first linearly accelerate for some time and then decelerate exactly the same amount of time. For larger distances (seek times  $t \geq T^*$ ) the

**FIGURE 8.2** A simplified disk head velocity diagram. (From Dujmovic, J., Tomasevich, D., and Au-Yeung, M., *Proc. CMG*, 1999, Reno, NV. With permission.)

heads linearly accelerate until they achieve the maximum speed  $v_{\max}$ , then travel at this constant speed, and eventually decelerate linearly.

The maximum time  $T^*$  that the disk mechanism can travel without being limited by the maximum velocity is called the critical seek time.  $T^*$  is the time to accelerate disk heads to the maximum speed and then to decelerate them to a standstill. In cases where disk heads travel at the constant maximum speed the critical seek time  $T^*$  denotes the acceleration plus deceleration time, i.e. the total seek time minus the time heads spend traveling at the constant maximum speed. Assuming constant acceleration/deceleration, the critical seek time is  $T^* = 2v_{\max}/a$ . During the critical seek time interval the mechanism travels the distance  $x^*$ , called the critical distance. In the case of constant acceleration/deceleration, we have  $v = at$ ,  $x(t) = at^2/2$ , and  $x^* = 2x(T^*/2) = v_{\max}^2/a$ .

Let us now investigate a general symmetrical case where the function  $v(t)$  has the property that the acceleration time equals the deceleration time. We differentiate the small distance model ( $T \leq T^*$ ) and the large distance model ( $T \geq T^*$ ) as follows:

$$\begin{aligned}
 x(T) &= \int_0^T v(t) dt \\
 &= \begin{cases} \underbrace{\int_0^{T/2} v(t) dt}_{\text{acceleration}} + \underbrace{\int_{T/2}^T v(t) dt}_{\text{deceleration}}, & T \leq T^* \\ \underbrace{\int_0^{T^*/2} v(t) dt}_{\text{acceleration}} + \underbrace{\int_{T^*/2}^{T-T^*/2} v_{\max} dt}_{\text{max velocity}} + \underbrace{\int_{T-T^*/2}^T v(t) dt}_{\text{deceleration}} = x^* + v_{\max}(T - T^*), & T \geq T^* \end{cases} \\
 x^* &= \underbrace{\int_0^{T^*/2} v(t) dt}_{\text{acceleration}} + \underbrace{\int_{T-T^*/2}^T v(t) dt}_{\text{deceleration}}
 \end{aligned}$$

The distance  $x^*$  is the total distance for acceleration from 0 to  $v_{\max}$  and deceleration from  $v_{\max}$  to 0. In the constant acceleration case ( $v(t) = at$ ), this model yields

$$x(T) = \begin{cases} \frac{aT^2}{4} = \frac{v_{\max}}{2T^*} T^2, & T \leq T^* = \frac{2v_{\max}}{a} \\ v_{\max} \left( T - \frac{v_{\max}}{a} \right) = v_{\max} \left( T - \frac{T^*}{2} \right), & T \geq T^* \end{cases}$$

The critical distance  $x^*$  is

$$x^* = x(T^*) = \frac{a(T^*)^2}{4} = \frac{v_{\max} T^*}{2} = \frac{v_{\max}^2}{a}$$

Therefore, the acceleration and the maximum speed depend on the critical values  $x^*$  and  $T^*$ :

$$a = 4x^*/(T^*)^2, \quad v_{\max} = 2x^*/T^*$$

They can also be numerically determined from the linear segment of the seek time characteristic, using arbitrary points  $(x_1, T_1)$  and  $(x_2, T_2)$ :

$$v_{\max} = \frac{x_2 - x_1}{T_2 - T_1}, \quad a = \frac{(x_2 - x_1)^2}{(T_1 x_2 - T_2 x_1)(T_2 - T_1)}$$

The seek time characteristic follows from  $x(T)$ :

$$T(x) = \begin{cases} 2\sqrt{\frac{x}{a}} = 2\sqrt{\frac{xx^*}{v_{\max}^2}} = T^* \sqrt{\frac{x}{x^*}}, & x \leq x^* \\ \frac{x + x^*}{v_{\max}} = \frac{T^*}{2} + \frac{x}{v_{\max}} = \frac{T^*}{2} \left( \frac{x}{x^*} + 1 \right), & x \geq x^* \end{cases}$$

This function satisfies the following properties:

- The initial nonlinear segment, for  $x \leq x^*$ , is a square root function.
- The second segment, for  $x > x^*$ , is a linear function.
- At the critical point  $x = x^*$ , the first derivative of the square root function equals the first derivative of the linear function ( $dT/dx = 1/v_{\max}$ ).

From  $T = T^*(1 + x/x^*)/2$  we can easily see that both  $x^*$  and  $T^*$  can be determined from the linear segment of the measured seek time characteristic using the following four steps, illustrated in Fig. 8.3:

1. Extend the linear segment of the measured seek time characteristic to the vertical axis. For  $x = 0$  we get the point  $T^*/2$  on the vertical axis.
2. Move vertically up to the point  $T^*$  (this value is twice the distance between the origin and the intersection of the linear segment and the vertical axis).

**FIGURE 8.3** Graphical method for determining  $x^*$  and  $T^*$ . (From Dujmovic, J., Tomasevich, D., and Au-Yeung, M., *Proc. CMG*, 1999, Reno, NV. With permission.)

3. Move horizontally to the intersection with the linear segment.
4. Move down to the horizontal axis and determine the point  $x^*$ .

Because the linear segment of the seek time characteristic determines the values of  $x^*$  and  $T^*$  (as well as  $a$  and  $v_{\max}$ ), it follows that the nonlinear segment must terminate exactly in the  $(x^*, T^*)$  point. A numerical method for computing  $x^*$  and  $T^*$  can be based on any two points  $(x_1, T_1)$  and  $(x_2, T_2)$  taken on the linear segment. From the linear segment function  $T = T_1 + (x - x_1)(T_2 - T_1)/(x_2 - x_1)$ , it follows:

$$x^* = \frac{T_1 x_2 - T_2 x_1}{T_2 - T_1}, \quad T^* = 2 \frac{T_1 x_2 - T_2 x_1}{x_2 - x_1}$$

The presented model is suitable for a qualitative description of the seek time behavior and for providing insight into disk characteristics, but its flexibility is limited because it has only two parameters. In addition to limited flexibility, this model is not appropriate for those disk units that do not satisfy the assumptions of constant acceleration/deceleration, and for units where the seek time for short distances is significantly affected by the head settling time. The accuracy of modeling can be improved using numerical models that fit the measured characteristic and use more than two adjustable parameters.

## Numerical Computation of the Average Seek Time

A simple numerical model can be based on three points:  $(x_1, T_1)$ ,  $(x^*, T^*)$ , and  $(x_2, T_2)$ , where  $x_1 < x^* < x_2$ . Here,  $(x_1, T_1)$  is the point from the initial nonlinear segment. Contrary to the approach presented in the section on "A Fixed Maximum Velocity Model of Seek Time," the middle point  $(x^*, T^*)$  is not computed from the linear part of the measured characteristic, but directly selected from the seek time graph as the beginning of the linear segment. The point  $(x_2, T_2)$  denotes the end of the linear segment (the maximum distance heads can travel). The corresponding model is

$$T(x) = \begin{cases} T^* \left( \frac{x}{x^*} \right)^r = tx^r, & t = \frac{T^*}{(x^*)^r}, \quad x \leq x^* \\ T^* + \frac{T_2 - T^*}{x_2 - x^*} (x - x^*) = Ax + B, & x \geq x^* \end{cases}$$

From  $T_1 = tx_1^r$  and  $T^* = t(x^*)^r$  it follows that  $T^*/T_1 = (x^*/x_1)^r$ . Therefore, the parameters are

$$r = \frac{\log(T^*/T_1)}{\log(x^*/x_1)}, \quad t = T_1/x_1^r = T^*/(x^*)^r$$

$$A = \frac{T_2 - T^*}{x_2 - x^*}, \quad B = T^* - Ax^*$$

Using this model it is possible to numerically compute the mean seek time. Suppose that a file occupies  $N$  cylinders. The probability that the seek distance  $x$  is less than or equal to a given value  $z$  is

$$P_x(z) = P[x \leq z] = (2Nz - z^2)/N^2$$

This probability distribution function yields the following probability density function:

$$p_x(z) = dP/dz = 2(N - z)/N^2$$

Hence, the average seek time for the  $N$ -cylinder file can be computed as follows:

$$\bar{T}_{\text{seek}} = \int_0^N T(z)p_x(z)dz = \frac{2}{N^2} \int_0^N T(z)(N-z)dz$$

Using the presented seek time model for  $N \leq x^*$ , we have

$$\bar{T}_{\text{seek}} = \frac{2t}{N^2} \int_0^N z^r(N-z)dz = \frac{2tN^r}{(r+1)(r+2)}$$

Similarly, for  $N \geq x^*$ , we get

$$\begin{aligned} \bar{T}_{\text{seek}} &= \frac{2}{N^2} \left[ \int_0^{x^*} T(z)(N-z)dz + \int_{x^*}^N T(z)(N-z)dz \right] \\ &= \frac{2}{N^2} \left[ \int_0^{x^*} tz^r(N-z)dz + \int_{x^*}^N (Az+B)(N-z)dz \right] \\ &= \frac{2t(x^*)^{r+1}}{N^2} \left( \frac{N}{r+1} - \frac{x^*}{r+2} \right) + \frac{(N-x^*)[N(AN+3B+Ax^*) - x^*(3B+2Ax^*)]}{3N^2} \end{aligned}$$

Therefore, the average seek time as a function of file size is given by the following function:

$$\bar{T}_{\text{seek}}(N) = \begin{cases} \frac{2tN^r}{(r+1)(r+2)}, & N \leq x^* \\ \frac{2t(x^*)^{r+1}}{N^2} \left( \frac{N}{r+1} - \frac{x^*}{r+2} \right) + \frac{(N-x^*)[N(AN+3B+Ax^*) - x^*(3B+2Ax^*)]}{3N^2}, & N \geq x^* \end{cases}$$

Advantages of the presented exponential model are: (1) parameters can be quickly computed from three selected points of the characteristic, and (2) parameter  $r$  enables modeling of disk characteristics that are different from the square root model. From  $T(1) = t$  it follows that  $t$  is interpreted as the single cylinder seek time. The limitation of this model is that by determining  $t$  and  $r$  from points  $(x_1, T_1)$  and  $(x^*, T^*)$  it is not possible to have the exact value of  $t$  and optimum modeling of the curvature. To improve this model we can introduce one more parameter as follows:

$$T(x) = \begin{cases} 0, & x = 0 \\ t + c(x-1)^r, & 1 \leq x \leq x^* \\ Ax + B, & x \geq x^* \end{cases}$$

This new model has a nonlinear part (for  $x \leq x^*$ ) and a linear part (for  $x \geq x^*$ ). Since  $T(1) = t$  and  $T(2) = t + c$  the parameter  $t$  is the single cylinder seek time and the parameter  $c$  is the difference  $c = T(2) - T(1)$ . The parameters of this model  $(t, c, r, A, B, x^*)$  are not independent. First, for  $x = x^*$  the nonlinear part must be connected to the linear part:

$$t + c(x^* - 1)^r = Ax^* + B.$$

In addition, to assure perfect continuity of this model, for  $x = x^*$  the nonlinear and linear model must have the same first derivatives:

$$\left. \frac{dT}{dx} \right|_{x=x^*} = A = cr(x^* - 1)^{r-1}. \quad (8.1)$$

Inserting this value of  $A$  in the connection relation, we have the expression for  $B$ :

$$B = t + c(x^* - 1)^r - cr(x^* - 1)^{r-1}x^*. \quad (8.2)$$

The linear function can now be written as

$$Ax + B = \frac{cr(x - x^*)}{(x^* - 1)^{1-r}} + t + c(x^* - 1)^r.$$

Therefore, using formulas (8.1) and (8.2) our exponential model is now

$$T(x) = \begin{cases} t + c(x - 1)^r, & 1 \leq x \leq x^* \\ \frac{cr(x - x^*)}{(x^* - 1)^{1-r}} + t + c(x^* - 1)^r, & x \geq x^* \end{cases}$$

The model has four independent parameters  $t, c, r, x^*$  that can be determined using a calibration procedure. The objective of calibration is to make the model as close as possible to the measured values  $(x_1, T_1), \dots, (x_n, T_n)$ . Optimum values of parameters can be computed from the measured values  $(x_1, T_1), \dots, (x_n, T_n)$  by minimizing one of the following criterion functions:

$$E_1(t, c, r, x^*) = \frac{1}{n} \sum_{i=1}^n (T(x_i) - T_i)^2$$

$$E_2(t, c, r, x^*) = \frac{1}{n} \sum_{i=1}^n |T(x_i) - T_i|$$

$$E_3(t, c, r, x^*) = \max_{1 \leq i \leq n} |T(x_i) - T_i|$$

$E_1$  is a traditional mean square error,  $E_2$  is the mean absolute error and  $E_3$  is used to minimize the maximum error (“minimax”). These criterion functions yield consistent or similar results and in this paper we primarily used  $E_1$ . For all the above criteria the most suitable minimization method is the Nelder-Mead simplex algorithm [8]. The resulting calibrated (optimum) values of parameters  $t, c, r, x^*$  are those that yield the minimum value of the selected criterion function.

Experiments with modern disk units show that the four-parameter exponential model regularly achieves high accuracy. Typical average relative errors are between 2% and 3%. The quality of this model is illustrated in Fig. 8.4 for the Quantum Atlas III disk that has 8057 cylinders, and capacity of 9.1 GB. The optimum parameters of the model are  $t = 1.55$  ms,  $c = 0.32$  ms,  $r = 0.387$ , and  $x^* = 1686$  cylinders. Note that the optimum value of the exponent  $r$  is not  $\frac{1}{2}$  as expected from constant acceleration/deceleration models, and frequently used in disk performance literature.

**FIGURE 8.4** Four-parameter exponential seek time model of the Quantum Atlas III disk (based on DiskSim measurements of G.R. Ganger available at <http://www.ece.cmu.edu/~ganger>.) (From Dujmovic, J. and Tomasevich, D., *Proc. CMG*, 2001, Anaheim, CA. With permission.)

The mean seek time for accessing a file (or database) occupying  $N$  adjacent cylinders is

$$\bar{T}_{\text{seek}}(N) = \begin{cases} \frac{2}{N^2} \int_0^N T(z)(N-z)(dz), & N \leq x^* \\ \frac{2}{N^2} \left[ \int_0^{x^*} T(z)(N-z)dz + \int_{x^*}^N T(z)(N-z)dz \right], & N \geq x^* \end{cases}$$

The final result is:

$$\bar{T}_{\text{seek}}(N) = \begin{cases} \frac{2(N-1)^2}{N^2} \left[ \frac{t}{2} + \frac{c(N-1)^r}{(r+1)(r+2)} \right], & N \leq x^* \\ \frac{2}{N^2} \left[ \frac{t(x^*-1)(2N-x^*-1)}{2} + \frac{c(x^*-1)^{r+1} [N(r+2) - x^*(r+1) - 1]}{(r+1)(r+2)} + \frac{(N-x^*)^2 (AN + 2Ax^* + 3B)}{6} \right], & N \geq x^* \end{cases}$$

Here  $A$  and  $B$  are defined by formulas (8.1) and (8.2).

Numerical models based on best fit do not provide a direct correspondence between disk performance and physical attributes such as mass, force, acceleration, maximum speed, etc.; however, they are popular with many authors because of their low numerical errors. For example, Ruemmler and Wilkes [11] use the following simple model:

$$T(x) = \begin{cases} a + b\sqrt{x}, & \text{for short seeks } (a, b = \text{const.}) \\ Ax + B, & \text{for long seeks } (A, B = \text{const.}) \end{cases}$$

Similarly, Ng [9] uses the model

$$T(x) = a + b\sqrt{x} + c \log(d), \quad a, b, c = \text{const.}$$

where  $d$  denotes the recording areal density in tracks per inch. Lee and Katz [6] propose a model having no linear segment:

$$T(x) = \begin{cases} 0, & x = 0 \\ A\sqrt{x-1} + B(x-1) + T_{\min \text{ seek}}, & x > 0 \end{cases}$$

In this model,  $A$  and  $B$  are constants and  $T_{\min \text{ seek}}$  is the minimum seek time corresponding to the minimum nonzero number of cylinders  $x = 1$ . Finally, Shriver [12] suggests slightly higher model granularity:

$$T(x) = \begin{cases} 0, & x = 0 \\ a + b\sqrt{x}, & 0 < x \leq x_1 \\ c + d\sqrt{x}, & x_1 < x \leq x_2 \\ Ax + B, & x > x_2 \end{cases} \quad (a, b, c, d, A, B = \text{const.})$$

The accuracy of these models is less than the accuracy of the 4-parameter exponential model.

## A Simple Model of Cached Disk Access Time

Modern operating systems use the main memory as a disk cache. In such cases disk access is illustrated in Fig. 8.5. If data are not in the cache, it is necessary to fetch data from the disk. This causes one or more disk accesses, taking time  $T_{\text{disk}}$ . If data are already in the cache, access is very fast,  $T_{\text{cache}} \ll T_{\text{disk}}$ . The mean access time  $T_a$  of a cached disk depends on the cache hit probability  $p$ :

$$T_a = pT_{\text{cache}} + (1-p)(T_{\text{cache}} + T_{\text{disk}}) = T_{\text{cache}} + (1-p)T_{\text{disk}}$$

Probability  $p$  depends on the data access locality properties and for a large number of accesses, assuming  $C < F$ , it satisfies the inequality  $p \geq C/F$ . The lowest hit ratio,  $p = C/F$ , is obtained in the case of minimum locality, i.e., in the case of uniform distribution of disk accesses. If  $T_{\text{disk}} = T_{\text{access}}$ , the upper bound of the cached disk access time is a function of the disk file size  $F$ , which can be modeled as follows:

$$T_a(F) = \begin{cases} T_{\text{cache}}, & F \leq C \\ T_{\text{cache}} + \left(1 - \frac{C}{F}\right) \left[ T_{\max \text{ seek}} \left(\frac{F}{F_{\max}}\right)^r + \frac{30}{N_{\text{rev}}} \right], & F \geq C \end{cases}$$

This model has four adjustable parameters:  $T_{\text{cache}}$ ,  $C$ ,  $r$ , and  $T_{\max \text{ seek}}$ . Two adjustable parameters ( $T_{\text{cache}}$  and  $C$ ) represent the disk cache, and two parameters ( $T_{\max \text{ seek}}$  and  $r$ ) represent the seek time model. The simple 2-parameter seek time model  $T = T_{\max \text{ seek}}(F/F_{\max})^r$  yields sufficiently good accuracy for the most frequent cases of relatively small databases where the seek time is nonlinear. For example, in the case of the Quantum Atlas III disk, the nonlinear segment corresponds to data sizes up to  $(1686/8057) \cdot 9.1 \text{ GB} = 1.9 \text{ GB}$ . For larger databases (that require the linear segment of the seek time characteristic) we can apply the 3- and 4-parameter models described in the previous section.

**FIGURE 8.5** File access using a disk cache. (From Dujmovic, J., Tomasevich, D., and Au-Yeung, M., *Proc. CMG*, 1999, Reno, NV. With permission.)

**FIGURE 8.6** Measured and computed access times. (From Dujmovic, J., Tomasevich, D., and Au-Yeung, M., *Proc. CMG*, 1999, Reno, NV. With permission.)

**FIGURE 8.7** Measured and computed access times showing the cache size of 48 MB (magnified detail of Fig. 8.5). (From Dujmovic, J., Tomasevich, D., and Au-Yeung, M., *Proc. CMG*, 1999, Reno, NV. With permission.)

If we measure disk access times  $T_1, \dots, T_n$  for a sequence of file sizes  $F_1, \dots, F_n$ , the calibration of the above model can be performed by selecting the optimum values of  $T_{\text{cache}}$ ,  $C$ ,  $r$ , and  $T_{\text{max seek}}$ , which minimize the criterion function

$$E(T_{\text{cache}}, C, r, T_{\text{max seek}}) = \sum_{i=1}^n |T_i - T_a(F_i, T_{\text{cache}}, C, r, T_{\text{max seek}})|^q$$

The exponent  $q$  is usually selected in the range  $1 \leq q \leq 4$ , where larger values are selected in cases where the primary goal is to minimize large errors. The minimization can be performed using the traditional Nelder–Mead simplex method [8].

A verification of this model is shown in Figs. 8.6 and 8.7 for a 300 MHz PC with 64 MB of memory, Windows NT 4.5, and a 4-GB SCSI disk that has  $N_{\text{rev}} = 7200$  rev/min. The resulting parameters are  $T_{\text{cache}} = 96 \mu\text{s}$ ,  $C = 48$  MB,  $r = 0.234$ , and  $T_{\text{max seek}} = 7.51$  ms for  $F_{\text{max}} = 1400$  MB. In the majority of 245 measured points (only some of them shown in Fig. 8.6) the mean relative error of this model is less than 1%.

## Disk Access Optimization Model

The disk access time model described in the previous section assumes a single program that generates disk access requests. In such a case, all requests are served strictly in the order they are submitted and disk access optimization is not possible; however, in the case of multiprogramming, the disk queue contains multiple requests independently generated by various programs. It is possible to use a disk access optimization algorithm that increases the global disk throughput by minimizing the movement of I/O head mechanism. The simplest such an algorithm is the “shortest seek time first” (SSTF) [13,14], which can be easily analyzed.

**FIGURE 8.8** Comparing simulation and analytic models of seek time. (From Dujmovic, J., Tomasevich, D., and Au-Yeung, M., *Proc. CMG*, 1999, Reno, NV. With permission.)

A simulator for the SSTF technique can be easily written according to the following algorithm:

1. Create a disk queue with  $n$  random requests.
2. Select an arbitrary initial position of disk heads.
3. Find the request that yields the shortest distance  $x$ .
4. Compute the relative seek time  $t = \sqrt{x/x_{\max}}$  (this is a normalized time with a maximum value of 1).
5. The position of the processed request becomes the new position of the disk head mechanism.
6. Replace the processed request with a new random request.
7. Repeat steps 3–6 many times and compute the average relative (normalized) seek time.

The results of the simulation yield a decreasing relative seek time function presented in Fig. 8.8. Taking into account this function, the optimized disk access time can be well approximated, using the following model:

$$T_d(n) = t_{\min} + (t_{\max} - t_{\min})e^{\alpha(n-1)}$$

The parameter  $t_{\min}$  is introduced to reflect the mean latency time. The value of  $t_{\max}$  corresponds to the maximum seek distance. The quality of this approximation is rather good, as shown in Fig. 8.8. The exponent  $\alpha$  has a negative value, which reflects the quality of the optimization algorithm (as the quality of optimization increases, so does the absolute value of the exponent  $\alpha$ ).

## Disk Service Time Model

Generally, the mean disk access time is a decreasing function of the disk queue length and is an increasing function of file size. If we want to combine the disk cache access model and the disk access optimization model, the result can be the following formula for load dependent and cached disks:

$$T_d(F, n) = \begin{cases} T_{\text{cache}}, & F \leq C \\ T_{\text{cache}} + \frac{F-C}{F} \left[ T_{\text{max seek}} \left( \frac{F}{F_{\max}} \right)^r e^{\alpha(n-1)} + \frac{30}{N_{\text{rev}}} \right], & F > C \end{cases}$$

The disk service time is different from the mean disk access time. Disk service time is affected by caching and access optimization, but it includes only the cases of actual disk access, excluding the cases of fetching data from the cache without disk access. Consequently, we propose the following model of the load dependent cached disk service time:

$$S_d(F, n) = T_{\text{max seek}} \left( \frac{F}{F_{\max}} \right)^r e^{\alpha(n-1)} + \frac{30}{N_{\text{rev}}} + t_0, \quad F > C$$

The first term in this model reflects the optimized seek time, the second term is the latency time, and the third term reflects the data transfer time and related cache I/O operations. This model is successfully applied for the analysis of a cached system presented in the “MVA Models and Their Limitations” section. The presented load dependent service time model can also be developed using other seek time models described in the section on “Numerical Computation of the Average Seek Time.”

## Disk Subsystem Benchmark Workload

Disk subsystem workloads always lie between two obvious extremes: sequential access and uniformly distributed random access. Sequential access is more frequent, but random access is more general because it includes seek operations. Similarly, benchmark workloads must balance write and read operations. This balance is based on two facts: (1) read operations are generally more frequent than write operations and (2) write operations are less desirable in benchmarking because performance results are rather sensitive to tuning of disk formats and/or blocking factors, which frequently yields questionable results. Finally, the benchmark workload can be symmetric (i.e., balanced load, where all disks have the same load) and asymmetric (usually with bottleneck disks). Symmetric loads are more desirable in benchmarking because they better expose the capabilities of disk controller(s) and central processor(s).

A simple classification of disk workloads is presented in Table 8.1. Workload type 0 or 1 can be used for creating files that are then processed by other workloads. Workload types 2 and 3 are used for benchmarking systems using sequential access. Similarly, workloads 6 and 7 are used for benchmarking, using random access. We use workload type 6 as the basic workload for measurement of disk subsystem performance. It consists of  $n$  copies of a disk random access program DRAN that uniformly accesses files that are uniformly distributed over all disk units [3]. This is a simple balanced workload that should properly reflect disk subsystem performance and be suitable for both performance measurement and modeling. Typical results of running the DRAN workload type 6 are presented in Fig. 8.9.

The analyzed computer, VAX 8650, has 14 disk units (RA 81) and one or two disk controllers (HSC 50). Each program generates 7000 visits to the central processor, and 7000 visits to disks. Since the disk load is uniformly distributed, each program creates 500 accesses to each disk. In the case of a single program, the measured processor time for a single disk controller is 4.99 s and the total elapsed time is 163.16 s. The processor time can be interpreted as processor demand  $D_p = 4.99$  s. A queuing model of this system, in the case of two disk controllers, is shown in Fig. 8.10. The next step is to develop an analytic model for the analysis of this system.

## MVA Models and Their Limitations

Let us introduce the following variables:

$N$  = degree of multiprogramming (number of jobs in the system)

$K$  = number of service centers (processors, disks, and disk controllers)

$P_k(j|n)$  = probability that there are  $j$  jobs at the  $k$ th service center, if the total number of jobs in the system (degree of multiprogramming) is  $n$

FIGURE 8.9 Measured response times for VAX 8650. (From Dujmovic, J., Tomasevich, D., and Au-Yeung, M., *Proc. CMG*, 1999, Reno, NV. With permission.)

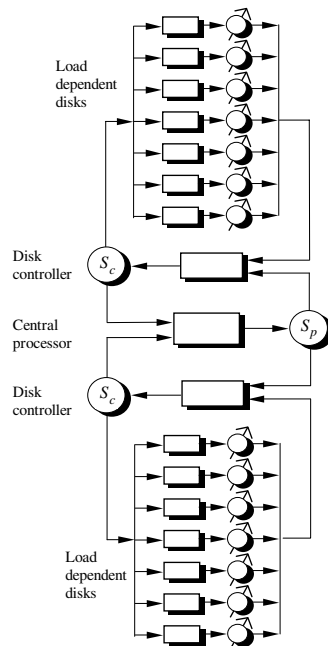

FIGURE 8.10 A queuing model of VAX 8650. (From Dujmovic, J., Tomasevich, D., and Au-Yeung, M., *Proc. CMG*, 1999, Reno, NV. With permission.)

- $R_k(n)$  = response time of the  $k$ th service center in the case of  $n$  jobs in the system ( $n = 1, \dots, N$ )
- $R(n)$  = response time of the whole system
- $U_k(n)$  = utilization of the  $k$ th server
- $Q_k(n)$  = queue length at the  $k$ th server
- $S_k(j)$  = service time of the  $k$ th server if  $j$  jobs are in the queue; if the  $k$ th server is load independent then  $S_k(j) = S_k = \text{const.}$ ,  $k \in \{1, \dots, K\}$
- $V_k$  = number of visits to the  $k$ th server per job
- $D_k$  = service demand for the  $k$ th server; in the case of load-independent servers  $D_k = V_k S_k$
- $X(n)$  = system throughput (completed jobs per time unit)
- $X_k(n)$  = throughput of the  $k$ th service center when there are  $n$  jobs in the system:  $X_k(n) = V_k X(n)$

The traditional load independent mean value analysis program (LIMVA) is based on assumption that the service times of all servers are constant. The goal of MVA models is to compute system response times, utilizations, and throughputs. Following is the traditional LIMVA model:

$$Q_k(0) = 0, \quad k = 1, \dots, K$$

**for**  $n = 1$  **to**  $N$  **do**

$$R_k(n) = S_k[1 + Q_k(n-1)], \quad k = 1, \dots, K$$

$$R(n) = \sum_{k=1}^K V_k R_k(n)$$

$$X(n) = n/R(n)$$

$$X_k(n) = V_k X(n), \quad k = 1, \dots, K$$

$$U_k(n) = S_k X_k(n) = D_k X(n), \quad k = 1, \dots, K$$

$$Q_k(n) = V_k X(n) R_k(n), \quad k = 1, \dots, K$$

**end\_for**

For perfectly balanced systems where all demands are equal ( $D = V_1 S_1 = V_2 S_2 = \dots = V_K S_K$ ), this algorithm yields equal distribution of jobs in service centers

$$Q_k(n) = n/K, \quad k = 1, \dots, K$$

This is a consequence of equal residence times:

$$V_k R_k(n) = D_k[1 + Q_k(n-1)] = D[1 + (n-1)/K], \quad k = 1, \dots, K$$

and their use for computing  $Q_k(n) = V_k X(n) R_k(n)$ . Furthermore, this yields linear response times, and other relations:

$$R(n) = K V_k R_k(n) = (n-1 + K)D$$

$$R_k(n) = (n-1 + K)S_k/K, \quad k = 1, \dots, K$$

$$X(n) = n/(n-1 + K)D$$

$$X_k(n) = n/(n-1 + K)S_k, \quad k = 1, \dots, K$$

$$U_k(n) = n/(n-1 + K), \quad k = 1, \dots, K$$

Of course, in a general case we have different demands, and the response time is no longer linear. Unfortunately, the nature of the LIMVA model is essentially quasi-linear. Even for different demands the response time curves remain similar to straight lines.

Limitations of the LIMVA model are exemplified in [Fig. 8.11](#). In this case the processor service time obtained from measurements is  $S_p = 825 \mu\text{s}$ , the number of processor visits per job is  $V_p = 7000$ , yielding processor demand  $D_p = 5.775 \text{ s}$ . The number of disks is 14 and the number of disk visits per job is  $V_d = 7000/14 = 500$ . The available resources include the central processor and 14 equally loaded disk units. A spectrum of LIMVA models can be obtained for disk service times varying in the range  $12 \text{ ms} \leq S_d \leq 24 \text{ ms}$ ,

FIGURE 8.11 A family of LIMVA models and measured VAX 8650 response time. (From Dujmovic, J., Tomasevich, D., and Au-Yeung, M., *Proc. CMG*, 1999, Reno, NV. With permission.)

and yielding disk demands in the range,  $6 \leq D_d \leq 12$  s. The corresponding response times presented in Fig. 8.11 are, in the whole range, practically straight lines and obviously inadequate for representing the measured response time function. The best approximation would be obtained for  $S_d = 16$  ms, but this approximation is equally poor as the attempt to use a straight line to approximate a parabola. The nature of the dynamic behavior of VAX 8650 is quite different from what can be modeled by LIMVA regardless how well we adjust its parameters. Thus, a more flexible model is needed. Taking into account that disks are never load-independent, because they regularly use either access optimization or access optimization and caching, we hope that better results should be expected from load dependent MVA models.

For batch systems we apply the load dependent mean value analysis model (LDMVA) introduced in [1] (see also [5,7]):

$$P_k(0|0) = 1, \quad k = 1, \dots, K$$

**for**  $n = 1$  **to**  $N$  **do**

$$R_k(n) = \sum_{j=1}^n j S_k(j) P_k(j-1|n-1), \quad k = 1, \dots, K$$

$$R(n) = \sum_{k=1}^K V_k R_k(n)$$

$$X(n) = n/R(n)$$

$$P_k(j/n) = \begin{cases} V_k S_k(j) X(n) P_k(j-1|n-1), & j = 1, \dots, n \\ 1 - \sum_{i=1}^n P_k(i|n), & j = 0 \end{cases}, \quad k = 1, \dots, K$$

$$Q_k(n) = \sum_{j=1}^n j P_k(j|n), \quad k = 1, \dots, K$$

$$Q_k(n) = 1 - P_k(0|n), \quad k = 1, \dots, K$$

**end\_for**

### Experimental Results for LDMVA Model of a Disk Subsystem with Access Optimization

Let us now apply the LDMVA model for the VAX 8650 disk subsystem modeling. The measured response and processor times can be used to adjust parameters of the LDMVA model. This is called calibration of the queuing model. The calibration process is based on measured response times  $T_{m1}(n)$  and  $T_{m2}(n)$ , which correspond to systems with one and two disk controllers. Suppose that the load dependent disk service time is approximated by  $S_d(n) = t_{\min} + (t_{\max} - t_{\min})e^{\alpha(n-1)}$ . The parameters of the LDMVA model are  $t_{\min}$ ,  $t_{\max}$ ,  $\alpha$ ,  $S_p$ ,  $S_c$ . Let  $R_{c1}(n, t_{\min}, t_{\max}, \alpha, S_p, S_c)$  and  $R_{c2}(n, t_{\min}, t_{\max}, \alpha, S_p, S_c)$  be the response times computed from the LDMVA model, respectively using one and two controllers. The model calibration procedure is based on the minimization of the compound criterion function

$$C(t_{\min}, t_{\max}, a, S_p, S_c) = \max \left( \sum_{i=1}^n [T_{m1}(n) - R_{c1}(t_{\min}, t_{\max}, a, S_p, S_c)]^2, \sum_{i=1}^n [T_{m2}(n) - R_{c2}(t_{\min}, t_{\max}, a, S_p, S_c)]^2 \right)$$

The results of calibration performed using the Nelder-Mead simplex method [8] are the following values of parameters:  $t_{\min} = 11.5$  ms,  $t_{\max} = 20$  ms,  $a = -4$ ,  $S_p = 0.822$  ms, and  $S_c = 0.89$  ms. The mean relative error for all presented points is 1% (Fig. 8.12). At this level of description error it is realistic to expect good prediction results.

### Experimental Results for LDMVA Model of a Disk Subsystem with Caching and Access Optimization

In this experiment, we use the same 300 MHz PC presented in the “Numerical Computation of the Average Seek Time” section and Figs. 8.6 and 8.7. Its memory capacity is 64 MB with two disk units, and the disk cache size under Windows NT 4.5 is  $C = 48$  MB. The measured response times for DRAN

**FIGURE 8.13** Measured response times and the results of the LDMVA model. (From Dujmovic, J., Tomasevich, D., and Au-Yeung, M., *Proc. CMG*, 1999, Reno, NV. With permission.)

benchmarks accessing a 100 MB file and 1 GB file are presented in Fig. 8.13. The LDMVA model we used is based on measured disk parameters reported in the “Numerical Computation of the Average Seek Time” section and on the disk service time model  $S_d(F, n)$  proposed in the section on “Disk Access Optimization Model.” Disk accesses to a file of size  $F$  occur with the probability  $(F - C)/F$  and cache accesses with the probability  $C/F$ . The number of disk visits  $V_d$  now depends on the number of processor visits  $V_p$  and the size of file. If the number of disks is  $k$  then  $V_d(F) = V_p(F - C)/kF$ . Therefore, the disk cache causes both the disk service time and the number of visits to be functions of the file size. Processor service time is not constant. For cache accesses it can be expressed as  $S_p = t_p^{\text{prog}} + t_p^{\text{cache}}$  and for disk accesses as  $S_p = t_p^{\text{prog}} + t_p^{\text{cache}} + t_p^{\text{disk}}$ , where the three components correspond to the processor activity for the benchmark program, cache access, and serving the file management system during the disk access. The mean service time is  $S_p = t_p^{\text{prog}} + t_p^{\text{cache}} + t_p^{\text{disk}}(F - C)/F$ . The calibrated model in Fig. 8.13 has the mean modeling error of 7.4%.

### Predictive Power of Queuing Models

All queuing models have adjustable parameters (e.g., the processor and disk service times). The default values of these parameters, taken from manufacturers specifications, regularly yield rather large prediction errors. These errors can be reduced by corrections of parameters in a calibration process. During the model calibration the parameters are adjusted to minimize the difference between the measured values and computed values from the model. In essence, this is just a standard curve fitting process, and the resulting low description error is not necessarily a proof of the quality of the model. The only way to assess the quality of the model is through the analysis of the prediction errors.

Let  $n$  be the number of measured response times  $R_1, \dots, R_n$  and let us use the first  $m$  measured values,  $R_1, \dots, R_m$ ,  $m \leq n$ , for the model calibration. The indicator  $p = 100 m/n$  shows the percent of values used for calibration. Let  $e(p)$  denote the average relative error between the measured vales and the values of the calibrated model for the whole range of  $n$  data points. Generally,  $e(p)$  is expected to be a decreasing function, and three typical such functions are presented in Figs. 8.14 and 8.15.

In all cases, we measured the processor time and used this value in our LDMVA model. The calibration process included three parameters of the disk subsystem (minimum service time  $t_{\text{min}}$ , maximum service time  $t_{\text{max}}$  and the exponent  $\alpha$  introduced in the section on “A Simple Model of Cached Disk Access Time”). Consequently, the  $e(p)$  function starts with  $m = 3$  points.

**FIGURE 8.14** Prediction errors  $e(p)$  for VAX 11/785. (From Dujmovic, J., Tomasevich, D., and Au-Yeung, M., *Proc. CMG*, 1999, Reno, NV. With permission.)

**FIGURE 8.15** Prediction errors  $e(p)$  for VAX 8650. (From Dujmovic, J., Tomasevich, D., and Au-Yeung, M., *Proc. CMG*, 1999, Reno, NV. With permission.)

In the ideal theoretical case of a perfect model, we expect  $e(p) = 0$  for all  $m \geq 3$ . Good predictive power of a model is indicated by  $e(p)$ , approaching a constant low value as soon as possible. Consequently, the predictive power is related to the smallest value of  $p$  after which  $e(p)$  remains in the  $\delta$  neighborhood of the minimum  $e_{\min} = \min_{p \leq 100\%} e(p)$ . Let us denote this value as  $p^*(\delta)$ . In other words

$$e(p) > (1 + \delta)e_{\min}, \quad \forall p < p^*(\delta)$$

Now, we can define the following predictive power quality indicator:

$$q(\delta) = \frac{1 - p^*(\delta)}{1 - p_{\min}} 100\%$$

where  $p_{\min}$  denotes the minimum value of  $p$  necessary for calibration (in our examples  $p_{\min}$  corresponds to  $m = 3$ ).

The case in Fig. 8.14 reaches the minimum error  $e(100\%) = 2.16\%$ . Let us take  $\delta = 0.2$ . Then we have  $(1 + \delta)e_{\min} = 2.59\%$ ,  $p^*(0.2) = 0.875(87.5\%)$ , and the resulting predictive power is rather low:

$$q(0.2) = \frac{1 - 0.875}{1 - 0.375} 100\% = 20\%$$

In the case of Fig. 8.15, the model with 1 HSC50 disk controller yields  $e_{\min} = 1.53\%$ , and for  $\delta = 0.2$  we have:

$$(1 + \delta)e_{\min} = 1.84\%, \quad p^*(0.2) = 0.7, \quad q(0.2) = 35.3\%$$

Finally, the predictive power in the case with two HSC50 disk controllers is much better: we have  $e_{\min} = 0.64\%$  yielding

$$(1 + \delta)e_{\min} = 0.77\%, \quad p^*(0.2) = 0.35, \quad q(0.2) = 76.5\%$$

## Conclusions

Even in cases of fully controlled simple synthetic workloads, the performance modeling of disk subsystems is not a simple task. Basic popular load independent queuing models (load independent convolution algorithm or MVA) cannot be used for modeling modern disk subsystems, which use caching and disk access optimization. The use of load dependent MVA models is rather efficient and we proposed models for optimized disk access, cached disk access, and combined optimized and cached disk access. Presented models need a careful calibration procedure. In the majority of cases based on symmetric random disk accesses the modeling errors for optimized disk access were less than 2%. In more complex cases with optimized disk accesses and caching, our models regularly achieve errors below 10%. Experimental verification of our models has been successfully performed in both VAX/VMS and PC/NT environments.

## 8.2 Performance Evaluation: Techniques, Tools, and Benchmarks

*Lizy Kurian John*

### Introduction

State-of-the-art high performance microprocessors contain tens of millions of transistors and operate at frequencies close to 2 GHz. These processors perform several tasks in overlap, employ significant amounts of speculation and out-of-order execution, and other microarchitectural techniques, and are true marvels of engineering. Designing and evaluating these microprocessors is a major challenge, especially considering the fact that one second of program execution on these processors involves several billion instructions and analyzing one second of execution may involve dealing with tens of billion pieces of information.

In general, design of microprocessors and computer systems involves several steps (i) understanding applications and workloads that the systems will be running, (ii) innovating potential designs, (iii) evaluating performance of the candidate designs, and (iv) selecting the best design. The large number of potential designs and the constantly evolving nature of workloads have resulted in designs being largely adhoc. In this article, we investigate major techniques used in the performance evaluation process.

It should be noted that performance evaluation is needed at several stages of the design. In early stages, when the design is being conceived, performance evaluation is used to make early design tradeoffs. Usually, this is accomplished by simulation models, because building prototypes of state-of-the-art microprocessors is expensive and time consuming. Several design decisions are made before any prototyping is done. Once the design is finalized and is being implemented, simulation is used to evaluate functionality and performance of subsystems. Later, performance measurement is done after the product is available in order to understand the performance of the actual system to various real world workloads and to identify modifications to incorporate in future designs.

Performance evaluation can be classified into performance modeling and performance measurement, as illustrated in [Table 8.2](#). Performance measurement is possible only if the system of interest is available for measurement and only if one has access to the parameters of interest. Performance measurement may further be classified into on-chip hardware monitoring, off-chip hardware monitoring, software monitoring, and microcoded instrumentation. Performance modeling is typically used when actual systems are not available for measurement or, if the actual systems do not have test points to measure every detail of interest. Performance modeling may further be classified into simulation modeling and analytical modeling. Simulation models may further be classified into numerous categories depending

on the mode/level of detail of simulation. Analytical models use probabilistic models, queueing theory, Markov models or Petri nets.

Performance modeling/measurement techniques and tools should possess several desirable features

- They must be accurate. It is easy to build models that are heavily sanitized, however, such models will not be accurate.
- They must be noninvasive. The measurement process must not alter the system or degrade the system's performance.
- They must not be expensive. Building the performance measurement facility should not cost significant amount of time or money.
- They must be easy to change or extend. Microprocessors and computer systems constantly undergo changes and it must be easy to extend the modeling/measurement facility to include the upgraded system.
- They must not need source code of applications. If tools and techniques necessitate source code, it will not be possible to evaluate commercial applications where source is not often available.
- They should measure all activity including kernel and user activity. Often it is easy to build tools that measure only user activity. This was acceptable in traditional scientific and engineering workloads; however, in database, Web server, and Java workloads, significant operating system activity exists, and it is important to build tools that measure operating system activity as well.
- They should be capable of measuring a wide variety of applications including those that use signals, exceptions, and DLLs (dynamically linked libraries).
- They should be user-friendly. Hard-to-use tools often are underutilized. Hard-to-use tools also result in more user error.
- They should be fast. If a performance model is very slow, long-running workloads, which take hours to run, may take days or weeks to run on the model. If an instrumentation tool is slow, it can be invasive.
- Models should provide control over aspects that are measured. It should be possible to selectively measure what is required.
- Models and tools should handle multiprocessor systems and multithreaded applications. Dual and quad-processor systems are very common nowadays. Applications are becoming increasingly multithreaded especially with the advent of Java, and it is important that the tool handles these.
- It will be desirable for a performance evaluation technique to be able to evaluate the performance of systems that are not yet built.

Many of these requirements are often conflicting. For instance, it is difficult for a mechanism to be fast and accurate. Consider mathematical models. They are fast, although several simplifying assumptions go into their creation, and often they are not accurate. Similarly, it is difficult for a tool to be noninvasive and user-friendly. Many users like graphical user interfaces (GUIs), however, most instrumentation and simulation tools with GUIs are slow and invasive.

Benchmarks and metrics to be used for performance evaluation have always been interesting and controversial issues. There has been a lot of improvement in benchmark suites since 1988. Before that computer performance evaluation has been largely with small benchmarks such as kernels extracted from applications (e.g., Lawrence Livermore Loops), Dhrystone and Whetstone benchmarks, Linpack, Sorting, Sieve of Eratosthenes, 8-queens problem, Tower of Hanoi, etc. [1]. The Standard Performance Evaluation Cooperative (SPEC) consortium and the Transactions Processing Council (TPC) formed in 1988 have made available several benchmark suites and benchmarking guidelines to improve the quality of benchmarking. Several state-of-the-art benchmark suites are described in the "Workloads and Benchmarks" section.

Another important issue in performance evaluation is the choice of performance metric. For a system level designer, execution time and throughput are two important performance metrics. Execution time

is generally the most important measure of performance. Execution time is the product of the number of instructions, cycles per instruction (CPI), and the clock period. Throughput of an application is a more important metric, especially in server systems. In servers that serve the banking industry, airline industry, or other similar businesses, what is important is the number of transactions that could be completed in unit time. Such servers, typically called transaction processing systems use transactions per minute (tpm) as a performance metric. Millions of instructions per second (MIPS) and million of floating point operations per second (MFLOPS) were very popular measures of performance in the past. Both of these are very simple and straightforward to understand and hence have been used often, however, they do not contain all three components of program execution time and hence are incomplete measures of performance. Several low level metrics are of interest to microprocessor designers, in order to help them identify performance bottlenecks and tune their designs. Cache hit ratios, branch misprediction ratios, number of off-chip memory accesses, etc. are examples of such measures.

Another major problem is the issue of reporting performance with a single number. A single number is easy to understand and easy to be used by the trade press. Use of several benchmarks also makes it necessary to find some kind of a mean. Arithmetic mean, geometric mean, and harmonic mean are three ways of finding the central tendency of a group of numbers; however, it should be noted that each of these means should be used in appropriate conditions depending on the nature of the numbers which need to be averaged. Simple arithmetic mean can be used to find average execution time from a set of execution times. Geometric mean can be used to find the central tendency of metrics that are in the form of ratios (e.g., speedup) and harmonic mean can be used to find the central tendency of measures that are in the form of a rate (e.g., throughput). Cragon [2] and Smith [3] discuss the use of the appropriate mean for a given set of data. Cragon [2] and Patterson and Hennessy [4] illustrate several mistakes one could possibly make while finding a single performance number.

The rest of this chapter section is organized as follows. “Performance Measurement” describes performance measurement techniques including hardware on-chip performance monitoring counters on microprocessors. “Performance Modeling” describes simulation and analytical modeling of microprocessors and computer systems. “Workloads and Benchmarks” presents several state-of-the-art benchmark suites for a variety of workloads. Due to space limitations, we describe some typical examples of tools and techniques and provide the reader with pointers for more information.

## Performance Measurement

Performance measurement is used for understanding systems that are already built or prototyped. Performance measurement can serve two major purposes: tune this system or systems to be built and tune the application if source code and algorithms can still be changed. Essentially, the process involves (i) understanding the bottlenecks in the system that has been built, (ii) understanding the applications that are running on the system and the match between the features of the system and the characteristics of the workload, and (iii) innovating design features that will exploit the workload features. Performance measurement can be done via the following means:

- Microprocessor on-chip performance monitoring counters
- Off-chip hardware monitoring
- Software monitoring
- Microcoded instrumentation

### On-Chip Performance Monitoring Counters

All state-of-the-art high performance microprocessors including Intel’s Pentium III and Pentium IV, IBM’s POWER 3 and POWER 4 processors, AMD’s Athlon, Compaq’s Alpha, and Sun’s UltraSPARC processors incorporate on-chip performance monitoring counters, which can be used to understand performance of these microprocessors, while they run complex, real-world workloads. This ability has overcome a serious limitation of simulators, that they often could not execute complex workloads. Now, complex run-time systems involving multiple software applications can be evaluated and monitored very closely.

All microprocessor vendors nowadays release information on their performance monitoring counters, although they are not part of the architecture.

For illustration of on-chip performance monitoring, we use the Intel Pentium processors. The microprocessors in the Intel Pentium contain two performance monitoring counters. These counters can be read with special instructions (e.g., RDPMC) on the processor. The counters can be made to measure user and kernel activity in combination or in isolation. A variety of performance events can be measured using the counters [50]. For illustration of the nature of the events that can be measured, Table 8.3 lists a small subset of the events that can be measured on the Pentium III. Although more than 200 distinct events can be measured on the Pentium III, only two events can be measured simultaneously. For design simplicity, most microprocessors limit the number of events that can be simultaneously measured to 4 or 5. At times, certain events are restricted to be accessible only through a particular counter. These steps are necessary to reduce the overhead associated with on-chip performance monitoring. Performance counters do consume on-chip real estate. Unless carefully implemented, they can also impact the processor cycle time.

Several tools are available to measure performance using performance monitoring counters. Table 8.4 lists some of the available tools. Intel's *Vtune* software may be used to perform measurements using the Intel processor performance counters [5]. The *P6Perf* utility is a plug-in for Windows NT performance monitoring [6]. The Compaq DIGITAL Continuous Profiling Infrastructure (DCPI) is a very powerful

tool to profile programs on the Alpha processors [7,8]. The performance monitor *perf-mon* is a small hack that uses the on-chip counters on UltraSPARC-I/II processors to gather statistics [9]. Packages like Vtune perform extensive post-processing and present data in graphical forms; however, extensive post-processing can sometimes result in tools that are somewhat invasive. *PMON* [10] is a counter reading software written by Juan Rubio of the Laboratory for Computer Architecture at the University of Texas. It provides a mechanism to read specified counters with minimal or no perceivable overhead. All these tools measure user and operating system activity. Since everything on a processor is counted, effort should be made to have minimal or no other undesired process running during experimentation. This type of performance measurement can be done on binaries, and no source code is desired.

## **Off-Chip Hardware Measurement**

Instrumentation using hardware means can also be done by attaching off-chip hardware, two examples of which are described in this section.

### ***SpeedTracer from AMD***

AMD developed this hardware tracing platform to aid in the design of its x86 microprocessors. When an application is being traced, the tracer interrupts the processor on each instruction boundary. The state of the CPU is captured on each interrupt and then transferred to a separate control machine where the trace is stored. The trace contains virtually all valuable pieces of information for each instruction that executes on the processor. Operating system activity can also be traced; however, tracing in this manner can be invasive, and may slow down the processor. Although the processor is running slower, external events such as disk and memory accesses still happen in real time, thus looking very fast to the slowed-down processor. Usually, this issue is addressed by adjusting the timer interrupt frequency. Use of this performance monitoring facility can be seen in Merten [11] and Bhargava[12].

### ***Logic Analyzers***

Poursepanj and Christie [13] use a Tektronix TLA 700 logic analyzer to analyze 3D graphics workloads on AMD-K6-2-based systems. Detailed logic analyzer traces are limited by restrictions on sizes and are typically used for the most important sections of the program under analysis. Preliminary coarse level analysis can be done by performance monitoring counters and software instrumentation. Poursepanj and Christie used logic analyzer traces for a few tens of frames, which covered a second or two of smooth motion [13].

## **Software Monitoring**

Software monitoring is often performed by utilizing architectural features such as a trap instruction or a breakpoint instruction on an actual system, or on a prototype. The VAX processor from Digital (now Compaq) had a T-bit that caused an exception after every instruction. Software monitoring used to be an important mode of performance evaluation before the advent of on-chip performance monitoring counters. The primary advantage of software monitoring is that it is easy to do. The primary disadvantage is that the instrumentation can slow down the application. The overhead of servicing the exception, switching to a data collection process, and performing the necessary tracing can slow down a program by more than 1000 times. Another disadvantage is that software monitoring systems, typically, only handle the user activity.

## **Microcoded Instrumentation**

Digital used microcoded instrumentation to obtain traces of VAX and Alpha architectures. The ATUM tool [14] used extensively by Digital in the late 1980s and early 1990s uses microcoded instrumentation. This is a technique lying between trapping information on each instruction, using hardware interrupts (traps) or software traps. The tracing system essentially modified the VAX microcode to record all instruction and data references in a reserved portion of memory. Unlike software monitoring, ATUM could trace all processes including the operating system, but this kind of tracing is invasive, and can slow down the system by a factor of 10 without including the time to write the trace to the disk.

## Performance Modeling

Performance measurement as described in the previous section can be done only if the actual system or a prototype exists. It is expensive to build prototypes for early stage evaluation. Hence, one needs to resort to some kind of modeling in order to study systems yet to be built. Performance modeling can be done using simulation models or analytical models.

### Simulation

Simulation has become the de facto performance modeling method in the evaluation of microprocessor architectures for several reasons. The accuracy of analytical models in the past has been insufficient for the type of design decisions computer architects wish to make (for instance, what kind of caches or branch predictors are needed), therefore, cycle accurate simulation has been used extensively by architects. Simulators model existing or future machines or microprocessors. They are essentially a model of the system being simulated, written in a high-level computer language such as C or Java, and running on some existing machine. The machine on which the simulator runs is called the host machine and the machine being modeled is called the target machine. Such simulators can be constructed in many ways.

Simulators can be functional simulators or timing simulators. They can be trace driven or execution driven simulators. They can be simulators of components or that of the complete system. Functional simulators simulate functionality of the target processor, and in essence provide a component similar to the one being modeled. The register values of the simulated machine are available in the equivalent registers of the simulator. In addition to the values, the simulators also provide performance information in terms of cycles of execution, cache hit ratios, branch prediction rates, etc. Thus, the simulator is a virtual component representing the microprocessor or subsystem being modeled plus a variety of performance information.

If performance evaluation is the only objective, one does not need to model the functionality. For instance, a cache performance simulator does not need to actually store values in the cache; it only needs to store information related to the address of the value being cached. That information is sufficient to determine a future hit or miss. Although it is nice to have the values as well, a simulator that models functionality in addition to performance is bound to be slower than a pure performance simulator. Register transfer language (RTL) models used for functional verification may also be used for performance simulations, however, these models are very slow for performance estimation with real-world workloads and are not discussed in this article.

### *Trace Driven Simulation*

Trace driven simulation consists of a simulator model whose input is modeled as a trace or sequence of information representing the instruction sequence that would have actually executed on the target machine. A simple trace driven cache simulator needs a trace consisting of address values. Depending on whether the simulator is modeling a unified instruction or data cache, the address trace should contain addresses of instruction and data references.

Cachesim5 and Dinero IV are examples of cache simulators for memory reference traces. Cachesim5 comes from Sun Microsystems along with its Shade package [15]. Dinero IV [16] is available from the University of Wisconsin, Madison. These simulators are not timing simulators. There is no notion of simulated time or cycles, only references. They are not functional simulators. Data and instructions do not move in and out of the caches. The primary result of simulation is hit and miss information. The basic idea is to simulate a memory hierarchy consisting of various caches. The various parameters of each cache can be set separately (architecture, mapping policies, replacement policies, write policy, statistics). During initialization, the configuration to be simulated is built up, one cache at a time, starting with each memory as a special case. After initialization, each reference is fed to the appropriate top-level cache by a single simple function call. Lower levels of the hierarchy are handled automatically. One does not need to store a trace while using Cachesim5, because Shade can directly feed the trace into Cachesim5.

Trace driven simulation is simple and easy to understand. The simulators are easy to debug. Experiments are repeatable because the input information is not changing from run to run; however, trace

driven simulation has two major problems:

1. Traces can be prohibitively long if entire executions of some real-world applications are considered. The storage needed by the traces may be prohibitively large. Trace size is proportional to the dynamic instruction count of the benchmark.
2. The traces do not represent the actual stream of processors with branch predictions. Most trace generators generate traces of only completed or retired instructions in speculative processors. Hence, they do not contain instructions from the mispredicted path.

The first problem is typically solved using trace sampling and trace reduction techniques. Trace sampling is a method to achieve reduced traces; however, the sampling should be performed in such a way that the resulting trace is representative of the original trace. It may not be sufficient to periodically sample a program execution. Locality properties of the resulting sequence may be widely different from that of the original sequence. Another technique is to skip tracing for a certain interval, then collect for a fixed interval, and then skip again. It may also be needed to leave a warm-up period after the skip interval, to let the caches and other such structures to warm up [17]. Several trace sampling techniques are discussed by Crowley and Baer [18]. The QPT trace collection system [19] solves the trace size issue by splitting the tracing process into a trace record generation step and a trace regeneration process. The trace record has a size similar to the static code size, and the trace regeneration expands it to the actual full trace upon demand.

The second problem can be solved by reconstructing the mispredicted path [20]. An image of the instruction memory space of the application is created by one pass through the trace, and, thereafter, fetching from this image as opposed to the trace. Although 100% of the mispredicted branch targets may not be in the recreated image, studies show that more than 95% of the targets can be located.

### ***Execution Driven Simulation***

Researchers and practitioners assign two meanings to this term. Some refer to simulators that take program executables as input as execution driven simulators. These simulators utilize the actual input executable and not a trace. Hence, the size of the input is proportional to the static instruction count and not the dynamic instruction count. Mispredicted branches can be accurately simulated as well. Thus, these simulators solve the two major problems faced by trace driven simulators. The widely used SimpleScalar simulator [21] is an example of such an execution driven simulator. With this tool set, the user can simulate real programs on a range of modern processors and systems, using fast execution driven simulation. There is a fast functional simulator and a detailed, out-of-order issue processor that supports non-blocking caches, speculative execution, and state-of-the-art branch prediction.

Some others consider execution driven simulators to be simulators that rely on actual execution of parts of code on the host machine (hardware acceleration by the host instead of simulation) [22]. These execution driven simulators do not simulate every individual instruction in the application. Only the instructions that are of interest are simulated. The remaining instructions are directly executed by the host computer. This can be done when the instruction set of the host is the same as that of the machine being simulated. Such simulation involves two stages. In the first stage or preprocessing, the application program is modified by inserting calls to the simulator routines at events of interest. For instance, for a memory system simulator, only memory access instructions need to be instrumented. For other instructions, the only important thing is to make sure that they get performed and that their execution time is properly accounted for. The advantage of execution driven simulation is speed. By directly executing most instructions at the machine's execution rate, the simulator can operate orders of magnitude faster than cycle by cycle simulators that emulate each individual instruction. Tango, Proteus, and FAST are examples of such simulators [22].

### ***Complete System Simulation***

Many execution and trace driven simulators only simulate the processor and memory subsystem. Neither I/O activity nor operating system activity is handled in simulators such as SimpleScalar. But in many workloads, it is extremely important to consider I/O and operating system activity. Complete system simulators are complete simulation environments that model hardware components with enough detail to boot and

**TABLE 8.5** Examples of Complete System Simulators

run a full-blown commercial operating system. The functionality of the processors, memory subsystem, disks, buses, SCSI/IDE/FC controllers, network controllers, graphics controllers, CD-ROM, serial devices, timers, etc. are modeled accurately in order to achieve this. Although functionality stays the same, different microarchitectures in the processing component can lead to different performance. Most of the complete system simulators use microarchitectural models that can be plugged in and out. For instance, SimOS [23], a popular complete system simulator, provides a simple pipelined processor model and an aggressive superscalar processor model. SimOS and SIMICS [24,25] can simulate uniprocessor and multiprocessor systems. Table 8.5 lists popular complete system simulators.

#### ***Stochastic Discrete Event Driven Simulation***

It is possible to simulate systems in such a way that the input is derived stochastically rather than as a trace/executable from an actual execution. For instance, one can construct a memory system simulator in which the inputs are assumed to arrive according to a Gaussian distribution. Such models can be written in general purpose languages such as C, or using special simulation languages such as SIMSCRIPT. Languages such as SIMSCRIPT have several built-in primitives to allow quick simulation of most kinds of common systems. Built-in input profiles including resource templates, process templates, queue structures, etc., facilitate easy simulation of common systems. An example of the use of event driven simulators using SIMSCRIPT may be seen in the performance evaluation of multiple-bus multiprocessor systems in Kurian et. al [26,27].

#### ***Program Profilers***

Software profiling tools is a class of tools that is similar to simulators and performance measurement tools. These tools are used to generate traces, to obtain instruction mix, and a variety of instruction statistics. They can be thought of as software monitoring on a simulator. They input an executable and decode and analyze each instruction in the executable. These program profilers can be used as the front end of simulators. A popular program profiling tool is Shade for the UltraSparc [15].

#### ***Shade***

Shade is a fast instruction-set simulator for execution profiling. It is a simulation and tracing tool that provides features of simulators and tracers in one tool. Shade analyzes the original program instructions and cross-compiles them to sequences of instructions that simulate or trace the original code. Static cross-compilation can produce fast code, but purely static translators cannot simulate and trace all details of dynamically linked code. One can develop a variety of analyzers to process the information generated by Shade and create the performance metrics of interest. For instance, one can use shade to generate address traces to feed into a cache analyzer to compute hit-rates and miss rates of cache configurations. The Shade analyzer Cachesim5 does exactly this.

#### ***Jaba***

Jaba [46] is a Java Bytecode Analyzer developed at the University of Texas for tracing Java programs. Although Java programs can be traced using shade to obtain profiles of native execution, Jaba can yield profiles at the bytecode level. It uses JVM specification 1.1. It allows the user to gather information about the dynamic execution of a Java application at the Java bytecode level. It provides information on bytecodes executed, load operations, branches executed, branch outcomes, etc. Use of this tool can be found in [47].

A variety of profiling tools exist for different platforms. In addition to describing the working of Shade, Cmelik et. al [15] also compares Shade to several other profiling tools for other platforms. A popular one for the x86 platform is Etch [51]. Conte and Gimarc [52] is a good source of information to those interested in creating profiling tools.

## Analytical Modeling

Analytical performance models, while not popular for microprocessors, are suitable for evaluation of large computer systems. In large systems, where details cannot be modeled accurately for cycle accurate simulation, analytical modeling is an appropriate way to obtain approximate performance metrics. Computer systems can generally be considered as a set of hardware and software resources and a set of tasks or jobs competing for using the resources. Multicomputer systems and multiprogrammed systems are examples.

Analytical models rely on probabilistic methods, queuing theory, Markov models, or Petri nets to create a model of the computer system. A large body of literature on analytical models of computer exists from the 1970s and early 1980s. Heidelberger and Lavenberg [28] published an article summarizing research on computer performance evaluation models. This article contains 205 references, which cover all important work on performance evaluation until 1984. Readers interested in analytical modeling should read this article.

Analytical models are cost-effective because they are based on efficient solutions to mathematical equations; however, in order to be able to have tractable solutions, often, simplifying assumptions are made regarding the structure of the model. As a result, analytical models do not capture all the detail typically built into simulation models. It is generally thought that carefully constructed analytical models can provide estimates of average job throughputs and device utilizations to within 10% accuracy and average response times within 30% accuracy. This level of accuracy, while insufficient for microarchitectural enhancement studies, is sufficient for capacity planning in multicomputer systems, I/O subsystem performance evaluation in large server farms, and in early design evaluations of multiprocessor systems.

Only a small amount of work has been done on analytical modeling of microprocessors. The level of accuracy needed in trade off analysis for microprocessor structures is more than what typical analytical models can provide; however, some effort into this arena came from Noonburg and Shen [29] and Sorin et al. [30]. Those interested in modeling superscalar processors using analytical models should read Noonburg et al.'s work [29] and Sorin et al.'s work [30]. Noonburg et al. used a Markov model to model a pipelined processor. Sorin et al. used probabilistic techniques to processor a multiprocessor composed of superscalar processors. Queuing theory is also applicable to superscalar processor modeling, as modern superscalar processors contain instruction queues in which instructions wait to be issued to one among a group of functional units.

## Workloads and Benchmarks

Benchmarks used for performance evaluation of computers should be representative of applications that are run on actual systems. Contemporary computer applications include a variety of applications, and different benchmarks are appropriate for systems targeted for different purposes. [Table 8.6](#) lists several popular benchmarks for different classes of workloads.

### CPU Benchmarks

**SPEC CPU2000** is the industry-standardized CPU-intensive benchmark suite. The System Performance Evaluation Cooperative (SPEC) was founded in 1988 by a small number of workstation vendors who realized that the marketplace was in desperate need of realistic, standardized performance tests. The basic SPEC methodology is to provide the benchmarker with a standardized suite of source code based upon existing applications that has already been ported to a wide variety of platforms by its membership. The benchmarker then takes this source code, compiles it for the system in question. The use of already accepted and ported source code greatly reduces the problem of making apples-to-oranges comparisons. SPEC designed CPU2000 to provide a comparative measure of compute intensive performance across the widest practical range of hardware. The implementation resulted in source code benchmarks developed from real user applications. These benchmarks measure the performance of the processor, memory, and compiler on the tested system. The suite contains 14 floating point programs written in C/Fortran and 11 integer

programs (10 written in C and 1 in C++). The SPEC CPU2000 benchmarks replace the SPEC89, SPEC92, and SPEC95 benchmarks.

**The Java Grande Forum Benchmark suite** consists of three groups of benchmarks—microbenchmarks that test individual low-level operations (e.g., arithmetic, cast, create), Kernel benchmarks which are the heart of the algorithms of commonly used applications (e.g., heapsort, encryption/decryption, FFT, Sparse matrix multiplication, etc.), and applications (e.g., Raytracer, Monte Carlo simulation, Euler equation solution, molecular dynamics, etc.) [48]. These are compute intensive benchmarks available in Java.

**SciMark** is a composite Java benchmark measuring the performance of numerical codes occurring in scientific and engineering applications. It consists of five computational kernels: FFT, Gauss-Seidel relaxation, Sparse matrix-multiply, Monte Carlo integration, and dense LU factorization. These kernels are chosen to provide an indication of how well the underlying Java Virtual Machines perform on applications utilizing these types of algorithms. The problems sizes are purposely chosen to be small in order to isolate the effects of memory hierarchy and focus on internal JVM/JIT and CPU issues. A larger version of the benchmark (SciMark 2.0 LARGE) addresses performance of the memory subsystem with out-of-cache problem sizes.

**ASCI**, the Accelerated Strategic Computing Initiative (ASCI) of the Lawrence Livermore laboratories contains several numeric codes suitable for evaluation of compute intensive systems. The programs are available from [34].

**SPLASH**, the SPLASH suite was created by Stanford researchers [35]. The suite contains six scientific and engineering applications, all of which are parallel applications.

**NAS Parallel Benchmarks (NPB)** are a set of eight programs designed to help evaluate the performance of parallel supercomputers. The benchmarks, which are derived from computational fluid dynamics (CFD) applications, consist of five kernels and three pseudo-applications.

## **Embedded and Media Benchmarks**

### ***EEMBC Benchmarks***

The EDN Embedded Microprocessor Benchmark Consortium (EEMBC—pronounced “embassy”) was formed in April 1997 to develop meaningful performance benchmarks for processors in embedded applications. EEMBC is backed by the majority of the processor industry and has therefore established itself as the industry-standard embedded processor benchmarking forum. EEMBC establishes benchmark standards and provides certified benchmarking results through the EEMBC Certification Labs (ECL) in Texas and California. The EEMBC’s benchmarks comprise a suite of benchmarks designed to reflect real-world applications, while it also includes some synthetic benchmarks. These benchmarks target the automotive/industrial, consumer, networking, office automation, and telecommunications markets. More specifically, these benchmarks target specific applications that include engine control, digital cameras, printers, cellular phones, modems, and similar devices with embedded microprocessors. The EEMBC consortium dissected these applications and derived 37 individual algorithms that constitutes the EEMBC’s Version 1.0 suite of benchmarks.

### ***BDTI Benchmarks***

Berkeley Design Technology, Inc. (BDTI) is a technical services company that has focused exclusively on digital signal processing (DSP) since 1991. BDTI provides the industry standard BDTI Benchmarks™, a proprietary suite of DSP benchmarks. BDTI also develops custom benchmarks to determine performance on specific applications. The benchmarks contain DSP routines such as FIR filter, IIR filter, FFT, dot-product, and Viterbi decoder.

### ***MediaBench***

The MediaBench benchmark suite consists of several applications belonging to the image processing, communications and DSP applications. Examples of applications that are included are JPEG, MPEG, GSM, G.721 Voice compression, Ghostscript, ADPCM, etc. JPEG is the compression program for images, MPEG involves encoding/decoding for video transmission, Ghostscript is an interpreter for the Postscript language, and ADPCM is adaptive differential pulse code modulation. The MediaBench is an academic effort to assemble several media processing related benchmarks. An example of the use of these benchmarks may be found in [49].

## **Java Benchmarks**

**SPECjvm98**, the SPECjvm98 suite consists of a set of programs intended to evaluate performance for the combined hardware (CPU, cache, memory, and other platform-specific performance) and software aspects (efficiency of JVM, the JIT compiler, and OS implementations) of the JVM client platform [31]. The SPECjvm98 uses common computing features such as integer and floating point operations, library calls and I/O, but does not include AWT (window), networking, and graphics. Each benchmark can be run with three different input sizes referred to as S1, S10, and S100. The 7 programs are compression/decompression (compress), expert system (jess), database (db), Java compiler (javac), mpeg3 decoder (mpegaudio), raytracer (mtrt), and a parser (jack).

**SPECjbb2000** (Java Business Benchmark) is SPEC’s first benchmark for evaluating the performance of server-side Java. The benchmark emulates an electronic commerce workload in a 3-tier system. The benchmark contains business logic and object manipulation, primarily representing the activities of the middle tier in an actual business server. It models a wholesale company with warehouses serving a number of districts. Customers initiate a set of operations such as placing new orders and checking the status of existing orders. It is written in Java, adapting a portable business oriented benchmark called pBOB written by IBM. Although it is a benchmark that emulates business transactions, it is very different from the

TPC benchmarks. There are no actual clients, but they are replaced by driver threads. Similarly, there is no actual database access. Data is stored as binary trees of objects.

**CaffeineMark 2.5** is the latest in the series of CaffeineMark benchmarks. The benchmark suite analyses Java system performance in eleven different areas, nine of which can be run directly over the internet. It is almost the industry standard Java benchmark. The CaffeineMark can be used for comparing applet-viewers, interpreters and JIT compilers from different vendors. The CaffeineMark benchmarks can also be used as a measure of Java applet/application performance across platforms.

**VolanoMark** is a pure Java server benchmark with long-lasting network connections and high thread counts. It can be divided into two parts: server and client, although they are provided in one package. It is based on a commercial chat server application, the VolanoChat, which is used in several countries worldwide. The server accepts connections from the chat client. The chat client simulates many chat rooms and many users in each chat room. The client continuously sends messages to the server and waits for the server to broadcast the messages to the users in the same chat room. VolanoMark creates two threads for each client connection. VolanoMark can be used to test both speed and scalability of a system. In speed test, it is run in an iterative fashion on a single machine. In scalability test, the server and client are run on separate machines with high-speed network connections.

### **Transaction Processing Benchmarks (TPC)**

The TPC is a nonprofit corporation founded in 1988 to define transaction processing and database benchmarks and to disseminate objective, verifiable TPC performance data to the industry. The term transaction is often applied to a wide variety of business and computer functions. Looked at it as a computer function, a transaction could refer to a set of operations including disk read/writes, operating system calls, or some form of data transfer from one subsystem to another. TPC regards a transaction as it is commonly understood in the business world: a commercial exchange of goods, services, or money. A typical transaction, as defined by the TPC, would include the updating to a database system for such things as inventory control (goods), airline reservations (services), or banking (money). In these environments, a number of customers or service representatives input and manage their transactions via a terminal or desktop computer connected to a database. Typically, the TPC produces benchmarks that measure transaction processing (TP) and database (DB) performance in terms of how many transactions a given system and database can perform per unit of time, e.g., transactions per second or transactions per minute. The TPC benchmarks can be classified into two categories, online transaction processing (OLTP) and decision support systems (DSS). OLTP systems are used in day-to-day business operations (airline reservations, banks), and are characterized by large number of clients who continually access and update small portions of the database through short running transactions. Decision support systems are primarily used for business analysis purposes, to understand business trends, and for guiding future business directions. Information from the OLTP side of the business is periodically fed into the DSS database and analyzed. DSS workloads are characterized by long running queries that are primarily read-only and may span a large fraction of the database. Four benchmarks are active: TPC-C, TPC-W, TPC-R, and TPC-H. These benchmarks can be run with different data sizes, or scale factors. In the smallest case (or scale factor = 1), the data size is approximately 1 GB. The earlier TPC benchmarks, namely TPC-A, TPC-B, and TPC-D have become obsolete.

#### **TPC-C**

TPC-C is an OLTP benchmark. It simulates a complete computing environment where a population of users executes transactions against a database. The benchmark is centered around the principal activities (transactions) of a business similar to that of a worldwide wholesale supplier. The transactions include entering and delivering orders, recording payments, checking the status of orders, and monitoring the level of stock at the warehouses. Although the benchmark portrays the activity of a wholesale supplier, TPC-C is not limited to the activity of any particular business segment, but rather, represents any industry that must manage, sell, or distribute a product or service. TPC-C involves a mix of five concurrent transactions of

different types and complexity either executed on-line or queued for deferred execution. There are multiple on-line terminal sessions. The benchmark can be configured to use any commercial database system such as Oracle, DB2 (IBM), or Informix. Significant disk input and output are involved. The databases consist of many tables with a wide variety of sizes, attributes, and relationships. The queries result in contention on data accesses and updates. TPC-C performance is measured in new-order transactions per minute. The primary metrics are the transaction rate (tpmC) and price per transaction (\$/tpmC).

### **TPC-H**

The TPC Benchmark™ H (TPC-H) is a decision support system (DSS) benchmark. It consists of a suite of business oriented ad-hoc queries and concurrent data modifications. The queries and the data populating the database have been chosen to have broad industry-wide relevance. This benchmark is modeled after decision support systems that examine large volumes of data, execute queries with a high degree of complexity, and give answers to critical business questions. The benchmark contains 22 queries. The performance metric reported by TPC-H is called the TPC-H Composite Query-per-Hour Performance Metric (QphH@Size), and the TPC-H Price/Performance Metric, \$/QphH@Size. One may not perform optimizations based on apriori knowledge of queries in TPC-H.

### **TPC-R**

The TPC Benchmark™ R (TPC-R) is a decision support benchmark similar to TPC-H, but which allows additional optimizations based on advance knowledge of the queries. It consists of a suite of business oriented queries and concurrent data modifications. As in TPC-H, there are 22 queries. The performance metric reported by TPC-R is called the TPC-R Composite Query-per-Hour Performance Metric (QphR@Size), and the TPC-R Price/Performance Metric, \$/QphR@Size.

### **TPC-W**

TPC Benchmark™ W (TPC-W) is a transactional web benchmark. The workload simulates the activities of a business oriented transactional Web server in an electronic commerce environment. It supports many of the features of the TPC-C benchmark and has several additional features related to dynamic page generation with database access and updates. Multiple on-line browser sessions and on-line transaction processing are supported. Contention on data accesses and updates are modeled. The performance metric reported by TPC-W is the number of Web interactions processed per second (WIPS). Multiple Web interactions are used to simulate the activity of a retail store, and each interaction is subject to a response time constraint. Different profiles can be simulated by varying the ratio of browsing and buying i.e., simulating customers who are primarily browsing and those who are primarily shopping.

## **Web Server Benchmarks**

**SPECweb99** is the SPEC benchmark for evaluating the performance of World Wide Web servers. It measures a system's ability to act as a Web server. The initial effort from SPEC in this direction was SPECweb96, but it contained only static workloads, meaning that the requests were for simply downloading web pages that do not involve any computation. But if one examines the use of the web, it is clear that many downloads involve computation to generate the information the client is requesting. Such Web pages are referred to as dynamic web pages. SPECweb99 includes dynamic Web pages. The file accesses are made to closely match today's real-world Web server access patterns. The pages also contain dynamic ad rotation using cookies and table lookups.

**TPC-W**, see the "Transaction Processing Benchmarks" subsection.

## **E-commerce Benchmarks**

See SPECjbb2000 in the subsection on "Java Benchmarks" and TPC-W in the subsection on "Transaction Processing Benchmarks."

## **Mail Server Benchmarks**

**SPECmail2001** is a standardized mail server benchmark designed to measure a system's ability to act as a mail server servicing e-mail requests. The benchmark characterizes throughput and response time of a mail server

system under test with realistic network connections, disk storage, and client workloads. The benchmark focuses on the ISP as opposed to enterprise class of mail servers, with an overall user count in the range of approximately 10,000 to 1,000,000 users. The goal is to enable objective comparisons of mail server products.

**File Server Benchmarks**

**System File Server Version 2.0** (SFS 2.0) is SPEC’s benchmark for measuring NFS (network file system) file server performance across different vendor platforms. It contains a workload that was developed based on a survey of more than 1,000 file servers in different application environments.

**PC Benchmarks**

A variety of benchmarks are available, primarily from Ziff Davis and Bapco to benchmark the Windows-based personal computer. [Table 8.7](#) lists the most common PC benchmarks. Ziff Davis Winstone and Bapco SYSMARK are benchmarks that measure overall performance while the other benchmarks are intended to measure performance of one subsystem such as video or audio or one aspect such as power.

Techniques and tools for performance evaluation improve year by year. For instance, performance monitoring counters were not available to the public until 1997. Benchmarks get updated almost every year. Those interested in experimental performance evaluation should continuously monitor the state of the art.

**TABLE 8.7** Popular Personal Computer Benchmarks

Benchmark	Description
Business Winstone [44]	A system-level, application-based benchmark that measures a PC’s overall performance when running today’s top-selling Windows-based, 32-bit applications. It runs real 32-bit business applications through a series of scripted activities and uses the time a PC takes to complete those activities to produce its performance scores. The suite includes five Microsoft Office 2000 applications (Access, Excel, FrontPage, PowerPoint, and Word), Microsoft Project 98, Lotus Notes R5, NicoMak WinZip, Norton AntiVirus, and Netscape Communicator.
WinBench99 [44]	A subsystem-level benchmark that measures the performance of a PC’s graphics, disk, and video subsystems in a Windows environment.
3DwinBench [44]	Tests the bus used to carry information between the graphics adapter and the processor subsystem. Hardware graphics adapters, drivers, and enhancing technologies such as MMX/SSE are tested.
CD WinBench99 [44]	Measures the performance of a PC’s CD-ROM subsystem, which includes the CD drive, controller, and driver, and the system processor.
Audio WinBench 99 [44]	Measures the performance of a PC’s audio subsystem, which includes the sound card and its driver, the processor, the DirectSound and DirectSound 3D software, and the speakers.
Battery Mark [44]	Measures battery life on notebook computers.
I-bench [44]	A comprehensive, cross-platform benchmark that tests the performance and capability of Web clients. The benchmark provides a series of tests that measure both how well the client handles features and the degree to which network access speed affects performance.
Web Bench [44]	Measures Web server software performance by running different Web server packages on the same server hardware or by running a given Web server package on different hardware platforms.
NetBench [44]	A portable benchmark program that measures how well a file server handles file I/O requests from clients. NetBench reports throughput and client response time measurements.
3Dmark MAX 99 [45]	From Futuremark Corporation. Is a nice 3D benchmark that measures 3D gaming performance. Results are dependent on CPU, memory architecture, and the 3D accelerator employed.
SYSMARK [43]	Measures a system’s real-world performance when running typical business applications. This benchmark suite comprises the retail versions of eight application programs and measures the speed with which the system under test executes predetermined scripts of user tasks typically performed when using these applications. The performance times of the individual applications are weighted and combined into both category-based performance scores as well as a single overall score. The application programs employed by SYSMark 32 are: Microsoft Word 7.0 and Lotus WordPro 96 for word processing, Microsoft Excel 7.0 (for spreadsheet), Borland Paradox 7.0 (for database), CorelDraw 6.0 (for desktop graphics), Lotus Freelance Graphics 96 and Microsoft Powerpoint 7.0 (for desktop presentation), and Adobe Pagemaker 6.0 (for desktop publishing).

Table 8.8 provides sources for the benchmarks described in this article. The references at the end can provide new information on tools and benchmarks. Microprocessor vendors are inclined to show off their products in the best light, to projecting results for benchmarks that run well on their system, developing special optimizations within their compilers just for the sake of improving benchmark scores, and stretching the benchmark's behavior while staying within the "legal" limits of the benchmark guidelines. It is extremely important to understand benchmarks, their features and metrics used for performance evaluation to really understand the performance results.

## 8.3 Trace Caching and Trace Processors

---

*Eric Rotenberg*

A superscalar processor executes multiple instructions in parallel each cycle. Because there are data dependencies among instructions, finding multiple independent instructions that can execute in parallel requires examining an even larger group of instructions, called the *instruction window*. Figure 8.16 shows a high-level view of a superscalar processor, including instruction buffers that make up the window and the decoupled fetch and execution engines. The fetch engine predicts branches, fetches and renames instructions, and dispatches them into the window. Meanwhile, each cycle, the execution engine identifies instructions in the window whose operands are available, and issues them to parallel functional units (FUs).

Peak performance is increased by adding more parallel functional units. But adding more functional units has ramifications for other parts of the processor. First, instruction fetch bandwidth must be commensurate with peak execution bandwidth. Second, the window must be correspondingly larger. A larger window enables the processor to probe deeper into the dynamic instruction stream, increasing the chance of finding enough independent instructions each cycle to keep functional units operating at peak efficiency.

Next-generation, high-performance processors will need to issue 8, 12, or even 16 instructions per cycle. Unfortunately, at high issue rates, supporting mechanisms—instruction supply and the instruction window—are difficult to scale. This chapter section deals with *the instruction fetch bottleneck* and *inefficient execution mechanisms*, and surveys a next-generation microarchitecture, the *trace processor* [21,24,27,29, 31], that attacks these problems. A third problem, *control and data dependence bottlenecks*, is also covered; however, because this aspect is more involved, it is left to the reader to investigate the trace processor literature [24,25].

FIGURE 8.16 High-level view of a superscalar processor: instruction window and decoupled fetch and execute engines.

### Instruction Fetch Bottleneck

Taken branches in the dynamic instruction stream cause frequent disruptions in the flow of instructions into the window. The best conventional instruction cache and next-program-counter logic incurs a single-cycle disruption when a taken branch is encountered. At best, sustained fetch bandwidth is equal to the average number of instructions between taken branches, which is typically from 6 to 8 instructions per cycle for integer programs [2,19,32]. Moreover, conventional branch predictors predict at most one branch per cycle, limiting fetch bandwidth to a single basic block per cycle.

It is possible to modify conventional instruction caches and the next-program-counter logic to remove taken-branch disruptions, however, that approach is typically complex. Low latency is sacrificed for high bandwidth. A *trace cache* [8,14,18,20] changes the way instructions are stored to optimize instruction fetching for both high bandwidth and low latency.

### Inefficient High-Bandwidth Execution Mechanisms

The scheduling mechanism in a superscalar processor converts an artificially sequential program into an instruction-level parallel program. The scheduling mechanism is composed of register rename logic (identifies true dependences among instructions and removes artificial dependences), the scheduling window (resolves dependences near-optimally by issuing instructions out-of-order), and the register file with result bypasses (moves data to and from the functional units as instructions issue and complete, respectively). All of the circuits are *monolithic* and their speed does not scale well for 8 or more instructions per cycle [13].

*Trace processors* [21,24,27,29,31] use a more efficient, *hierarchical* scheduling mechanism to optimize for both high-bandwidth execution and a fast clock.

### Control and Data Dependence Bottlenecks

Most control dependences are removed by branch prediction, but branch mispredictions incur large performance penalties because all instructions after a mispredicted branch are flushed from the window, even control- and data-independent instructions. Exploiting *control independence* preserves useful instructions

FIGURE 8.17 Example dynamic sequence stored in an instruction cache and trace cache.

and their results [9], which would otherwise be thrown away due to branch mispredictions, but control independence mechanisms have numerous difficult implementation issues [22]. Moreover, a large instruction window does nothing to reduce the execution time of long data dependence chains, which ultimately limit performance if branch mispredictions do not. Value prediction and other forms of *data speculation* break data dependence chains [10], but difficult implementation issues must be resolved, such as providing high-bandwidth value prediction and high-performance recovery mechanisms.

The hierarchical organization of trace processors can be leveraged to overcome implementation barriers to data speculation and control independence. The interested reader may learn more about trace processor control independence mechanisms and data speculation from other sources [21,24,25].

## Trace Cache and Trace Predictor: Efficient High-Bandwidth Instruction Fetching

Conventional instruction caches are unable to meet future fetch bandwidth requirements because of taken branches in the dynamic instruction stream. A taken branch instruction and its target instruction reside in different cache lines, or in the same cache line with unwanted instructions in between, as shown in Fig. 8.17(a). Figure 8.17(a) shows a long dynamic sequence of instructions made up of four fetch blocks separated by taken branches. Ideally, to keep a 16-issue machine well-supplied, the entire sequence needs to be fetched in a single cycle. But, because the fetch blocks are noncontiguous, it takes at least four cycles to fetch and assemble the desired sequence.

The fundamental problem is instruction caches store instructions in their static order. A *trace cache* [8,14,18,20] stores instructions the way they appear in the dynamic instruction stream. Figure 8.17(b) shows the same sequence of four fetch blocks stored contiguously in one trace cache line. The trace cache allows multiple, otherwise noncontiguous fetch blocks to be fetched in a single cycle. A *trace* in this context is a dynamic sequence of instructions with a hardware-defined length limit (e.g., 16 or 32 instructions), containing any number of embedded taken and not-taken branches.

A trace cache can be incorporated in the fetch mechanism in several ways. One possibility is to replace the conventional instruction cache with a trace cache. More likely, both a trace cache and instruction cache are used. In trace processors, described in the next section, the trace cache is accessed first and, if it does not have the desired trace, the trace is quickly constructed from the back-up instruction cache. Early trace cache fetch units [14,20] access the trace cache and instruction cache in parallel, as shown in Fig. 8.18. If the trace exists in the trace cache, it supplies instructions and the instruction cache's instructions are discarded since they are subsumed by the trace. Otherwise, the instruction cache supplies a smaller fetch block.

A trace is uniquely identified by the program counter of the first instruction in the trace (start PC) and embedded branch outcomes (taken/not-taken bit for every branch; this assumes indirect branches terminate a trace, since taken/not-taken is insufficient for indirect branches). The start PC and branch outcomes are collectively called the *trace identifier*, or *trace id*. Looking up a trace in the trace cache is similar to looking up instructions/data in conventional caches, except the trace id is used instead of an address. A subset of the trace id forms an index into the trace cache and the remaining bits form a tag.

FIGURE 8.18 Instruction fetch unit with trace cache.

One or more traces and their identifying tags are accessed at that index (the number of traces depends on the trace cache's set-associativity). If one of the tags matches the tag of the supplied trace id, there is a trace cache hit. Otherwise, there is a trace cache miss. New traces are constructed and written into the trace cache either speculatively, as instructions are fetched from the instruction cache (as shown in Fig. 8.18), or non-speculatively, as instructions retire from the processor.

A new *predicted trace id* is supplied to the trace cache each cycle. Conventional branch prediction, with a throughput of only one branch prediction per cycle, is not designed to produce trace ids. Multiple-branch predictor counterparts of single-branch predictors have been proposed but they tend to be unwieldy [19]. A conceptually simpler approach is to not predict branches directly. *Explicit trace prediction* [6] predicts trace ids directly and, in doing so, implicitly predicts any number of embedded branches in a single cycle. The *trace predictor* shown in Fig. 8.18 supplies a predicted trace id—start PC and multiple branch predictions—to both the trace cache and instruction cache.

The trace cache design space is extensive. In addition to typical parameters such as size, set-associativity, and replacement policy, the design space includes: indexing methods (which PC bits and which, if any, branch prediction bits are used), path associativity (ability to simultaneously store different traces with the same start PC), partial matching (ability to use prefix of a trace if the trace id only partially matches), trace selection (policies for beginning and ending traces), trace cache fill policy, parallel or sequential accessing of the trace and instruction caches, and other aspects. The interested reader is referred to trace cache literature to gain an appreciation for the trace cache design space [4,5,7,14–20,23].

A problem of trace caches is they necessarily use storage less efficiently than instruction caches. A given static instruction appears exactly once in the instruction cache. In a trace cache, however, there may be multiple copies of the same static instruction. Redundancy within a trace is caused by dynamic unrolling of small loops. Redundancy among different traces is caused by partial overlap of different paths through a region. For example, two traces may start at the same program counter but diverge at a common branch, such that the two traces share a common prefix; the paths may reconverge before both traces end, causing even more redundancy.

Trace cache redundancy is the price paid for simplicity and a direct approach to high-bandwidth instruction fetching. There are other high-bandwidth fetch mechanisms that work solely out of the conventional instruction cache [2,3,26,32]. They all use the same basic approach. First, the branch predictor is modified to generate pointers to multiple noncontiguous fetch blocks. Second, the instruction cache is highly multiported so that pointers can access noncontiguous cache lines in parallel. Finally, a sophisticated instruction alignment network re-orders the blocks fetched in the previous step to construct the desired dynamic sequence of instructions. The approach is certainly high-bandwidth but the number of stages in the fetch pipeline is increased, and additional fetch unit latency impacts performance negatively [19]. The trace cache approach is less efficient in terms of storage. But other approaches are inefficient in terms of repeatedly constructing dynamic traces on-the-fly from the static instruction cache. The trace cache incurs the latency to construct a trace once and then efficiently reuses it many times.

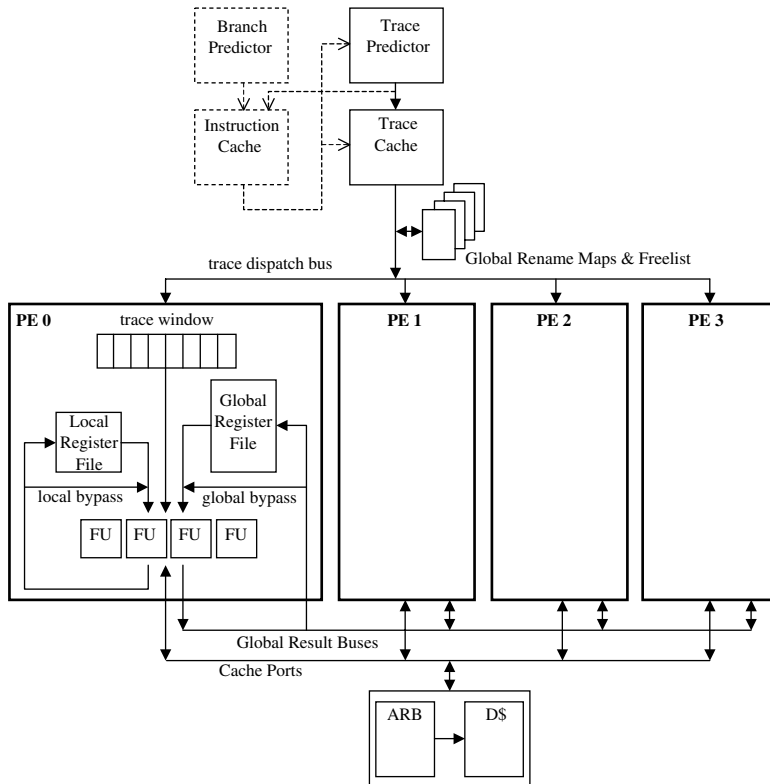

FIGURE 8.19 Trace processor.

## Trace Processor: Efficient High-Bandwidth Instruction Execution

Instruction execution is inefficient in wide-issue superscalar processors because all data dependences are handled *uniformly*. When an instruction issues, its data dependent instructions wakeup with uniform latency, usually a single cycle, regardless of their location in the window. Resolving all dependences in a single cycle optimizes parallelism, but cycle time is extended to accommodate the full length of the window. Increasing processor cycle time penalizes the entire pipeline. A better alternative is to increase the number of cycles to resolve data dependences, e.g., two cycles instead of one, so other pipeline stages are unaffected. However, it still remains the case that *all data dependences are slow to resolve*.

Fortunately, there is a compromise between optimizing for parallelism and optimizing for cycle time if data dependences are handled *nonuniformly*. A *trace processor* [21,24,27–29,31] hierarchically divides the processor into smaller processing elements (PEs), as shown in Fig. 8.19. The approach preserves a fast clock and resolves many data dependences in one clock cycle (data dependences *within* PEs), at the expense of resolving some data dependences in two or more clock cycles (data dependences *among* PEs). The microarchitecture shown in Fig. 8.19 is described in the remainder of this section.

### Instruction Supply

The trace predictor and trace cache supply a single trace per cycle. The conventional branch predictor and instruction cache shown in Fig. 8.19 are secondary, back-up mechanisms for constructing traces that miss in the cache or that were mispredicted [21,23,24].

### Register Renaming

Register renaming determines data dependences among all newly-fetched instructions, and between newly-fetched instructions and other instructions already in the window. The first aspect—determining data dependences among 16 or 32 fetched instructions—almost certainly takes more than a single clock cycle.

**FIGURE 8.20** Data flow hierarchy of traces.

Each instruction compares its source registers to the destination registers of all logically preceding instructions. The second aspect—linking incoming instructions with previous and future instructions in the window—requires an impractical number of read and write ports to the register rename map table and high bandwidth to the register freelist.

The efficiency of register renaming and later execution stages is improved by hierarchically dividing data flow into intra-trace and inter-trace values [31], as shown in Fig. 8.20. *Local values* are produced and consumed solely within a trace and are not visible to other traces. *Global values* are communicated among traces. Global input values to a trace are called *live-ins* and global output values of a trace are called *live-outs*.

Local dependences in a trace are static because control flow is pre-determined. Thus, intra-trace dependence checking is performed only once, when the trace is first constructed and written into the trace cache. Furthermore, the local values that correspond to intra-trace dependences can be statically bound to registers in a local register file, a process called *pre-renaming* [31]. Each PE has a small private local register file, large enough to hold all local values produced by a trace. Local register files are private because their values do not need to be communicated to other PEs. Pre-*rename* information is computed once and stored along with the trace in the trace cache. Pre-*rename* eliminates the first aspect of register renaming from the rename stage—dependence checking among newly fetched instructions.

The second aspect of renaming—linking fetched instructions with other instructions in the window—is still performed, but the hierarchical treatment of values makes this aspect efficient. The only linkages are inter-trace dependences. Live-in and live-out values are dynamically renamed to what is logically a single shared global register file. The global register file communicates values among traces.

Although the global register file, its map table, and its freelist are similar to a superscalar processor’s monolithic register file and renaming structures, the trace processor’s register file is more efficient because fewer values are processed. Reduced register file complexity is described below in the context of instruction issue logic. Global renaming structures are simplified in three ways. First, fewer read and write ports lead to the global rename map table because only live-ins/live-outs are renamed, and not local values. Second, bandwidth to the global register freelist is reduced since only live-outs consume free registers, and not local values. Third, to support trace misprediction recovery, the global rename map table is checkpointed only at trace boundaries instead of at every branch, so fewer shadow maps are required.

## Instruction Dispatch

Merging instructions into the window is also simplified. A single trace is routed to a single PE. A conventional processor routes multiple instructions to as many, possibly noncontiguous instruction buffers.

## Instruction Issue Logic, Register File, and Result Bypasses

The instruction issue mechanism is possibly the most complex aspect of current dynamically scheduled superscalar processors [13]. Each cycle, the processor examines the instruction window for instructions whose input values are available and are ready to issue (*wakeup logic*). Of the ready instructions, a number of them are selected for issue based on resource constraints (*select logic*). The selected instructions read values from the register file and are routed to functional units, where they execute and write results to the register file. Each result must also be quickly bypassed to functional units to be consumed by pipelined, data dependent instructions (*result bypasses*). The wakeup logic, select logic, register file, and result bypasses all grow in complexity as the size of the instruction window and the number of parallel execution units are increased [13].

The large trace processor instruction window is distributed among multiple smaller processing elements (PEs), as shown in Fig. 8.19. Each PE resembles a small superscalar processor and at any given time is allocated a single trace to process. A PE has (1) enough instruction issue buffers to hold an entire trace, (2) multiple dedicated functional units, and (3) a dedicated local register file for storing and communicating local values.

Logically, a single global register file stores and communicates global values. Each PE contains a copy of the global register file for private read ports. Write ports to the global register file are shared, however. All PEs are connected to shared global result buses, which write values simultaneously into all copies of the global register file.

A hierarchical instruction window simplifies the wakeup logic, select logic, register file, and result bypasses. Each aspect is described below.

Waiting instructions monitor fewer “tags” to determine when to wakeup. Tags are broadcast by producer instructions soon after issuing, to wakeup dependent instructions. Although each PE monitors both its own local tags and all global tags, overall, fewer tags are monitored than in an equivalent, nonhierarchical processor. The number of local tags is small, e.g., four tags for a four-issue PE. Even the number of global tags is small due to reduced global register traffic, e.g., typically two to four tags are sufficient [24]. Also, tags are broadcast on shorter wires—the length of a PE trace window instead of the length of the entire window (of course, global tags and values first incur one cycle of delay on the global result buses, as discussed below). The combination of fewer tags and a smaller wakeup window greatly reduces wakeup circuit delay, allowing a faster clock.

Instruction select logic is fully distributed. Each PE independently selects ready instructions from its trace and routes them to dedicated functional units. Here, fewer instruction candidates and fewer functional units reduce select circuit delay, allowing a faster clock.

The local register file is quite fast because it contains few registers (e.g., typically eight registers [24]) and has relatively few read and write ports, comparable to today’s four-issue superscalar processors. The complexity of the global register file is reduced because much of the register traffic is off-loaded to the local register files. For an equivalent instruction window, the global register file requires far fewer registers and read/write ports than the monolithic file of nonhierarchical processors.

Finally, result bypasses, which are primarily long interconnect, are receiving much attention lately due to technology trends. In deep sub-micron technologies, interconnect delay improves less with technology scaling than logic delay does [1,13]. This trend highlights the importance of purposeful, nonuniform bypass latencies. Local values are bypassed quickly among functional units in a PE. Global values incur an extra cycle (or more) on the global result buses, but at least not all values are broadcast on global interconnect. In a conventional superscalar processor, all bypasses are effectively global.

## Summary via Analogy

Prior to superscalar processors, comparatively simple out-of-order processors fetched, dispatched, issued, and executed one instruction per cycle, as shown in the left-hand side of Fig. 8.21. The branch predictor predicts up to one branch each cycle and a single PC fetches one instruction from a simple instruction cache. The renaming mechanism, e.g., Tomasulo’s algorithm [30], performs simple dependence checking by looking up a couple of source tags in the register file. And at most one instruction is steered to the reservation station of a functional unit each cycle. After completing, instructions arbitrate for a common data bus, and the winner writes its result and tag onto the bus and into the register file.

The superscalar paradigm “widens” each of these pipeline stages and increases complexity with each additional instruction per cycle. This is clearly manageable up to a point: high-speed, dynamically scheduled 4-issue superscalar processors currently set the performance standard in microprocessors. But there is a crossover point beyond which it becomes more efficient to manage instructions in groups, that is, hierarchically.

A trace processor manages instructions hierarchically. In the right-hand side of Fig. 8.21, the top-most level of the trace processor hierarchy is shown (the trace-level). The picture is virtually identical to the

FIGURE 8.21 Analogy between a single instruction and a single trace.

single-issue, out-of-order processor on the left-hand side. The unit of operation has changed from one instruction to one trace, but the pipeline bandwidth remains 1 unit per cycle.

In essence, grouping instructions within traces is a reprieve. Complexity (cycle time) does not necessarily increase with each additional instruction added to a trace. Additional branches are absorbed by the trace cache and trace predictor, and additional source and destination operands are absorbed by handling data flow hierarchically. Also, complexity (cycle time) does not necessarily increase with one or two additional PEs. Hardware parallelism is allowed to expand incrementally—up to a point, at which time perhaps another level of hierarchy, and another reprieve, is needed.

Perhaps the most important thing to remember about trace processors is that the whole processor contributes to parallelism, but cycle time is influenced more by an individual processing element than the whole processor.

### 9.1 High-Speed Computer Arithmetic

---

*Earl E. Swartzlander, Jr.*

#### Introduction

The speed of a computer is determined to a first order by the speed of the arithmetic unit and the speed of the memory. Although the speed of both units depends directly on the implementation technology, arithmetic unit speed also depends strongly on the logic design. Even for an integer adder, speed can easily vary by an order of magnitude while the complexity varies by less than 50%.

This chapter section begins with a brief discussion of binary fixed point number systems in the subsection on “Fixed Point Number Systems.” The subsection on “Fixed Point Arithmetic Algorithms” provides examples of fixed point implementations of the four basic arithmetic operations (i.e., add, subtract, multiply, and divide). Finally, the “Floating Point Arithmetic” subsection describes algorithms for floating point arithmetic.

Regarding notation, capital letters represent digital numbers (i.e.,  $n$ -bit words), while subscripted lower case letters represent bits of the corresponding word. The subscripts range from 0 to  $n - 1$  to indicate the bit position within the word ( $x_0$  is the least significant bit of  $X$ ,  $x_{n-1}$  is the most significant bit of  $X$ , etc.). The logic designs presented in this chapter are based on positive logic with AND, OR, and INVERT operations. Depending on the technology used for implementation, different logical operations (such as NAND and NOR) or direct transistor realizations may be used, but the basic concepts do not change significantly.

#### Fixed-Point Number Systems

Most arithmetic is performed with fixed-point numbers, which have constant scaling (i.e., the position of the binary point is fixed). The numbers can be interpreted as fractions, integers, or mixed numbers, depending on the application. Pairs of fixed-point numbers are used to create floating-point numbers, as discussed in “Floating-Point Arithmetic” subsection.

At the present time, fixed-point binary numbers are generally represented using the two’s complement number system. This choice has prevailed over the sign magnitude and one’s complement number systems, because the frequently performed operations of addition and subtraction are easiest to perform on two’s

complement numbers. Sign magnitude numbers are more efficient for multiplication, but the lower frequency of multiplication and the development of the efficient modified Booth's two's complement multiplication algorithm have resulted in the nearly universal selection of the two's complement number system for most applications. The algorithms presented in this chapter section assume the use of two's complement numbers.

Fixed-point number systems represent numbers, say  $A$ , by  $n$  bits: a sign bit, and  $n - 1$  data bits. By convention the most significant bit,  $a_{n-1}$ , is the sign bit, which is a ONE for negative numbers and a ZERO for positive numbers. The  $n - 1$  data bits are  $a_{n-2}, a_{n-3}, \dots, a_1, a_0$ . In the section that follows fixed point fractions will be described for each of the three systems.

In the two's complement fractional number system, the value of a number is the sum of  $n - 1$  positive binary fractional bits and a sign bit which has a weight of  $-1$ :

$$A = -a_{n-1} + \sum_{i=0}^{n-2} a_i 2^{i-n+1} \quad (9.1)$$

Examples of 4-bit two's complement fractions are shown in Table 9.1. A couple of significant points are shown in the table: first, there is only a single representation of zero (specifically 0, which is represented by 0000) and second, the system is not symmetric (there is a negative number, specifically  $-1$ , which is represented by 1000, for which there is no positive equivalent). The latter property means that negating a valid number can produce a nonrepresentable result.

Two's complement numbers are negated by complementing all bits and adding a ONE to the least significant bit position. For example, to form  $-3/8$ :

$$\begin{array}{rcl}
 +3/8 & = & 0011 \\
 \text{invert all bits} & = & 1100 \\
 \text{add 1} & & 0001 \\
 & & 1101 = -3/8 \\
 \text{Check: invert all bits} & = & 0010 \\
 \text{add 1} & & 0001 \\
 & & 0011 = +3/8
 \end{array}$$

Truncation of two's complement numbers is shown in Fig. 9.1. This figure shows the relationship between an infinitely precise number  $A$  and its representation with a two's complement fraction  $T(A)$ .

**FIGURE 9.1** Relationship between an infinitely precise number,  $A$ , and its representation by a truncated four-bit two's complement fraction  $T(A)$ .

As can be seen from the figure, truncation never increases the value of the number. The truncated numbers have values that are either unchanged or shifted toward negative infinity. If a large number of numbers are truncated, on the average there is a downward shift of one-half the value of a least significant bit (LSB). Summing many truncated numbers (which may occur in scientific, matrix, and signal processing applications) can cause a significant accumulated error.

## Fixed-Point Arithmetic Algorithms

This subsection presents a reasonable assortment of typical fixed point algorithms for addition, subtraction, multiplication, and division.

### Fixed-Point Addition

Addition is performed by summing the corresponding bits of the two  $n$ -bit numbers, including the sign bit. Subtraction is performed by summing the corresponding bits of the minuend and the two's complement of the subtrahend. Overflow is detected in a two's complement adder by comparing the carry signals into and out of the most significant adder stage (i.e., the stage which computes the sign bit). If the carries differ, the arithmetic has overflowed and the result is invalid.

### Full Adder

The full adder is the fundamental building block of most arithmetic circuits. Its operation is defined by the truth table shown in [Table 9.2](#). The sum and carry outputs are described by the following equations:

$$s_k = a_k \bar{b}_k \bar{c}_k + \bar{a}_k b_k \bar{c}_k + \bar{a}_k \bar{b}_k c_k + a_k b_k c_k \quad (9.2)$$

$$c_{k+1} = \bar{a}_k b_k c_k + a_k \bar{b}_k c_k + a_k b_k \bar{c}_k + a_k b_k c_k = a_k b_k + a_k c_k + b_k c_k \quad (9.3)$$

**TABLE 9.2** Full Adder Truth Table

where  $a_k$ ,  $b_k$ , and  $c_k$  are the inputs to the  $k$ th full adder stage, and  $s_k$  and  $c_{k+1}$  are the sum and carry outputs, respectively.

In evaluating the relative complexity of implementations it is often convenient to assume a nine gate realization of the full adder, as shown in Fig. 9.2. For this implementation, the delay from either  $a_k$  or  $b_k$  to  $s_k$  is six gate delays and the delay from  $c_k$  to  $c_{k+1}$  is two gate delays. Some technologies, such as CMOS, form inverting gates (e.g., NAND and NOR gates) more efficiently than the non-inverting gates that are assumed in this chapter. Circuits with equivalent speed and complexity can be constructed with inverting gates.

**Ripple Carry Adder**

A ripple carry adder for  $n$ -bit numbers is implemented by concatenating  $n$  full adders, as shown in Fig. 9.3. At the  $k$ th bit position, bits  $a_k$  and  $b_k$  of operands  $A$  and  $B$  and the carry signal from the preceding adder stage,  $c_k$ , are used to generate the  $k$ th bit of the sum,  $s_k$ , and the carry,  $c_{k+1}$ , to the next adder stage. This is called a ripple carry adder, since the carry signals “ripple” from the least significant bit position to the most significant. If the ripple carry adder is implemented by concatenating  $n$  of the nine gate full adders, which were shown in Fig. 9.2, an  $n$ -bit ripple carry adder requires  $2n + 4$  gate delays to produce the most significant sum bit and  $2n + 3$  gate delays to produce the carry output. A total of  $9n$  logic gates are required to implement the  $n$ -bit ripple carry adder. In comparing the delay and complexity of adders,

the delay from data input to most significant sum output denoted by DELAY and the gate count denoted by GATES will be used. These DELAY and GATES are subscripted by RCA to indicate ripple carry adder. Although these simple metrics are suitable for first order comparisons, more accurate comparisons require more exact modeling since the implementations may be effected with transistor networks (as opposed to gates), which will have different delay and complexity characteristics.

$$\text{DELAY}_{\text{RCA}} = 2n + 4 \tag{9.4}$$

$$\text{GATES}_{\text{RCA}} = 9n \tag{9.5}$$

### Carry Lookahead Adder

Another popular adder approach is the carry lookahead adder [1,2]. Here specialized logic computes the carries in parallel. The carry lookahead adder uses modified full adders (modified in the sense that a carry output is not formed) for each bit position and lookahead modules, which have carry outputs and block carry generate and propagate outputs that indicate that a carry is generated within the module, or that an incoming carry would propagate across the module. This is seen by rewriting Eq. (9.3) with  $g_k = a_k b_k$  and  $p_k = a_k + b_k$ .

$$c_{k+1} = g_k + p_k c_k \tag{9.6}$$

This helps to explain the concept of carry generation and propagation: At a given stage a carry is generated if  $g_k$  is true (i.e., both  $a_k$  and  $b_k$  are ONES), and a stage propagates an input carry to its output if  $p_k$  is true (i.e., either  $a_k$  or  $b_k$  is a ONE). The nine gate full adder shown in Fig. 9.2 has AND and OR gates that produce  $g_k$  and  $p_k$  with no additional complexity. In fact, because the carry out is produced in the lookahead logic, the OR gate that produces the  $c_{k+1}$  can be eliminated. The result is the eight gate modified full adder shown in Fig. 9.4.

Extending Eq. (9.6) to a second stage:

$$\begin{aligned} c_{k+2} &= g_{k+1} + p_{k+1} c_{k+1} \\ &= g_{k+1} + p_{k+1} (g_k + p_k c_k) \\ &= g_{k+1} + p_{k+1} g_k + p_{k+1} p_k c_k \end{aligned} \tag{9.7}$$

Equation(9.7) results from evaluating Eq. (9.6) for the  $(k + 1)$ th stage and substituting  $c_{k+1}$  from Eq. (9.6). Carry  $c_{k+2}$  exits from stage  $k + 1$  if: (a) a carry is generated there or (b) a carry is generated in stage  $k$  and propagates across stage  $k + 1$  or (c) a carry enters stage  $k$  and propagates across both stages  $k$  and

FIGURE 9.4 Eight gate modified full adder.

$k + 1$ , etc. Extending to a third stage:

$$\begin{aligned}
 c_{k+3} &= g_{k+2} + p_{k+2}c_{k+2} \\
 &= g_{k+2} + p_{k+2}(g_{k+1} + p_{k+1}g_k + p_{k+1}p_kc_k) \\
 &= g_{k+2} + p_{k+2}g_{k+1} + p_{k+2}p_{k+1}g_k + p_{k+2}p_{k+1}p_kc_k
 \end{aligned} \tag{9.8}$$

Although it would be possible to continue this process indefinitely, each additional stage increases the fan-in (i.e., the number of inputs) of the logic gates. Four inputs (as required to implement Eq. (9.8)) is frequently the maximum number of inputs per gate for current technologies. To continue the process, block generate and block propagate signals are defined over four bit blocks (stages  $k$  to  $k + 3$ ),  $g_{k:k+3}$  and  $p_{k:k+3}$ , respectively:

$$g_{k:k+3} = g_{k+3} + p_{k+3} g_{k+2} + p_{k+3} p_{k+2} g_{k+1} + p_{k+3} p_{k+2} p_{k+1} g_k \tag{9.9}$$

and

$$p_{k:k+3} = p_{k+3} p_{k+2} p_{k+1} p_k \tag{9.10}$$

Equation (9.6) can be expressed in terms of the 4-bit block generate and propagate signals:

$$c_{k+4} = g_{k:k+3} + p_{k:k+3} c_k \tag{9.11}$$

Thus, the carry out from a 4-bit wide block can be computed in only four gate delays (the first to compute  $p_i$  and  $g_i$  for  $i = k$  through  $k + 3$ , the second to evaluate  $p_{k:k+3}$ , the second and third to evaluate  $g_{k:k+3}$ , and the third and fourth to evaluate  $c_{k+4}$  using Eq. (9.11)).

An  $n$ -bit carry lookahead adder requires  $\lceil (n - 1)/(r - 1) \rceil$  lookahead blocks, where  $r$  is the width of the block. A 4-bit lookahead block is a direct implementation of Eqs. (9.6)–(9.10), with 14 logic gates. In general, an  $r$ -bit lookahead block requires  $\frac{1}{2}(3r + r^2)$  logic gates. The Manchester carry chain [3] is an alternative switch-based technique for the implementation of the lookahead block.

Figure 9.5 shows the interconnection of 16 adders and five lookahead logic blocks to realize a 16-bit carry lookahead adder. The sequence of events, which occur during an add operation, is as follows: (1) apply  $A$ ,  $B$ , and carry in signals, (2) each adder computes  $P$  and  $G$ , (3) first level lookahead logic computes the 4-bit propagate and generate signals, (4) second level lookahead logic computes  $c_4$ ,  $c_8$ , and  $c_{12}$ , (5) first level lookahead logic computes the individual carries, and (6) each adder computes the sum outputs. This process may be extended to larger adders by subdividing the large adder into 16-bit blocks and using additional levels of carry lookahead (a 64-bit adder requires three levels).

The delay of carry lookahead adders is evaluated by recognizing that an adder with a single level of carry lookahead (for 4-bit words) has six gate delays, and that each additional level of lookahead increases the maximum word size by a factor of four and adds four gate delays. More generally [4, pp. 83–88], the number of lookahead levels for an  $n$ -bit adder is  $\lceil \log_r n \rceil$  where  $r$  is the maximum number of inputs per gate. Since an  $r$ -bit carry lookahead adder has six gate delays and there are four additional gate delays per carry lookahead level after the first,

$$\text{DELAY}_{\text{CLA}} = 2 + 4 \lceil \log_r n \rceil \tag{9.12}$$

The complexity of an  $n$ -bit carry lookahead adder implemented with  $r$ -bit lookahead blocks is  $n$  modified full adders (each of which requires eight gates) and  $\lceil (n - 1)/(r - 1) \rceil$  lookahead logic blocks [each of which requires  $\frac{1}{2}(3r + r^2)$  gates].

$$\text{GATES}_{\text{CLA}} = 8n + \frac{1}{2}(3r + r^2) \left\lceil \frac{n-1}{r-1} \right\rceil \tag{9.13}$$

FIGURE 9.5 16-bit carry lookahead adder.

If  $r = 4$

$$\text{GATES}_{\text{CLA}} \approx 12\frac{2}{3}n - 4\frac{2}{3} \quad (9.14)$$

The carry lookahead approach reduces the delay of adders from increasing linearly with the word size (as is the case for ripple carry adders) to increasing in proportion to the logarithm of the word size. As with ripple carry adders, the carry lookahead adder complexity grows linearly with the word size (for  $r = 4$ , this occurs at a 40% faster rate than the ripple carry adders).

FIGURE 9.6 16-bit carry skip adder.

### Carry Skip Adder

The carry skip adder divides the words to be added into blocks (like the carry lookahead adder). The basic structure of a 16-bit carry skip adder is shown on Fig. 9.6. Within each block, a ripple carry adder produces the sum bits and the carry (which is used as a block generate). In addition, an AND gate is used to form the block propagate signal. These signals are combined using Eq. (9.11) to produce the carry signal for the next block.

For example, with  $k = 3$ , Eq. (9.11) yields  $c_6 = g_{3:5} + p_{3:5}c_3$ . The carry out of the second ripple carry adder is a block generate signal if it is evaluated when carries generated by the data inputs (i.e.,  $a_{3:5}$  and  $b_{3:5}$  on Fig. 9.6) are valid, but before the carry that results from the  $c_3$ . Normally, these two types of carries coincide in time, but in the carry skip adder, the  $c_3$  signal is produced by a 3-bit ripple carry adder, so the carry output is a block generate from nine gate delays after application of  $A$  and  $B$  until it becomes  $c_6$  at 15 gate delays after application of  $A$  and  $B$ .

In the carry skip adder, the first and last blocks are simple ripple carry adders while the  $\lceil n/k \rceil - 2$  intermediate blocks are ripple carry adders augmented with three gates. The delay of a carry skip adder is the sum of  $2k + 3$  gate delays to produce the carry in the first block, two gate delays through each of the intermediate blocks, and  $2k + 1$  gate delays to produce the most significant sum bit in the last block. To simplify the analysis, the ceiling function in the count of intermediate blocks is ignored. If the block width is  $k$ :

$$\begin{aligned} \text{DELAY}_{\text{SKIP}} &= 2k + 3 + 2\left(\frac{n}{k} - 2\right) + 2k + 1 \\ &= 4k + 2\frac{n}{k} \end{aligned} \quad (9.15)$$

where  $\text{DELAY}_{\text{SKIP}}$  is the total delay of the carry skip adder with a single level of  $k$ -bit wide blocks. The optimum block size is determined by taking the derivative of  $\text{DELAY}_{\text{SKIP}}$  with respect to  $k$ , setting it to zero and solving for  $k$ . The resulting optimum values for  $k$  and  $\text{DELAY}_{\text{SKIP}}$  are

$$k = \sqrt{\frac{n}{2}} \quad (9.16)$$

$$\text{DELAY}_{\text{SKIP}} = 4\sqrt{2n} \quad (9.17)$$

Better results can be obtained by varying the block width so that the first and last blocks are smaller and the intermediate blocks are larger, and by using multiple levels of carry skip [5,6].

The complexity of the carry skip adder is only slightly greater than that of a ripple carry adder because the first and last blocks are ripple carry adders and the intermediate stages are ripple carry adders with three gates added for carry skipping.

$$\text{GATES}_{\text{SKIP}} = 9n + 3\left(\left\lceil \frac{n}{k} \right\rceil - 2\right) \quad (9.18)$$

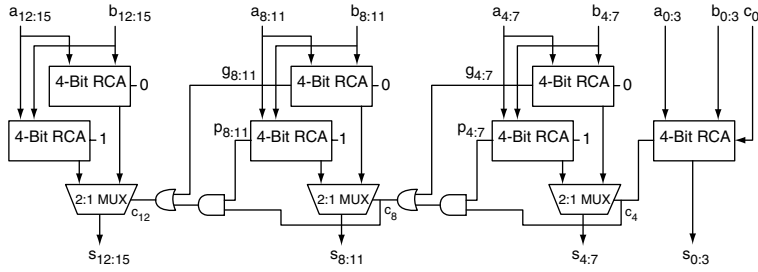

FIGURE 9.7 16-bit carry select adder.

### Carry Select Adder

The carry select adder divides the words to be added into blocks and forms two sums for each block in parallel (one with a carry in of ZERO and the other with a carry in of ONE). As shown for a 16-bit carry select adder on Fig. 9.7, the carry out from the previous block controls a multiplexer that selects the appropriate sum. The carry out is computed using Eq. (9.11), since the block propagate signal is the carry out of an adder with a carry input of ONE and the block generate signal is the carry out of an adder with a carry input of ZERO.

If a constant block width of  $k$  is used, there will be  $\lceil n/k \rceil$  blocks and the delay to generate the sum is  $2k + 3$  gate delays to form the carry out of the first block, two gate delays for each of the  $\lceil n/k \rceil - 2$  intermediate blocks, and three gate delays (for the multiplexer) in the final block. To simplify the analysis, the ceiling function in the count of intermediate blocks is ignored. The total delay is thus

$$\text{DELAY}_{C\text{-SEL}} = 2k + 2\frac{n}{k} + 2 \quad (9.19)$$

where  $\text{DELAY}_{C\text{-SEL}}$  is the total delay. The optimum block size is determined by taking the derivative of  $\text{DELAY}_{C\text{-SEL}}$  with respect to  $k$ , setting it to zero and solving for  $k$ . The result is

$$k = \sqrt{n} \quad (9.20)$$

$$\text{DELAY}_{C\text{-SEL}} = 2 + 4\sqrt{n} \quad (9.21)$$

As for the carry skip adder, better results can be obtained by varying the width of the blocks. In this case the optimum is to make the two least significant blocks are the same size and each successively more significant block is one bit larger. For this configuration, the delay for each block's most significant sum bit will equal the delay to the multiplexer control signal [7, p. A-38].

The complexity of the carry select adder is  $2n - k$  ripple carry adder stages, the intermediate carry logic and  $(\lceil n/k \rceil - 1)$   $k$ -bit wide 2:1 multiplexers.

$$\begin{aligned} \text{GATES}_{C\text{-SEL}} &= 9(2n - k) + 2(\lceil n/k \rceil - 2) + 3(n - k) + \lceil n/k \rceil - 1 \\ &= 21n - 12k + 3\lceil n/k \rceil - 5 \end{aligned} \quad (9.22)$$

This is somewhat more than twice the complexity of a ripple carry adder.

FIGURE 9.8 Two's complement subtracter.

### Fixed-Point Subtraction

As noted in previous subsection, subtraction of two's complement numbers is accomplished by adding the minuend to the inverted bits of the subtrahend and adding a one at the least significant position. Figure 9.8 shows a two's complement subtracter which computes  $A - B$ . The inverters complement the bits of  $B$ ; formation of the two's complement is completed by setting the carry into the least significant adder stage to a ONE.

### Fixed-Point Multiplication

Multiplication is generally implemented either via a sequence of addition, subtraction, and shift operations or with direct logic implementations.

#### Sequential Booth Multiplier

The Booth algorithm [8] is widely used for two's complement multiplication, since it is easy to implement. Earlier two's complement multipliers (e.g., [9]) required data dependent correction cycles if either operand is negative. To multiply  $A B$ , the product,  $P$ , is initially set to ZERO. Then, the bits of the multiplier,  $A$ , are examined in pairs of adjacent bits starting with the least significant bit (i.e.,  $a_0 a_{-1}$ ) and assuming  $a_{-1} = 0$ :

- If  $a_i = a_{i-1}$ ,  $P = P/2$
- If  $a_i = 0$  and  $a_{i-1} = 1$ ,  $P = (P + B)/2$
- If  $a_i = 1$  and  $a_{i-1} = 0$ ,  $P = (P - B)/2$

The division by 2 is not performed on the last stage (i.e., when  $i = n - 1$ ). All of the divide-by-two operations are simple arithmetic right shifts (i.e., the word is shifted right one position and the old sign bit is repeated for the new sign bit), and overflows in the addition process are ignored. The algorithm is illustrated in Fig. 9.9, which shows the formation of products for all combinations of  $\pm 5/8$  times  $\pm 3/4$  for 4-bit operands. The sequential Booth multiplier requires  $n$  cycles to form the product of a pair of  $n$ -bit numbers, where each cycle consists of an  $n$ -bit addition and a shift, an  $n$ -bit subtraction and a shift, or a shift without any other arithmetic operation.

#### Sequential Modified Booth Multiplier

The radix-4 modified Booth multiplier described by MacSorley [2] uses  $n/2$  cycles where each cycle examines three adjacent bits, adds or subtracts  $0$ ,  $B$ , or  $2B$  and shifts two bits to the right. Table 9.3 shows the operations as a function of the three bits  $a_{i+1}$ ,  $a_i$ , and  $a_{i-1}$ . The radix-4 modified Booth multiplier takes half the number of cycles as the "standard" Booth multiplier, although the operations performed during a cycle are slightly more complex (since it is necessary to select one of five possible addends instead of one of three). Extensions to higher radices that examine more than three bits [10] are possible, but generally not attractive because the addition/subtraction operations involve non-power of two multiples (such as 3, 5, etc.) of  $B$ , which raises the complexity.

**TABLE 9.3** Radix-4 Modified Booth Multiplication

$a_{i+1}$	$a_i$	$a_{i-1}$	Operation
0	0	0	$P = P/4$
0	0	1	$P = (P + B)/4$
0	1	0	$P = (P + B)/4$
0	1	1	$P = (P + 2B)/4$
1	0	0	$P = (P - 2B)/4$
1	0	1	$P = (P - B)/4$
1	1	0	$P = (P - B)/4$
1	1	1	$P = P/4$

**FIGURE 9.9** Example of sequential booth multiplication.

**Array Multipliers**

An alternative approach to multiplication involves the combinational generation of all bit products and their summation with an array of full adders. The block diagram of a 6 by 6 array multiplier is shown in Fig. 9.10. It uses a 6 by 6 array of cells to form the bit products and five adders (at the bottom of the array) to complete the evaluation of the product. Three types of cells are used in the square array: gate cells (marked G in Fig. 9.10), which use a single gate to form the logic AND of the  $x$  and  $y$  inputs to the cell; half adder cells (marked HA), which sum the second input to the cell with the logic AND of the  $x$

FIGURE 9.10 Unsigned 6 by 6 array multiplier.

and  $y$  inputs to the cell; and full adder cells (marked FA), which sum the second and third inputs to the cell with the logic AND of the  $x$  and  $y$  inputs to the cell. Standard half adders and full adders are used in the 5 cell strip at the bottom. An  $n$  by  $n$  array multiplier requires  $2n - 1$  gate cells,  $n$  half adders, and  $n^2 - 2n$  full adders. Of the half and full adder cells  $(n - 1)^2$  have an extra AND gate.

The complexity of the array multiplier is  $n^2$  AND gates,  $n$  half adders, and  $n^2 - 2n$  full adders. If a half adder comprises four gates and a full adder comprises nine gates, the total complexity of an  $n$ -bit by  $n$ -bit array multiplier is

$$\text{GATES}_{\text{ARRAY MPY}} = 10n^2 - 14n \quad (9.23)$$

The delay of the array multiplier is evaluated by following the pathways from the inputs to the outputs. The longest path starts at the upper left corner, progresses to the lower right corner, and then across the bottom to the lower left corner. If it is assumed that the delay from any adder input (for either half or full adders) to any adder output is  $k$  gate delays then the total delay of an  $n$ -bit by  $n$ -bit array multiplier is:

$$\text{DELAY}_{\text{ARRAY MPY}} = k(2n - 2) + 1 \quad (9.24)$$

Array multipliers are easily laid out in a cellular fashion, making them suitable for VLSI implementation, where minimizing the design effort may be more important than maximizing the speed.

Modification of the array multiplier to multiply two's complement numbers requires inverting the bits of the multiplier and multiplicand in the most significant row and column while forming the bit product matrix and adding a few correction terms [11,12].

### Wallace Tree/Dadda Fast Multiplier

A method for fast multiplication was developed by Wallace [13] and refined by Dadda [14,15]. With this method, a three-step process is used to multiply two numbers: (1) the bit products are formed, (2) the bit product matrix is "reduced" to a two row matrix where the sum of the rows equals the sum of the bit products, and (3) the two numbers are summed with a fast adder to produce the product. Although this may seem to be a complex process, it yields multipliers with delay proportional to the logarithm of

FIGURE 9.11 Unsigned 6 by 6 Dadda multiplier.

the operand word size, which is “faster” than the Booth multiplier, the modified Booth multiplier, or array multipliers, which all have delays proportional to the word size.

The second step in the fast multiplication process is shown for a 6 by 6 Dadda multiplier on Fig. 9.11. An input 6 by 6 matrix of dots (each dot represents a bit product) is shown as matrix 0. Columns having more than four dots (or that will grow to more than four dots due to carries) are reduced by the use of half adders (each half adder takes in two dots and outputs one in the same column and one in the next more significant column) and full adders (each full adder takes in three dots from a column and outputs one in the same column and one in the next more significant column) so that no column in matrix 1 will have more than four dots. Half adders are shown by a “crossed” line in the succeeding matrix and full adders are shown by a line in the succeeding matrix. In each case the right most dot of the pair that are connected by a line is in the column from which the inputs were taken in the preceding matrix for the adder. In the succeeding steps reduction to matrix 2, with no more than three dots per column, and finally matrix 3, with no more than two dots per column, is performed.

The height of the matrices is determined by working back from the final (two row) matrix and limiting the height of each matrix to the largest integer that is no more than 1.5 times the height of its successor. Each matrix is produced from its predecessor in one adder delay. Since the number of matrices is logarithmically related to the number of rows in matrix 0, which is equal to the number of bits in the words to be multiplied, the delay of the matrix reduction process is proportional to  $\log n$ . Since the adder that reduces the final two row matrix can be implemented as a carry lookahead adder (which also has logarithmic delay), the total delay for this multiplier is proportional to the logarithm of the word size.

### Fixed Point Division

Division is traditionally implemented as a recurrence, which uses a sequence of shift, subtract, and compare operations, in contrast to the shift and add approach employed for multiplication. The comparison operation is significant. It results in a serial process, which is not amenable to parallel implementation.

### Digit Recurrent Division

The most common division algorithms are digit recurrent algorithms [16,17] based on selecting digits of the quotient  $Q$  (where  $Q = N/D$ ) to satisfy the following equation:

$$P_{k+1} = rP_k - q_{n-k-1} D \quad \text{for } k = 1, 2, \dots, n - 1 \quad (9.25)$$

where  $P_k$  is the partial remainder after the selection of the  $k$ th quotient digit,  $P_0 = N$  (subject to the constraint  $|P_0| < |D|$ ),  $r$  is the radix,  $q_{n-k-1}$  is the  $k$ th quotient digit to the right of the binary point, and  $D$  is the divisor. In this section it is assumed that both  $N$  and  $D$  are positive, see [18] for details on handling the general case.

### Restoring Divider

The restoring division algorithm is similar to paper and pencil division. The basic scheme is shown in Fig. 9.12. Block 1 initializes the algorithm. In step 2, a trial dividend,  $TP_{k+1}$ , is computed based on the assumption that the quotient bit is a 1. In the third step,  $TP_{k+1}$  is compared to 0. If  $TP_{k+1}$  is negative, step 4 restores the trial dividend to what it would be if the quotient digit had been assumed to be 0. This restoring operation gives the algorithm its name. Step 5 is performed if  $TP_{k+1}$  is zero or positive. Finally, step 6 tests whether all bits of the quotient have been formed and goes to step 2 if more need to be computed. Each pass through steps 2–6 forms one bit of the quotient. As shown in Fig. 9.12, each pass through steps 2–6 requires an addition in step 2, a comparison in step 3, and may require an addition in step 4. If half of the quotient bits are 0 and half are 1, computing an  $n$ -bit quotient will involve  $3n/2$  additions and  $n$  comparisons. This is the performing version of the restoring division algorithm, which means that the restoring operation is actually performed in step 4.

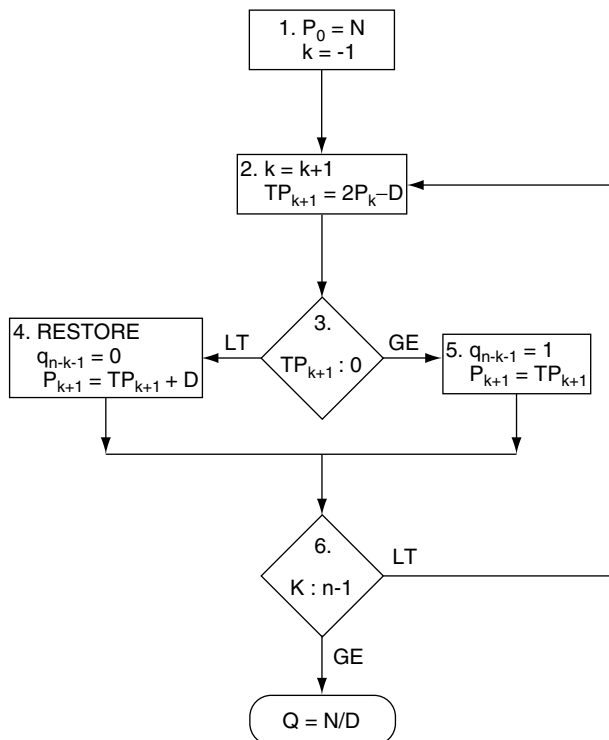

FIGURE 9.12 Restoring division.

$$\begin{aligned}

D &= \frac{7}{8} \\
n &= 4 \\
k = 0, TP_1 &= 2 P_0 - D = \frac{3}{8} \text{ Since } TP_1 > 0, \text{ then } q_3 = 1 \text{ and } P_1 = TP_1 = \frac{3}{8} \\

Q &= 0.1011
\end{aligned}$$

**FIGURE 9.13** Example of restoring division.

Figure 9.13 shows an example of the restoring division algorithm where the first 4-bits of quotient of 5/8 divided by 7/8 is evaluated.

The alternative non-performing version of the algorithm places  $2P_k$  in a temporary register in step 2 and uses that value for  $P_{k+1}$  in step 4. The nonperforming version computes an  $n$ -bit quotient in  $n$  additions and  $n$  comparisons.

### Nonrestoring Divider

In nonrestoring division, the quotient digits are constrained to be either  $\pm 1$  (i.e.,  $q_k$  is selected from  $\{1, \bar{1}\}$ ). The digit selection and resulting partial remainder are given for the  $k$ th iteration by the following relations:

$$\text{If } P_k \geq 0, \quad q_{n-k-1} = 1 \quad \text{and} \quad P_{k+1} = rP_k - D \quad (9.26)$$

$$\text{If } P_k < 0, \quad q_{n-k-1} = \bar{1} \quad \text{and} \quad P_{k+1} = rP_k + D \quad (9.27)$$

The basic scheme is shown in Fig. 9.14. Block 1 initializes the algorithm. In step 3,  $P_k$  is compared to 0. If  $P_k$  is negative, in step 4 the quotient digit is set to  $\bar{1}$  and  $P_{k+1} = 2P_k + D$ . If  $P_k$  is positive, in step 5 the quotient digit is set to 1 and  $P_{k+1} = 2P_k - D$ . Finally, step 6 tests whether all bits of the quotient have been formed and goes to step 2 if more need to be computed. Each pass through steps 2–6 forms one bit of the quotient. As shown in Fig. 9.14, each pass through steps 2–6 requires a comparison in step 3 and an addition in either step 4 or step 5. Thus, computing an  $n$ -bit quotient will involve  $n$  additions and  $n$  comparisons.

Figure 9.15 shows an example of the restoring division algorithm where the first four bits of quotient of 5/8 divided by 7/8 is evaluated.

The signed digit number (comprises  $\pm 1$  digits) can be converted into a conventional binary number by subtracting, NEG, the number formed by the  $\bar{1}$  (with ZEROS where there are +ONES and ONES where there are  $\bar{1}$ s in Q) from, POS, the number formed by the +ONES (with ZEROS where there are  $\bar{1}$ s in Q). For the example of Fig. 9.15:

$$\begin{aligned}
Q &= 0.11\bar{1}1 \\
POS &= 0.1101 \\
NEG &= 0.0010 \\
Q &= 0.1101 - 0.0010 \\
Q &= 0.1101 + 1.1110 \\
Q &= 0.1011
\end{aligned}$$

### Binary SRT Divider

The binary SRT division process is similar to nonrestoring division, but the set of allowable quotient digits is increased to  $\{1, 0, \bar{1}\}$  and the divisor is restricted to  $.5 \leq D < 1$ . The digit selection and resulting partial remainder are given for the  $k$ th iteration by the following relations:

$$\text{If } P_k \geq .5, \quad q_{n-k-1} = 1 \quad \text{and} \quad P_{k+1} = 2P_k - D \quad (9.28)$$

$$\text{If } -.5 < P_k < .5, \quad q_{n-k-1} = 0 \quad \text{and} \quad P_{k+1} = 2P_k \quad (9.29)$$

$$\text{If } P_k \geq .5, \quad q_{n-k-1} = \bar{1} \quad \text{and} \quad P_{k+1} = 2P_k + D \quad (9.30)$$

FIGURE 9.16 Binary SRT division.

The basic scheme is shown in Fig. 9.16. Block 1 initializes the algorithm. In steps 3 and 5,  $P_k$  is compared to  $\pm .5$ . If  $P_k \geq .5$ , in step 4 the quotient digit is set to 1 and  $P_{k+1} = 2P_k - D$ . If  $P_k \leq -.5$ , in step 6 the quotient digit is set to  $\bar{1}$  and  $P_{k+1} = 2P_k + D$ . If the value of  $P_k$  is between  $-.5$  and  $.5$ , step 7 sets  $P_{k+1} = 2P_k$ . Finally, step 8 tests whether all bits of the quotient have been formed and goes to step 2 if more need to be computed. Each pass through steps 2–8 forms one digit of the quotient. As shown on Fig. 9.16, each pass through steps 2–8 requires one or two comparisons in steps 3 and 5, and may require an addition (in step 4 or step 6). Thus computing an  $n$ -bit quotient will involve up to  $n$  additions and from  $n$  to  $2n$  comparisons.

### Higher Radix SRT Divider

The higher radix SRT division process is similar to the binary SRT algorithms. Radix 4 is the most common higher radix SRT division algorithm with either a minimally redundant digit sets of  $\{2, 1, 0, \bar{1}, \bar{2}\}$  or the maximally redundant digit sets of  $\{3, 2, 1, 0, \bar{1}, \bar{2}, \bar{3}\}$ . The operation of the algorithm is similar to the binary SRT algorithm shown on Fig. 9.16, except that  $P_k$  and  $Q$  are applied to a look up table or a programmable logic array (PLA) to determine the quotient digit. A research monograph provides a detailed treatment of SRT division [18].

### Newton–Raphson Divider

A second division technique uses a form of Newton–Raphson iteration to derive a quadratically convergent approximation to the reciprocal of the divisor which is then multiplied by the dividend to produce the quotient. In systems which include a fast multiplier, this process is often faster than conventional division [19].

The Newton–Raphson division algorithm to compute  $Q = N/D$  consists of three basic steps:

- (1) Calculating a starting estimate of the reciprocal of the divisor,  $R_{(0)}$ . If the divisor,  $D$ , is normalized (i.e.,  $\frac{1}{2} \leq D < 1$ ), then  $R_{(0)} = 3 - 2D$  exactly computes  $1/D$  at  $D = .5$  and  $D = 1$  and exhibits maximum error (of approximately 0.17) at  $D = \sqrt{1/2}$ . Adjusting  $R_{(0)}$  downward to by half the maximum error gives

$$R_{(0)} = 2.915 - 2D \quad (9.31)$$

This produces an initial estimate, that is, within about 0.087 of the correct value for all points in the interval  $\frac{1}{2} \leq D < 1$ .

- (2) Computing successively more accurate estimates of the reciprocal by the following iterative procedure:

$$R_{(i+1)} = R_{(i)}(2 - DR_{(i)}) \quad \text{for } i = 0, 1, \dots, k \quad (9.32)$$

- (3) Computing the quotient by multiplying the dividend times the reciprocal of the divisor.

$$Q = NR_{(k)}, \quad (9.33)$$

where  $i$  is the iteration count and  $N$  is the numerator. Figure 9.17 illustrates the operation of the Newton–Raphson algorithm. For this example, three iterations (one shift, four subtractions, and seven multiplications) produces an answer accurate to nine decimal digits (approximately 30 bits).

With this algorithm, the error decreases quadratically, so that the number of correct bits in each approximation is roughly twice the number of correct bits on the previous iteration. Thus, from a  $3\frac{1}{2}$ -bit initial approximation, two iterations produce a reciprocal estimate accurate to 14-bits, four iterations produce a reciprocal estimate accurate to 56-bits, etc.

The efficiency of this process is dependent on the availability of a fast multiplier, since each iteration of Eq. (9.32) requires two multiplications and a subtraction. The complete process for the initial estimate, three iterations, and the final quotient determination requires four subtraction operations and seven multiplication operations to produce a 16-bit quotient. This is faster than a conventional non-restoring divider if multiplication is roughly as fast as addition, a condition which may be satisfied for systems which include hardware multipliers.

## Floating-Point Arithmetic

Recent advances in VLSI have increased the feasibility of hardware implementations of floating point arithmetic units. The main advantage of floating point arithmetic is that its wide dynamic range virtually eliminates overflow for most applications.

### Floating-Point Number Systems

A floating point number,  $A$ , consists of a significand (or mantissa),  $S_a$ , and an exponent,  $E_a$ . The value of a number,  $A$ , is given by the equation:

$$A = S_a r^{E_a} \quad (9.34)$$

where  $r$  is the radix (or base) of the number system. Use of the binary radix (i.e.,  $r = 2$ ) gives maximum accuracy, but may require more frequent normalization than higher radices.

The IEEE Std. 754 single precision (32-bit) floating point format, which is widely implemented, has an 8-bit biased integer exponent which ranges between 1 and 254 [20]. The exponent is expressed in excess 127 code so that its effective value is determined by subtracting 127 from the stored value. Thus, the range of effective values of the exponent is  $-126$  to  $127$ , corresponding to stored values of 1 to 254, respectively. A stored exponent value of ZERO ( $E_{\min}$ ) serves as a flag for ZERO (if the significand is ZERO) and for denormalized numbers (if the significand is non-ZERO). A stored exponent value of 255 ( $E_{\max}$ ) serves as a flag for infinity (if the significand is ZERO) and for “not a number” (if the significand is non-zero). The significand is a 25-bit sign magnitude mixed number (the binary point is to the right of the most significant bit and is always a ONE except for denormalized numbers). More detail on floating point formats and on the various considerations that arise in the implementation of floating point arithmetic units are given in [7,21]. The IEEE 754 standard for floating point numbers is discussed in [22,23].

### Floating-Point Addition

A flow chart for floating point addition is shown in Fig. 9.18. For this flowchart, the operands are assumed to be “unpacked” and normalized with magnitudes in the range  $[1/2, 1)$ . On the flow chart, the operands are  $(E_a, S_a)$  and  $(E_b, S_b)$ , the result is  $(E_s, S_s)$ , and the radix is 2. In step 1 the operand exponents are compared; if they are unequal, the significand of the number with the smaller exponent is shifted right in step 3 or 4 by the difference in the exponents to properly align the significands. For example, to add the decimal operands  $0.867 \times 10^5$  and  $0.512 \times 10^4$ , the latter would be shifted right by one digit and 0.867 added to 0.0512 to give a sum of  $0.9182 \times 10^5$ . The addition of the significands is performed in step 5. Steps 6–8 test for overflow and correct, if necessary, by shifting the significand one position to the right and incrementing the exponent. Step 9 tests for a zero significand. The loop of steps 10–11 scales unnormalized (but non-ZERO) significands upward to normalize the result. Step 12 tests for underflow.

Floating point subtraction is implemented with a similar algorithm. Many refinements are possible to improve the speed of the addition and subtraction algorithms, but floating point addition and subtraction will, in general, be much slower than fixed-point addition as a result of the need for operand alignment and result normalization.

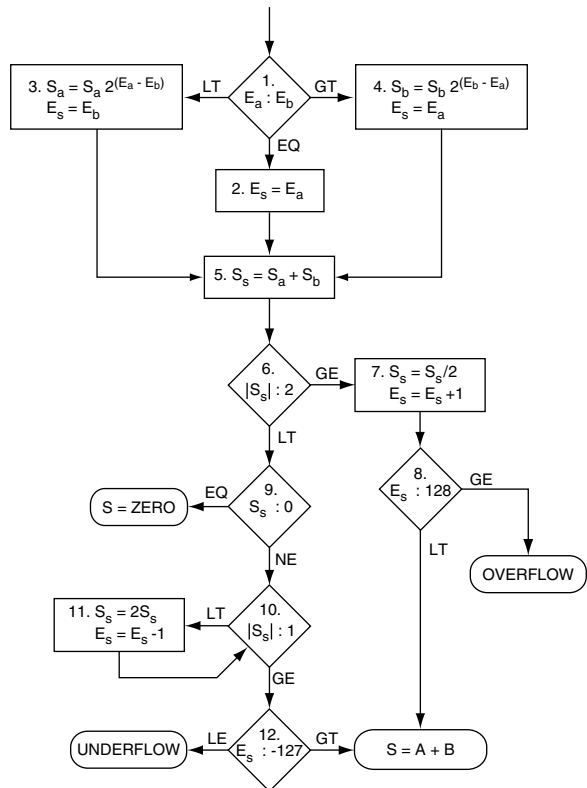

FIGURE 9.18 Floating-point addition.

**Floating-Point Multiplication**

The algorithm for floating-point multiplication forms the product of the operand significands and the sum of the operand exponents. For radix 2 floating point numbers, the significand values are greater than or equal to 1 and less than 2. The product of two such numbers will be greater than or equal to 1 and less than 4. At most a single right shift is required to normalize the product.

**Floating-Point Division**

The algorithm for floating-point division forms the quotient of the operand significands and the difference of the operand exponents. The quotient of two normalized significands will be greater than or equal to .5 and less than 2. At most a single left shift is required to normalize the quotient.

**Floating-Point Rounding**

All floating-point algorithms may require rounding to produce a result in the correct format. A variety of alternative rounding schemes have been developed for specific applications. Round to nearest, round toward ∞, round toward -∞, and round toward ZERO are required for implementations of the IEEE floating point standard. Selection should be based on both static and dynamic performance [24], although round to nearest is appropriate for most applications.

**Conclusions**

This chapter section has presented an overview of the two’s complement number system, algorithms for the basic integer arithmetic operations of addition, subtraction, multiplication, and division, and a brief discussion of floating point operations. When implementing arithmetic units there is often an opportunity to optimize the performance and the complexity to the requirements of the specific application. In general,

faster algorithms require more area or more complex control; it is often useful to use the fastest algorithm that will fit the available area.

## 9.2 Fast Adders and Multipliers

*Gensuke Goto*

### Introduction

All the logic circuits used in an electronic computer are constituted of combinations of basic logic gates such as inverters, NAND or NOR gates. There exist many varieties of circuits that realize the basic arithmetic logic functions for addition and multiplication due to the difference in viewpoint of circuit optimization [1–4].

In this chapter section we will discuss an essence and an overview of recent high-speed digital arithmetic logic circuits. The emphasis is on fast adders and multipliers that are the most important logic units for high-speed data processing. Several types of these units are discussed and compared from various viewpoints of circuit simplicity, easiness of design and power consumption, in addition to high-speed capability.

### Adder

#### Principle of Addition

In the Boolean logic, numeral values are often represented as 2's complement numbers because it is easy to deal with negative values. Therefore, we assume that if not explicitly stated, numerals are represented in 2's complement numbers in this chapter section. It is to be noted, however, the previous works that appear in this chapter do not necessarily obey to this rule.

Let us consider the addition of two binary numbers  $A$  and  $B$  with  $n$ -bit width.  $A$  is, for instance, represented by

$$A = -a_{n-1} 2^{n-1} + \sum_{i=0}^{n-2} (a_i 2^i) \quad (9.35)$$

where  $a_{n-1}$  is the sign bit ( $a_{n-1} = 1$  if  $A$  has a negative value, and  $a_{n-1} = 0$  if it has a positive value), and  $a_i \{1, 0\}$  is the bit at the  $i$ th position counted from the least significant bit (LSB)  $a_0$ . The sum  $S(S = A + B)$  is represented by an  $(n + 1)$ -bit binary number whose most significant bit (MSB) is the sign bit. An example of binary addition is shown in the following:

$$\begin{array}{r} 00101 \quad : A = 5 \text{ in decimal number} = 0101 \\ + 11001 \quad : B = -7 \text{ in decimal number} = 1001 \\ \hline 11110 \quad : S = -2 \text{ in decimal number} = 11110 \end{array}$$

This is a case of adding  $A = 5$  and  $B = -7$  in decimal numbers that are represented by 4-bit binary numbers. The third bit positions of these operands in binary numbers are the sign bits  $a_3 = a_s = 0$  and  $b_3 = b_s = 1$ , because  $A$  is a positive number and  $B$  is a negative number. Since the sum of these operands yields a 5-bit sum in principle, the fourth bit positions of these operands ( $a_4, b_4$ ) have to be considered existent as sign bits in adding procedure (sign bit extension). Thus, the output signal  $s_4$  at the sign bit position is obtained as 1. The effective number of bits in  $S$  is 4 ( $s_0$  to  $s_3$ ), one-bit extension as a result of summation. These bits are represented in 2's complement form of a negative number.

#### One-Bit Full Adder

First we consider a 1-bit full adder (FA), which is a basic unit for constituting an  $n$ -bit adder. The sum ( $s_i$ ) and carry ( $c_i$ ) signals at the  $i$ th bit position in the  $n$ -bit adder are generated according to the operation defined by Boolean equations:

$$s_i = a_i \oplus b_i \oplus c_{i-1} \quad (9.36)$$

$$c_i = a_i b_i + (a_i + b_i) c_{i-1} \quad (9.37)$$

(a)

(b)

(c)

(d)

**FIGURE 9.19** (a) XOR circuit-1, (b) XOR circuit-2, (c) XOR circuit-3, (d) XOR circuit-4.

where  $c_{i-1}$  is the output carry signal of the 1-bit adder at the  $(i-1)$ th bit position, and  $a_i \oplus b_i$  indicates an exclusive-OR (XOR) operation of  $a_i$  and  $b_i$ . From the above equation, we can understand that two XOR logic gates are necessary to yield a sum signal  $s_i$  in a 1-bit FA.

Many kinds of XOR gates implemented using CMOS transistors are proposed up to date. Some examples of such gates are shown in Fig. 9.19. Figure 9.19(a) is a popular XOR gate using a NOR gate and a 2-input AND-OR-inverter. The transistor count in this case is 10. Figure 9.19(b) is composed of two pass transistor switches, and this is another popular gate whose number of transistors is also 10. Figure 9.19(c) is of a six-transistor type [5]. Though this circuit is compact, driving ability of this gate

FIGURE 9.20 Half-adder circuit.

FIGURE 9.21 One-bit full adder.

is low because the output node has serial resistor to degrade the output signal [6], so the number of direct connection of this gate is practically limited to two. Figure 9.19(d) is of a 7-transistor type whose p-channel transistor is introduced to the gate of the output inverter to compensate for weak drivability to a high level when  $a = b = 1$  (at high level) [7].

To control the carry propagation efficiently, the following signals are defined for long-word addition at each bit position  $i$ :

$$\text{carry-propagate signal } p_i = a_i \oplus b_i \quad (9.38)$$

$$\text{carry-generate signal } g_i = a_i b_i \quad (9.39)$$

Using these notations, Eqs. (9.36) and (9.37) are rewritten by

$$s_i = p_i \oplus c_{i-1} \quad (9.40)$$

$$c_i = g_i + p_i c_{i-1} \quad (9.41)$$

respectively. A carry is generated if  $g_i = 1$ , and the stage  $i$ ( $i$ th bit position of an  $n$ -bit adder) propagates an input carry signal  $c_{i-1}$  to its output if  $p_i = 1$ . These signals are generated in a gate called a half adder (HA) as shown in Fig. 9.20, and used to constitute a high-speed but complicated carry control scheme such as a carry lookahead adder as described in the later sections. FA is often implemented according to the Boolean equations (9.40) and (9.41). Though there exist many variations to constructing a FA, only one example is shown in Fig. 9.21. In this construction, the transistor count is 30. By using pass transistor switches, we can reduce it to 24.

### Ripple Carry Adder

A ripple carry adder (RCA) is the simplest one as a parallel adder implemented in hardware. An  $n$ -bit RCA is implemented by simple concatenation of  $n$  1-bit FAs. As the carry signal ripples bit by bit from the least significant bit to the most significant bit, the worst-case delay time is in proportion to the number  $n$  of 1-bit full adders [1]. This is roughly equal to the critical path delay of RCA, if  $n$  is large enough as compared with 1.

Manchester carry chain (MCC) is one of the simplest schemes for RCA that utilizes MOS technology [8,9]. The carry chain is constructed of series-connected pass transistors whose gates are controlled by the carry-propagate signal  $p_i$  at every bit position  $i$  of  $n$  1-bit FAs. This scheme can offer simple hardware implementation with less power as compared with other elaborate schemes. Because of distortion due to RC time constant, the carry signal needs to be regenerated by inserting inverters or true buffers at appropriate locations in the carry chain. Though this compensation needs additional transistors, the total power may be reduced appreciably if buffers are equipped with efficiently.

**Carry Skip Adder**

If the carry-propagate signals  $p_i$  that belong to the bit positions from the  $m$ th to  $(m + k)$ th are all 1, the carry signal at the  $(m - 1)$ th bit position can bypass through  $(k + 1)$  bits to the  $(m + k)$ th bit position without rippling through these bits. A carry skip adder (CSKA) is a scheme to utilize this principle for shortening the longest path of the carry propagation. A fixed-group CSKA is such that the  $n$  1-bit FAs to construct an  $n$ -bit adder is divided equally into  $k$  groups over which the carry signal can bypass if the condition to skip is fulfilled. The maximum delay of the carry propagation is reduced to a factor of  $1/k$  as compared with RCA [1].

MCC is often used with several bypass circuits to speed up the carry propagation in longer word addition [10]. Figure 9.22(a) is a case of such implementation. Though this 4-bit bypass circuit may be considered to work well at a glance, it is not true because of the signal conflict during the transient phase from the former state to the new state to settle to, as shown in Fig. 9.22(c) with transition of the node voltage  $V_s(A)$  at the node A in Fig. 9.22(a) [11]. To avoid this unexpected transition delay, it is necessary to cut off all of other signal paths than expected logically as shown in Fig. 9.22(b). Under this modified scheme [11], the bypass circuit can function as expected like shown in Fig. 9.22(c), with change of the node voltage  $V_s(B)$  at the node B in Fig. 9.22(b).

A variable block adder (VBA) allows the groups to be different in size [12], so that the maximum delay is further reduced from the fixed group CSKA. The number of adders in a group is gradually increased from LSB toward the middle bit position, and then reduced toward MSB. This scheme may lead us to the total delay dependency on the carry propagation in the order of square root of  $n$ . Extension of this approach to multiple levels of carry skip is possible for further speeding up on a fast adder.

**Carry Lookahead Adder**

A carry lookahead adder (CLA) [13] utilizes fully two types of signals  $p_i$  and  $g_i$  at the  $i$ th bit position of an  $n$ -bit adder to control carry propagation. For instance, the carry signals  $c_i$ ,  $c_{i+1}$ , and  $c_{i+2}$  can be estimated

FIGURE 9.22(a) Carry skip circuit that causes conflict during signal transient.

FIGURE 9.22(b) Carry skip circuit that excludes conflict during signal transient.

FIGURE 9.22(c) Effect of signal conflict on circuit delay.

according to the following Boolean equations if the carry-in signal  $c_{i-1}$  to the  $i$ th 1-bit full adder is determined:

$$c_i = g_i + p_i c_{i-1} \quad (9.42)$$

$$c_{i+1} = g_{i+1} + p_i g_i + p_{i+1} p_i c_{i-1} \quad (9.43)$$

$$c_{i+2} = g_{i+2} + p_{i+2} g_{i+1} + p_{i+2} p_{i+1} g_i + p_{i+2} p_{i+1} p_i c_{i-1} \quad (9.44)$$

FIGURE 9.23 3-bit carry lookahead adder.

These three carry signals can be determined almost simultaneously after  $c_{i-1}$  is input to the  $i$ th adder if hardware to yield the above signals is equipped with as shown in Fig. 9.23 for a case of  $i = 0$ . Within this scheme, a 1-bit full adder at each bit position ( $i$ ) consists of a sum generator and a HA segment to yield  $p_i$  and  $g_i$  signals, and no carry generator is required at each bit position. Instead, the carry signals  $c_i$ ,  $c_{i+1}$ , and  $c_{i+2}$  are generated in a lookahead block whose Boolean expressions are given above.

Although the number  $k$  of carry signals to be determined simultaneously in a lookahead block can be extended to more than 4, hardware to implement CLA logic becomes more and more complicated in proportion to  $k$ . This increases the necessary number of logic gates, power consumption, and the delay time to generate a carry signal at a higher bit position in a lookahead block. Considering this situation, a practically available number is limited to 4, and this limitation reduces much of the attractiveness on CLA as architecture of a high-speed adder. To overcome the inconvenience, group (or block) carry-generate ( $G_j$ ) and carry-propagate ( $P_j$ ) signals are considered for dealing with longer word operation. With these signals, the carry equation can be expressed by

$$c_j = G_j + P_j c_{i-1} \quad (9.45)$$

where

$$G_j = g_{i+k} + p_{i+k} g_{i+k-1} + p_{i+k} p_{i+k-1} g_{i+k-2} + \cdots + p_{i+k} p_{i+k-1} \cdots p_{i+1} g_i \quad (9.46)$$

and

$$P_j = p_{i+k} p_{i+k-1} \cdots p_{i+1} p_i. \quad (9.47)$$

In a recursive way, a group of groups can be defined to handle wider-word operands.

Assuming that a single level of the carry lookahead group generates  $k$  carry signals simultaneously with two additional gate delays in the carry path, it can be shown that the total delay of an  $n$ -bit CLA is  $2 \log_k n$ -gate delay units [1]. Theoretically this may be considered one of the fastest adder structures, but the practical speed of CLA is not necessarily highest because of using complicated gates to implement a lookahead block in the carry path.

Recurrence solver-based adders are proposed with some popularity to systematically implement CLA blocks [14–16].

### Carry Select Adder

A carry select adder (CSLA) is one of the conditional-sum adder [1,17] that is based on the idea of selecting the most significant portion of the operands conditionally, depending on a carry-in signal to the least significant portion. This algorithm yields the theoretically fastest adder of two numbers [18]. In CSLA implementation, two operands are divided into blocks where two sum signals at each bit position are generated in parallel in order to be selected by the carry-in signal to the blocks. One is a provisional sum  $s_i^0$  to be selected as a true sum signal  $s_i$  at the  $i$ th bit position if the carry-in signal is 0, and the other provisional sum  $s_i^1$  is selected as a true sum signal if the carry-in signal is 1. This provisional sum signal pair can be selected immediately after the carry-in signal is fixed.

In Fig. 9.24 where a 16-bit adder is constructed of CSLA, the provisional carry signal pair ( $c_i^0, c_i^1$ ) is generated at the highest bit position within each block, in addition to the provisional sum signal pairs generated at all bit positions within the block. This carry signal pair is used to generate a true carry signal in a carry-selector block (CS) along with similar signals located at the different blocks. The provisional sum signals within the block are selected by  $c_{i-1}$  to yield true sum signals  $s_{i+3:i}$ . Figure 9.25 shows a combination of RCA and CSLA to construct a 16-bit adder. By such a combination, a high-speed and small size adder can be realized efficiently [19–21].

## Multiplier

### Algorithm of Multiplication

In the past when the scale of integration on VLSI was low, a multiplier circuit was implemented by a shift-and-add method because of simplicity in hardware. This method is, however, very time-consuming, so that the need of high-speed multiplication could scarcely be fulfilled in many practical applications. Now that a system-on-a-chip (SoC) with more than 10 million transistors has emerged with a rapid progress of the fine-pattern process technology of semiconductors, we are in a stage of using any parallel multipliers with full acceleration mechanisms for speeding up the processing.

In binary multiplication of an  $n$ -bit multiplicand  $A$  and multiplier  $B$ , we begin to calculate partial products  $p_j$  for implementation of a parallel multiplier, which is defined by

$$\begin{aligned}
 p_j &= \sum_{i=0}^{n-1} \{(a_i 2^i) (b_j 2^j)\} \\
 &= \sum_{i=0}^{n-1} (p_{ij} 2^{i+j}),
 \end{aligned} \tag{9.48}$$

where  $p_{ij}$  is a partial product bit at the  $(i + j)$ th position. Each bit in a partial product  $p_j$  is equal to 0 if  $b_j = 0$ , and  $a_i$  if  $b_j = 1$  for the case of multiplication of positive numbers. For multiplication of 2's complement numbers, the situation is a little complicated, because correction to sign-bit extension is necessary as described in the later section.

The product  $Z (= A \times B)$  is expressed by using the partial products as follows:

$$\begin{aligned}
 Z &= \sum_{j=0}^{2n-1} (z_j 2^j) \\
 &= \sum_{j=0}^{n-1} p_j.
 \end{aligned} \tag{9.49}$$

### Array-Type Multiplier

The simplest parallel multiplier is such that pairs of an AND gate and a 1-bit full adder are laid out repetitively and connected in sequence to construct an  $n^2$  array [1,22]. An example of a  $4 \times 4$ -bit parallel multiplier to manipulate two positive numbers is shown in Fig. 9.26. The operation time in this multiplier equals to sum of delays that consist of an AND gate, four FAs, and a 4-bit carry-propagate adder (CPA). The CPA may be consisted of a 4-bit RCA. It can be easily understood that the reduction process of partial products to two at each bit position dominates the operation time in this multiplier except for a CPA delay. Thus, the acceleration of the compression process for the partial product bits at each bit position is a key to obtain a fast multiplier. For the basic array-type multiplication in Fig. 9.26, this compression process constitutes ripple carry connection. The worst-case delay of this type is composed of  $2n$  FA delays. For most recent high-speed data processing systems that deal with wider word than 32 bits, this delay time is too large to be acceptable. Therefore, some kinds of speeding-up mechanisms

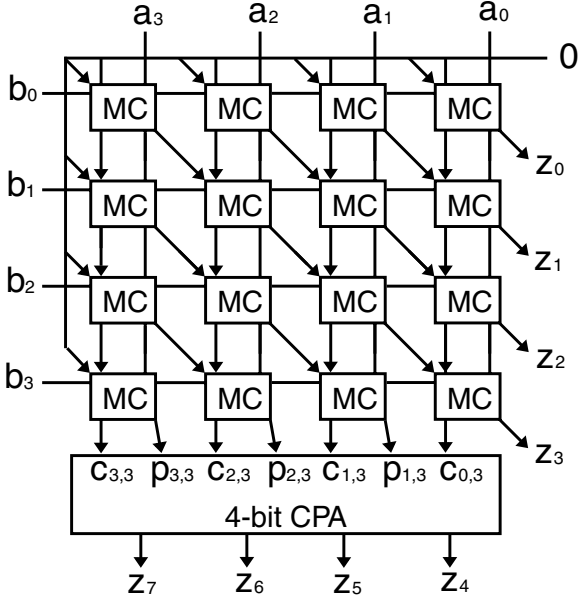

FIGURE 9.26  $4 \times 4$ -bit array-type multiplier.

are necessary to satisfy requirement for recent high-speed systems. A modified-array approach is an example of such a speeding-up mechanism [23].

The carry signal generated in FA (contained in MC in Fig. 9.26) at each bit position is never propagated to a higher bit position within the same partial product, but it is treated as if it is a part of a partial product at one-bit higher position. This enables us to avoid the carry propagation from LSB to MSB in the same partial product, and this structure is called a carry-save adder (CSA) [1]. For this structure, whether the carry path or the sum path may constitute the critical path cannot be predicted beforehand. Therefore, not only the carry generator but also the sum generator must be designed as a fast path in order to constitute a fast multiplier.

## Wallace Tree

Summing the partial product bits in parallel using a carry-save adder tree is called a Wallace tree, which is introduced by Wallace [24] and later refined by Dadda [25,26]. In a case of using FA's as a unique constituent of CSA, the maximum parallelism can be reached by adding three partial product bits at a time in the same FA. The total delay time of CSA part for an  $n \times n$ -bit parallel multiplier in this case is  $\log_{3/2} n$ , thus the drastic reduction of the delay time is possible for large  $n$  values as compared with a simple array-type multiplier. A multiplier with the Wallace tree is often called a tree-type one, in contrast with an array-type one shown in Fig. 9.26.

Although the Wallace tree can contribute much to realization of a fast long-word multiplier, its layout scheme is very complex as compared with the array-type because the wiring among FAs has little regularity. This is one of the reasons why this tree type had not been implemented widely as a long-word multiplier in the past. There exist many efforts that try to introduce regularity of layout on the Wallace tree [27–32], and now it is possible to implement it with higher regularity than ever.

## 4-2 Compressor

Weinberger disclosed a structure called “4-2 carry-save module” in 1981 [33]. This structure is considered to compress actually five partial product bits into three and is consisted of a combination of two FA's. The four of five inputs into this module come from the same bit position of the weight  $m(=i+j)$  while the rest 1-bit, known as an carry-in signal, comes from the neighboring position of the weight  $m-1$ . This module creates three signals: two of which are a pair of carry and sum signals, and the rest is an intermediate carry-out signal that is input to a module at the neighboring position of the weight  $m+1$ . As the four signals are compressed at a time to yield a pair of carry and sum signals except for an intermediate carry signal, this module is called a 4-2 compressor.

The 4-2 compressor designed for speeding up the compression operation has speed of three XOR gate delays in series [34–36], and this scheme makes it possible to shorten the compression delay to three-fourths of the original one. Using this type of a 4-2 compressor, we can relieve the complicated wiring design among the modules in the Wallace tree with enhanced speed of processing. Some examples of 4-2 compressors are given in Fig. 9.27. Figure 9.27(a) represents a typical circuit composed of 60 transistors [34]. Figure 9.27(b) utilizes pass transistor multiplexers to enhance speed of compression by 18% compared with a FA-based circuit, and is composed of 58 transistors [35]. Figure 9.27(c) is an optimized one in view of both small number of transistors (48) and keeping high-speed operation [36]. This transistor count is comparable to using a pair of series-connected FAs, yet the speed is 30% higher.

## Booth Recoding Algorithm

For multiplication of 2's complement numbers, the modified Booth recoding algorithm is the most frequently used method to generate partial products [37,38]. This algorithm allows for the reduction of the number of partial products to be compressed in a carry-save adder tree, thus the compression speed can be enhanced. This Booth–MacSorley algorithm is simply called the Booth algorithm, and the two-bit recoding using this algorithm scans a triplet of bits to reduce the number of partial products by roughly one half. The 2-bit recoding means that the multiplier  $B$  is divided into groups of two bits, and the algorithm is applied to this group of divided bits.

FIGURE 9.27(a) 4-2 compressor-1.

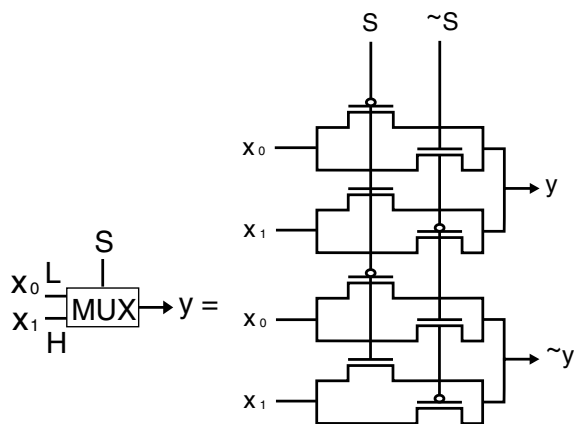

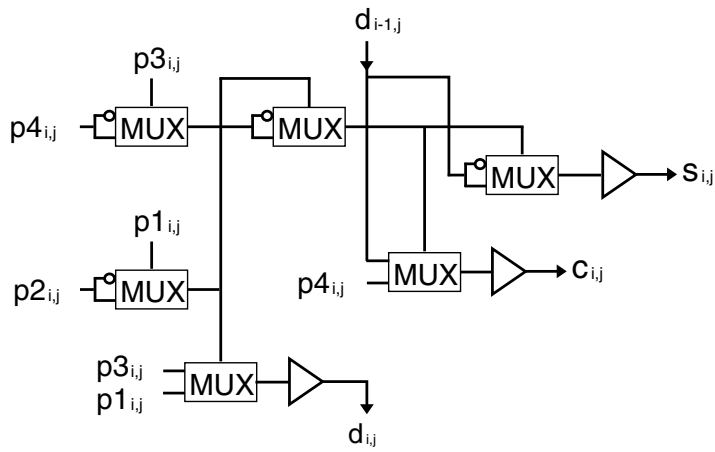

FIGURE 9.27(b) 4-2 compressor-2.

FIGURE 9.27(c) 4-2 compressor-3.

In general, the multiplier  $B$  in 2's complement representation is expressed by

$$\begin{aligned}
 B &= -b_{n-1} 2^{n-1} + \sum_{j=0}^{n-2} (b_j 2^j) \\
 &= (b_{n-3} + b_{n-2} - 2b_{n-1}) 2^{n-2} + (b_{n-5} + b_{n-4} - 2b_{n-3}) 2^{n-4} + \dots \\
 &\quad + (b_{n-k-1} + b_{n-k} - 2b_{n-k+1}) 2^{n-k} + \dots + (b_{-1} + b_0 - 2b_{-1}) 2^0 \\
 &= \sum_{k=0}^{n/2-1} (b_{2k-1} + b_{2k} - 2b_{2k+1}) 2^{2k}. \tag{9.50}
 \end{aligned}$$

Assumption is made that  $n$  is an even number,  $b_{n-1}$  represents the sign bit  $b_s$ , and  $b_{-1} = 0$ . The product  $Z (=A B)$  is then given by

$$Z = \sum_{j=0}^{n/2-1} (PP_j A 2^j) \quad j: \text{even number}, \tag{9.51}$$

where

$$PP_j = b_{j-1} \oplus b_j - 2b_{j+1} \tag{9.52}$$

The partial product  $PP_j$  is to be calculated in the 2-bit Booth algorithm. Therefore,  $n/2$  partial products and hence  $n^2/2$  partial product bits are generated according to this algorithm. The partial product  $PP_j$  has a value of one of  $0, \pm A$ , and  $\pm 2A$ , depending on the values of the adjacent three bits on the multiplier ( $b_{j-1}, b_j$  and  $b_{j+1}$ ). The generation of  $2A$  is easily realized by shifting each bit of  $A$  to one-bit higher position. The negative value on the 2's complement system is realized by negating each bit of  $A$  ( $\sim A$ ) and adding 1 to the LSB position of  $\sim A$ . The latter is done by placing a new partial product bit ( $M_j$ ) corresponding to 1 and adding it in a CSA. The Booth algorithm is implemented into two steps: Booth encoding and Booth selecting. The Booth encoding step is to generate one of the five values from the adjacent three bits  $b_{j-1}, b_j$  and  $b_{j+1}$ . This is realized according to the following Boolean equations,

$$A_j = b_{j-1} \oplus b_j \quad (9.53)$$

$$2A_j = \sim(b_{j-1} \oplus b_j)(b_j \oplus b_{j+1}) \quad (9.54)$$

$$M_j = b_{j+1}. \quad (9.55)$$

The Booth selector generates a partial product bit at the  $(i + j)$ th position by utilizing the output signals from the Booth encoder and the multiplicand bits as follows:

$$p_{i,j} = (a_i A_j + a_{i-1} 2A_j) \oplus M_j \quad (9.56)$$

An example of a partial product bit generator is shown in Fig. 9.28(a). As is seen in the figure, a typical partial product bit generator requires 18 transistors in CMOS implementation as compared with 6 transistors for a case of generating it with a simple AND gate. Thus a part of the effect of reducing the number of partial product bits at the same bit position is compensated for because of the complexity of the circuit to generate a partial product bit in the Booth recoding.

Goto proposed a new scheme to reduce the number of transistors for generating a partial product bit. This scheme is called "sign-select Booth encoding" [36]. In this scheme, the Booth encoding is done so as to generate two sign signals  $PL$  (positive) and  $M$  (negative) that are selected depending on the logic of an input multiplicand bit in the Booth encoding step. The Boolean equations are shown in the following,

$$A_j = b_{j-1} \oplus b_j \quad (9.57)$$

$$2A_j = \sim(b_{j-1} \oplus b_j) \quad (9.58)$$

$$M_j = \sim(b_{j-1} b_j) b_{j+1} \quad (9.59)$$

$$PL_j = (b_{j-1} + b_j) (\sim b_{j+1}). \quad (9.60)$$

FIGURE 9.28(a) Partial product bit generator-1.

FIGURE 9.28(b) Partial product bit generator-2.

The Booth selector is constructed to select either  $PL_j$  or  $M_j$  depending on the multiplicand bit ( $a_i$  or  $\sim a_i$ ) according to the following Boolean equation:

$$p_{i,j} = (a_i PL_j + \sim a_i M_j) A_j + (a_{i-1} PL_j + \sim a_{i-1} M_j) 2A_j \quad (9.61)$$

In this modified Booth selector implemented with pass transistors, the transistor count per bit is as small as 10 as illustrated in Fig. 9.28(b). Thus it is reduced roughly to one-half as compared with that of the regular selector without the speed degradation.

As can be seen from the above explanations, the sign bit, unlike other approaches [39], need not be treated as a special case of partial product bit, but it is manipulated similarly to other bits. Thus the correction circuit need not be equipped with for the Booth algorithm.

The Booth algorithm can be generalized to any radix with more than two bits. However, a 3-bit recoding requires  $\pm 3A$ , which requires addition of  $\pm A$  and  $\pm 2A$ , resulting in a carry propagation. The delay with such a mechanism degrades the high-speed capability of a 3-bit recoding. A 4-bit or higher bit recoding may be considered [40], but it requires very complex recoding circuitry. Eventually, only the 2-bit (radix 4) recoding is actually used.

### Sign Correction for Booth Algorithm

As mentioned in the former section on adders with 2's complement numbers, the sign bits of the operands need be extended to the MSB of the sum to correctly calculate these numbers. This sign extension can be simplified for addition of partial products based on the 2-bit Booth algorithm in the following way.

The sum SGN of the whole extended bits can be expressed by

$$\begin{aligned}
 \text{SGN} &= (2^{2n-1} + 2^{2n-2} + \dots + 2^n)P_{s(0)} + (2^{2n-1} + 2^{2n-2} + \dots + 2^{n+2})P_{s(2)} \\
 &+ \dots + (2^{2n-1} + 2^{2n-2} + \dots + 2^{n-j})P_{s(j)} + \dots \\
 &+ (2^{2n-1} + 2^{2n-2})P_{s(n-2)} \\
 &= \{ - (2^{2n} + 1) 2^0 P_{s(0)} - (2^{2n} + 1) 2^2 P_{s(2)} - \dots \\
 &\quad - (2^{2n} + 1) 2^j P_{s(j)} - \dots - (2^{2n} + 1) 2^{n-2} P_{s(n-2)} \} 2^n \\
 &= \{ -2^0 P_{s(0)} - 2^2 P_{s(2)} - \dots - 2^j P_{s(j)} - \dots - 2^{n-2} P_{s(n-2)} \} 2^n \\
 &\qquad\qquad\qquad (\text{Mod } 2^{2n}) \\
 &= \{ \sim P_{s(0)} + 2^1 + \sim P_{s(2)} + 2^3 + \dots + \sim P_{s(j)} + 2^{j+1} + \dots \\
 &\quad + \sim P_{s(n-2)} + 2^{n-1} + 1 \} 2^n,
 \end{aligned} \tag{9.62}$$

where  $j$  is an even number and  $P_{s(j)}$  indicates a sign bit of the partial product at the  $j$ th position. Considering the above result, the multiplication of  $n$ -bit 2's complement numbers are performed as illustrated in Fig. 9.29 for a case of  $8 \times 8$ -bit multiplication, where  $M_j$  indicates a partial product bit introduced to add 1 at the LSB position in the  $j$ th partial product if the encoded result is a negative value. For the 2-bit Booth recoding, the maximum number of partial product bits at the same position is  $n/2 + 1$  as the sign correction term or  $M_j$  term has to be considered.

### Overall Design of Parallel Multiplier

A high-speed but small-size parallel multiplier can be designed by devising recoding algorithm, arraying systematically well-configured components, and adopting a high-performance CPA. Most recent-day fast multipliers for mantissa multiplication of two double-precision numbers based on the IEEE standard [41] are designed according to the block diagram shown in Fig. 9.30. Under this standard, the mantissa

FIGURE 9.29  $8 \times 8$ -bit multiplication with sign correction.

FIGURE 9.30 Block diagram of high-speed parallel multiplier.

multiplication requires a  $54 \times 54$ -bit hardware multiplier, because the mantissa is represented by 52 bits internally, and a hidden bit and a sign bit must be added to manipulate 2's complement numbers.

A fast  $54 \times 54$ -bit parallel structured multiplier was developed by Mori, et al. in 1991 [7]. They adopted the 2-bit Booth algorithm and the Wallace tree composed of 58 transistor 4-2 compressors. By adopting the Wallace tree composed of the 4-2 compressors, only four addition stages suffice to compress the maximum number of the partial product bits at the same bit position. This design adopts an XOR gate that is a pseudo-CMOS circuit shown in Fig. 9.19(d) to increase the operation speed of 4-2 compressors and the final CPA. They obtained a  $54 \times 54$ -bit multiplier with a delay time of 10 ns and area of  $12.5 \text{ mm}^2$  (transistor count is 81,600) in  $0.5 \mu\text{m}$  CMOS technology.

Ohkubo, et al. implemented a  $54 \times 54$ -bit parallel multiplier by utilizing pass-transistor multiplexers [35]. The delay time constructed with them can be made smaller than that implemented in the conventional CMOS gates because of shorter critical path within the circuit. They constructed a CSA tree in Fig. 9.31 only by 4-2 compressors shown in Fig. 9.27(b). By combining a 4-2 compressor tree with a conditional carry-selection (CCS) adder [35], they obtained a fast multiplier with a delay time of 4.4 ns and area of  $12.9 \text{ mm}^2$  (transistor count is 100,200) in  $0.25 \mu\text{m}$  CMOS technology.

Goto proposed a new layout scheme named "Regularly Structured Tree (RST)" for implementing the Wallace tree in 1992 [34]. In this scheme, partial product bits with a maximum of 28 at the same bit position to be compressed into two for a  $54 \times 54$ -bit parallel multiplier are first divided into four 7-2 compressor blocks, as shown in Fig. 9.32. In this figure, a 4D2 block consists of two sets of four Booth selectors and a 4-2 compressor, and a 3D2 block consists of two sets of three Booth selectors and a FA. A 4W means a 4-2 compressor in the same figure. Thus, a 7D4 block constitutes four 7-2 compressors at the consecutive bit positions. Arranging this 7D4 block with regularity as shown in Fig. 9.33, the Booth selectors and the CSA part of a  $54 \times 54$ -bit parallel multiplier can be systematically laid out including the intermediate wiring among the blocks. This scheme simplifies drastically the complicated layout and wiring among not only the compressors in the CSA part but also the compressors and the Booth selectors. In a modified version of the RST multiplier, the delay time of 4.1 ns and as small size as  $1.27 \text{ mm}^2$  (transistor count is 60,797) were obtained in  $0.25 \mu\text{m}$  CMOS technology [36]. By adopting a 4-2 compressor with 48 transistors (Fig. 9.27(c)) and the sign-select Booth recoding algorithm as described earlier, the total number of transistors were reduced by 24% as compared with that of the earlier design.

## Conclusion

As has been mentioned in this chapter section, various attempts were tried and refined to implement fast adders and multipliers. The basic idea, however, is consistent among these studies in that the circuit components should be as simple as possible to shorten the critical path, and that the algorithm as a whole should be suitably refined for CMOS implementation. The well-prepared circuit components are in themselves valuable for easy implementation of fast and efficient arithmetic units.

The need for faster arithmetic logic units will be continually recognized for its importance among the application engineers of the up-to-date electronics systems, so that the design efforts will be continued to optimize the fast arithmetic algorithms in the advanced CMOS technology. With advance of the SoC technology, evaluating the merit of the algorithm and modifying it to fit to the execution model of the dedicated processor will increase its importance. The system-level performance optimization as a total system will be another subject for realization of the coming high-performance systems.

### 10.1 Design of High-Speed CMOS PLLs and DLLs

*John George Maneatis*

#### Introduction

Phase-locked loops (PLLs), a set of circuits that include delay-locked loops, have found many applications within the realm of microprocessors and digital chips in the past 15 years. These applications include clock frequency synthesis, clock de-skewing, and high-bandwidth chip interfaces. A typical chip interface application is shown in [Fig. 10.1](#) in which two chips synchronously send data to one another. To achieve high bandwidth, the data rate must be maximized with minimum data latency. Achieving this objective requires careful control over system timing in order to guarantee that setup and hold times are always satisfied.

Let us consider the requirements for receiving data by Chip 2. Chip 1 transmits this data synchronously along with a clock signal. Chip 2 would need to buffer this clock signal to drive all of the input latches and use it to sample the data. Buffering the clock signal will introduce a delay that will vary with process and environmental factors. The setup and hold time window for the input latches will then be shifted from the input clock edge by this varying delay amount. Such a delay can make it very difficult to insure that setup and hold times are always satisfied as the data rate is increased and this delay becomes a larger fraction of the clock cycle.

To alleviate the situation, it is desirable to eliminate this clock distribution delay and center the setup and hold time window on the input clock edge, which would remove any uncertainty in the window position relative to the clock signal. Such an approach also has the added benefit of avoiding the necessity for delay padding on the data wires to compensate for the clock distribution delay, which would increase the latency. It is also desirable to be able to multiply the frequency of the clock signal for use in the chip core so that the core logic can run with a higher clock frequency than available from the interface. These objectives can all be accomplished with a PLL [1,2].

FIGURE 10.1 Typical chip interface.

The PLL generates an on-chip clock from the input clock to drive the clock distribution network and ultimately all of the latches and registers on the chip. By sensing the clock at the input of the receiving latches and adjusting its output phase until this latch clock aligns with the input clock, the PLL is able to subtract out the clock distribution delay and make it appear as though the input clock directly connects to all of the latches. The result is that the setup and hold time window is centered on the input clock edge with no process or environmental dependencies. The amount of setup and hold time can also be controlled relative to the clock cycle by centering the setup and hold time window relative to a different part of the clock cycle.

Although PLLs may seem to be the universal cure to all clock generation and interface problems, they do not come without problems of their own. PLLs can introduce time-varying offsets in the phase of the output clock from its ideal value as a result of internal and environmental factors. These time-varying offsets in the output clock phase are commonly referred to as jitter. Jitter can have disastrous effects on the timing of an interface by causing setup and hold time violations, which lead to data transmission errors.

Jitter was not a significant issue when PLLs were first introduced into digital IC interfaces. The techniques employed were fairly effective in addressing the jitter issue. However, designers often reapply those same PLL design techniques even though the nature of the problem has changed. IC technologies have improved, leading to decreasing cycle times. The number of input/output (I/O) pins and I/O data rates have increased leading to an increasing on-chip noise environment. An increasing aggressiveness in I/O system design has led to a decreasing tolerance for jitter. The result is that PLL output jitter has increased while jitter tolerances have decreased, leading to significant jitter problems.

This chapter section focuses on the analysis and design of PLLs for interface applications in digital ICs with particular emphasis on achieving low output jitter. It begins by considering two basic PLL architectures in the section on “PLL Architectures.” The next two sections perform a stability analysis for each architecture in order to gain insight into the various design tradeoffs and then present a comprehensive design strategy to establish the various loop parameters for each architecture. More advanced PLL architectures are briefly discussed in “Advanced PLL Architectures.” “DLL/PLL Performance Issues” shifts gears to review the causes of output jitter in PLLs and examines circuit level techniques for reducing its magnitude. Circuits issues related to the implementation of the various PLL loop components are presented in the section on “DLL/PLL Circuits.” “Self-Biased Techniques” briefly discusses self-biased techniques that can be used to eliminate the process and environmental dependencies within the PLL designs themselves. This chapter section concludes with a presentation of PLL characterization techniques in “Characterization Techniques.”

## PLL Architectures

The basic operation of the PLLs considered in this chapter is the adjustment of the phase of the output so that no phase error is detected between the reference and feedback inputs. PLLs can be structured in a number of ways to accomplish this objective. Their structure can be classified based on how they react to phase errors and how they control the phase of the output. This chapter section focuses only on PLLs

FIGURE 10.3 Typical PLL block diagram (clock distribution omitted).

that integrate the phase error in the loop filter using charge pumps [3]. Charge pump PLLs have the property that in the locked state, the detected phase error is ideally zero.

In general, PLLs can control their output phases directly by delaying the reference signal or indirectly by changing the output frequency. The first is commonly referred to as a delay-locked loop (DLL) since it actually locks the delay between the reference input and the feedback input to some fraction of the reference input period. The second is referred to as a VCO-based PLL or simply as a PLL since it controls the frequency of a voltage-controlled oscillator (VCO) generating the output such that the feedback input is in phase with the reference input.

Figure 10.2 shows the general structure of a DLL. It is composed of a phase detector, charge pump, loop filter, and voltage-controlled delay line (VCDL). The negative feedback in the loop adjusts the delay through the VCDL by integrating the phase error that results between the periodic reference and delay line output. When in lock, the VCDL delays the reference input by a fixed amount to form the output such that the phase detector detects no phase error between the reference and feedback inputs. The clock distribution network, although not shown in the figure, is between the DLL output and the feedback input. Functionally, it can be considered as part of the VCDL.

Figure 10.3 shows the general structure of a PLL. It is composed of a phase detector, charge pump, loop filter, and VCO. Two key differences from the DLL are that the PLL contains a VCO instead of a VCDL and, as will be discussed below, requires a resistor in the loop for stability. The negative feedback in the loop adjusts the VCO output frequency by integrating the phase error that results between the periodic reference input and the divided VCO output. When in lock, the VCO generates an output frequency and phase such that the phase detector detects no phase error between the reference and feedback inputs. With no phase error between the reference and feedback inputs, the inputs must also be at the same frequency. If a frequency divider, which divides by  $N$ , is inserted between the PLL output and feedback input, the PLL output will be  $N$  times higher in frequency than the reference and feedback inputs, thus allowing the PLL to perform frequency multiplication.

The difference in loop structure between a DLL and a PLL gives rise to different properties and operating characteristics. DLLs tend to have short locking times and relatively low tracking jitter, but generally do not support frequency multiplication or duty cycle correction, have limited delay ranges, and require special lock reset functions. PLLs have unlimited phase ranges, support frequency multiplication and duty cycle correction, do not require special lock reset functions, but usually have longer lock times and higher tracking jitter. DLLs are less complex than PLLs from a loop architecture perspective, but are generally more complex from a design and system integration perspective.

## Loop Components

PLLs and DLLs share many common building blocks. These building blocks are the phase detector, charge pump, loop filter, voltage-controlled delay line, and voltage-controlled oscillator.

A phase detector, also known as a phase comparator, compares two input signals and generates “UP” and “DN” output pulses that represent the direction of the input phase error. There are many types of phase detectors; they differ in how they sense the input signals, what target input phase difference would cause them to detect no phase error, and how the phase error is represented in the output pulses.

For simplicity, we will initially only consider phase-frequency detectors. These detectors have the property that they are only rising or falling edge sensitive and, for each pair of input reference and feedback edges, produce a single pulse at either the UP or DN output, depending on which edge arrives first, with a duration equal to the time difference between the two edges or, equivalently, the input phase difference. When the reference and feedback edges arrive at the same time for zero input phase difference, the phase detector will effectively generate no UP or DN pulses; however, in actual implementation, the input phase difference may be represented by the phase detector as the difference between the pulse widths of the UP and DN outputs, where both are always asserted for some minimum duration in order to guarantee that no error information is lost due to incompletely rising pulses as the input phase difference approaches zero.

A charge pump, connected to the phase detector, sources or sinks current for the duration of the UP and DN pulses from the phase detector. The net output charge is proportional to the difference between the pulse widths of the UP and DN outputs. The charge pump drives the loop filter, which integrates and filters the charge current to produce the control voltage. The control voltage drives a VCDL in a DLL, which generates a delay proportional to the control voltage, or drives a VCO in a PLL, which generates a frequency proportional to the control voltage.

## Delay-Locked Loops

Before we consider a detailed analysis of the loop dynamics of a DLL, it is instructive to consider the control dynamics from a qualitative perspective as the loop approaches lock. Figure 10.4 illustrates the waveforms of signals and quantities inside a DLL during this locking process. Initially, the DLL is out of lock as the reference and output edges are not aligned.

FIGURE 10.4 DLL locking waveforms.

Because the first output edge arrives before the first corresponding reference edge, the phase detector outputs a pulse at the UP output equal in duration to this phase error. A pulse at the UP output indicates that the delay needs to be increased. The charge pump generates an output charge proportional to the phase error, which increases the control voltage and thus the delay of the VCDL. After several cycles, the phase error is corrected.

The error is sampled only once per cycle, so the DLL is a sampled system as represented by the phase error impulses. However, if we limit the response time of the system to be a decade below the operating frequency, we can make a continuous time approximation. This approximation assumes that the phase errors are determined continuously as represented by the dashed line. Such a bandwidth limit will be required anyway to guarantee stability.

The magnitude of the delay correction per cycle is proportional to the detected phase error, therefore, the phase error, control voltage, and delay should change with an exponential decay toward their final values, rather than linearly as shown, for simplicity, in the figure. Also, it should be noted that there are different ways of configuring the charge pump in the DLL. Some DLLs, for example, output a fixed charge independent of the size of the phase error. This type of charge pump converts the DLL into a nonlinear system and as such will not be considered in the following DLL analysis.

### DLL Frequency Response

More insight into DLL design issues can be gained by determining the frequency response of the DLL. This frequency response can be derived with a continuous time approximation, where the sampling behavior of the phase detector is ignored. This approximation holds for response bandwidths that are a decade or more below the operating frequency. This bandwidth constraint is also required for stability due to the reduced phase margin near the higher-order poles that result from the delay around the sampled feedback loop. The mathematical symbols used in deviations for both the DLL and PLL are defined in [Table 10.1](#).

Because the loop filter integrates the phase error, the DLL has a first order closed-loop response. The response could be formulated in terms of input phase and output phase. However, this set of variables is incompatible with the continuous time analysis since the sampled nature of the system must be considered. A better set of variables is input delay and output delay. The output delay is the delay between the reference input and the DLL output or, equivalently, the delay established by the VCDL. The input

delay is some fraction of the input clock period as determined by the phase detector. It is typically one, one half, or one quarter of the input clock period.

The output delay,  $D_O(s)$ , is related to the input delay,  $D_I(s)$ , by

$$D_O(s) = (D_I(s) - D_O(s)) \cdot F_{REF} \cdot I_{CH} / (s \cdot C) \cdot K_{DL}$$

where  $F_{REF}$  is the reference frequency (Hz),  $I_{CH}$  is the charge pump current (A),  $C$  is the loop filter capacitance (F), and  $K_{DL}$  is the VCDL gain (s/V). The product of the delay difference and the reference frequency is equal to the fraction of the reference period in which the charge pump is activated. The average charge pump output current is equal to this fraction times the peak charge pump current. The output delay is then equal to the product of the average charge pump current, the loop filter transfer function, and the delay line gain.

The closed-loop response is then given by

$$D_O(s)/D_I(s) = 1/(1 + s/\omega_N)$$

where  $\omega_N$ , defined as the loop bandwidth (rad/s), is given by

$$\omega_N = I_{CH} \cdot K_{DL} \cdot F_{REF}/C$$

This response is of first order with a pole at  $\omega_N$ . Thus, the DLL acts as a single-pole low-pass filter to changes in the input reference period with cutoff frequency  $\omega_N$ . The delay between the reference and feedback signal will be a filtered version of a set fraction of the reference period. It is unconditionally stable as long as the continuous time approximation holds or, equivalently, as long as  $\omega_N$  is a decade below  $\omega_{REF}$ . As  $\omega_N$  increases above  $\omega_{REF}/10$ , the delay in sampling the phase error will become more significant and will begin to undermine the stability of the loop.

### DLL Design Strategy

With an understanding of the DLL frequency response, we can consider how to structure the loop parameters to obtain desirable loop dynamics. Using the bandwidth results from the DLL frequency response and, limiting it to a decade below the reference frequency, we can determine the constraints on the charge pump current, VCDL gain, and loop filter capacitance as

$$\omega_N/F_{REF} = I_{ch} \cdot K_{DL}/C \leq \pi/5$$

The VCDL also must be structured so that it spans adequate delay range to guarantee lock for all operating, environmental, and process conditions. The delay range needed is constrained by the lock target delay of the phase detector,  $T_{LOCK}$ , and the range of possible values for the clock distribution delay,  $T_{DIST}$ , and the reference period,  $T_{CYCLE}$ , with the following equations:

$$VCDL_{MIN} = (T_{LOCK} - T_{DIST\_MAX}) \text{ modulo } T_{CYCLE\_MIN}$$

$$VCDL_{MAX} = (T_{LOCK} - T_{DIST\_MIN}) \text{ modulo } T_{CYCLE\_MAX}$$

where  $T_{LOCK}$  is 1 cycle for in-phase locks and 1/4 cycles for quadrature locks.

Also, special measures may be required to guarantee that the DLL reaches lock after being reset. These measures depend on the specific structure of the DLL. Typically, the VCDL delay is set to its minimum delay and the state of the phase detector is reset. However, for some DLLs, more complicated approaches may be required.

### Alternative DLL Structures

The complexity of designing a DLL is not so much in the control dynamics as it is in the underlying structure. Although the DLLs discussed in this chapter are analog-based, using VCDLs with analog control, many other approaches are possible that utilize different amounts of analog and digital control. These approaches can

circumvent the problems associated with limited delay ranges and reaching lock. One possible structure is a rotating phase DLL that digitally selects and optionally interpolates with analog or digital control between intermediate output phases from a VCDL or VCO phase-locked to the clock period [4]. A related structure interpolates with analog control between quadratures phases generated directly from the clock signal [5]. Another even simpler structure with reduced jitter performance digitally selects intermediate outputs from an inverter chain-based delay line [6]. While digital control provides more flexibility, analog control requires less power and area.

## Phase-Locked Loops

Similar to a DLL, a PLL aligns the phase of the output to match the input. The DLL accomplishes this by appropriately delaying the input signal. The PLL accomplishes this by controlling an oscillator to match the phases of the input signal. The control for the PLL is more indirect, which requires it to have the resistor in the loop filter for stability.

Consider the typical PLL shown in Fig. 10.3 as it starts out from an unlocked state with a VCO frequency that is relatively close to but slightly higher than the reference frequency. To help understand the function of the resistor in the loop filter, let's first assume that it is zero valued making the loop filter equivalent to that of the DLL. Initially, the PLL is out of lock as the reference and feedback edges are not aligned. With the first feedback edge arriving before the first corresponding reference edge, the phase detector outputs a pulse at the DN output equal in duration to this phase error. A pulse at the DN output indicates that the VCO frequency needs to be reduced. The charge pump generates an output charge proportional to the phase error, which reduces the control voltage and thus the VCO frequency.

In order to reduce the phase error, the feedback edges need to arrive later and later with respect to the reference edges or, equivalently, the VCO frequency must be reduced below the reference frequency. After several cycles, the phase error is reduced to zero, but the VCO frequency is now lower than the reference frequency. This frequency overshoot causes the feedback edges to begin to arrive later than the corresponding reference edges, leading to the opposite error condition from which the loop started. The loop then begins to increase the VCO frequency above the reference frequency to reduce the phase error, but at the point when the phase error is zero, the VCO frequency is now higher than the reference frequency. Thus, in the PLL with a zero-valued resistor, the phase error will oscillate freely around zero, which represents unstable behavior.

This unstable behavior can be circumvented by adding an extra frequency adjustment that is proportional to the phase error and is therefore applied only for the duration of the phase error. This proportional control allows the loop to adjust the VCO frequency past the reference frequency in order to reduce the phase error without the frequency difference persisting when the phase error is eliminated. When the phase error reaches zero and the extra adjustment is reduced to zero, the VCO frequency should match the reference frequency leading to a stable result. This proportional control can be implemented by adding a resistor in series with the loop filter capacitor. This resistor converts the charge pump current, which is proportional to the phase error, into an extra control voltage component, which is added to the control voltage already integrated on the loop filter capacitor.

From another perspective, this resistor dampens out potential phase and frequency overshooting. The amount of damping depends on the value of the resistor. Clearly, with zero resistance, there will be no damping and the loop will be unstable as the output phase will oscillate forever around zero phase difference. As the resistor value is increased, the loop will become increasingly less underdamped as the oscillations will decay to zero at an increasing rate. For some resistor value, the loop will become critically damped as the oscillations will go away entirely and the phase will approach zero without overshooting. As the resistor value is increased further, the loop becomes overdamped as the phase initially approaches zero rapidly, then slows down, taking a long time to reach zero.

The overdamped behavior results when the damping is so high that it creates a large frequency difference between the VCO and reference that initially drives the phase error rapidly toward zero; however, this added frequency difference goes away when the phase error approaches zero. The VCO frequency that

results from the voltage across the loop filter capacitor may still be different from the reference frequency. Unfortunately, the phase error has been reduced substantially so that there is little charge pump current to change the voltage on the loop filter capacitor very quickly. The phase will change rapidly to the point where the resultant phase error generates a proportional frequency correction that makes the VCO frequency match the reference frequency. As the proportionality constant, or, equivalently, the resistance, is increased, the rate at which the phase changes will also increase and the phase error after the initial phase change will decrease; however, as the initial phase error is reduced, the amount of time required to eliminate the phase error will increase because the charge pump current will also decrease.

### PLL Frequency Response

The different types of damping behavior can be quantified more carefully by deriving the frequency response of the PLL. As with the DLL, the frequency response of the PLL can be analyzed with a continuous time approximation for bandwidths a decade or more below the operating frequency. This bandwidth constraint is also required for stability due to the reduced phase margin near the higher-order poles that result from the delay around the sampled feedback loop. Because the loop filter integrates the charge representing the phase error and the VCO integrates the output frequency to form the output phase, the PLL has a second-order closed-loop response.

Considerable insight can be gained into the design of the PLL by first considering its open-loop response. This response can be derived by breaking the loop at the feedback input of the phase detector. The output phase,  $P_O(s)$ , is related to the input phase,  $P_I(s)$ , by

$$P_O(s) = P_I(s) \cdot I_{ch} \cdot (R + 1/(s \cdot C)) \cdot K_V/s$$

where  $I_{CH}$  is the charge pump current (A),  $R$  is the loop filter resistor (ohms),  $C$  is the loop filter capacitance (F), and  $K_V$  is the VCO gain (Hz/V). The open-loop response,  $H(s)$ , is then given by

$$H(s) = P_O(s)/P_I(s) = I_{CH} \cdot K_V \cdot (1 + s \cdot R \cdot C)/(s^2 \cdot C)$$

The loop gain,  $T(s)$ , which is the product of the gain through the forward path,  $H(s)$ , and the gain through the feedback path,  $1/N$ , is given by

$$T(s) = H(s)/N$$

The normalized loop gain magnitude and phase plots for the PLL are shown in [Fig. 10.5](#). At low frequencies, the loop gain drops at 40 dB per decade where the phase is at  $-180^\circ$ , since there are two poles at zero frequency. The zero caused by the resistor in the loop filter is at frequency  $1/(R \cdot C)$  and causes the loop gain at higher frequencies to only drop at 20 dB per decade and the loop phase to “decrease” to  $-90^\circ$ , which makes it possible to stabilize the loop.

The plotted loop gain magnitude is normalized with the gain normalization factor,  $G_O$ , given by

$$G_O = R^2 \cdot C \cdot I_{CH} \cdot K_V/N$$

The value of this factor will set the frequency at which the loop gain is unity. This frequency is significant because it determines the phase margin, which is a measure of the stability and the amount of damping for the PLL system. The phase margin is measured as  $180^\circ$  or  $\pi$  radians plus the loop gain phase at the unity gain frequency or, equivalently, the frequency where the loop gain magnitude is unity. The unity gain level on the plot is the inverse of the gain normalization factor. No phase margin exists at unity gain frequencies below  $0.1/(R \cdot C)$  because the loop gain phase is about  $-180^\circ$ . The phase margin gradually increases with increasing unity gain frequency as a result of the zero at frequency  $1/(R \cdot C)$ .

The loop is critically damped with a phase margin of  $76^\circ$ , corresponding to a normalized loop gain magnitude of 0.25, a gain normalization factor of 4, and a unity gain frequency of  $4.12/(R \cdot C)$  (rad/s). The loop will be underdamped for smaller phase margins and overdamped for greater phase margins.

FIGURE 10.5 PLL loop gain magnitude and phase (without  $C_2$ ).

The closed-loop response can be derived from the open-loop response by considering the feedback signal. In the closed-loop system, the output phase,  $P_O(s)$ , is related to the input phase,  $P_I(s)$ , by

$$P_O(s) = (P_I(s) - P_O(s)/N) \cdot H(s)$$

where  $N$  is the feedback clock divider value. The closed-loop response is then given by

$$\begin{aligned} P_O(s)/P_I(s) &= 1/(1/N + s/H(s)) \\ &= N \cdot 1 + s \cdot C \cdot R / \\ &\quad (1 + s \cdot C \cdot R + s^2/(I_{CH}/C \cdot K_V/N)) \end{aligned}$$

or, equivalently, by

$$\begin{aligned} P_O(s)/P_I(s) &= N \cdot (1 + 2 \cdot \zeta \cdot (s/\omega_N) / \\ &\quad (1 + 2 \cdot \zeta \cdot (s/\omega_N) + (s/\omega_N)^2)) \end{aligned}$$

where  $\zeta$ , defined as the damping factor, is given by

$$\zeta = 1/2 \cdot (1/N \cdot I_{CH} \cdot K_V \cdot R^2 \cdot C)^{0.5}$$

and  $\omega_N$ , defined as the loop bandwidth (rad/s), is given by

$$\omega_N = 2 \cdot \zeta / (R \cdot C)$$

The loop bandwidth and damping factor completely characterize the closed-loop response. The PLL is critically damped with a damping factor of one and overdamped with damping factors greater than one.

Treating the PLL as a standard second order system makes it much easier to analyze. The time domain impulse, step, and ramp responses are easily derived from the frequency domain closed-loop response. Equations for these responses are summarized in Table 10.2. The peak values of these responses are very useful in estimating the amount of frequency overshoot and the amount of supply and substrate noise

induced jitter for a set of loop parameters. The peak values and the point at which they occur are summarized in [Table 10.3](#).

The closed-loop frequency response of the PLL for different values of  $\zeta$  and for frequencies normalized to  $\omega_N$  is shown in [Fig. 10.6](#). This plot shows that the PLL is a low-pass filter to phase noise at frequencies below  $\omega_N$ . Phase noise at frequencies below  $\omega_N$  passes through the PLL unattenuated. Phase noise at frequencies above  $\omega_N$  is filtered with slope of  $-20$  dB per decade. For small values of  $\zeta$ , the filter cutoff at  $\omega_N$  is sharper with initial slopes as high as  $-40$  dB per decade. However, for these values of  $\zeta$ , the phase noise is amplified at frequencies near  $\omega_N$ . This phase noise amplification or peaking increases, along with the initial cutoff slope, for decreasing values of  $\zeta$ . This phase noise amplification can have adverse affects on the output jitter of the PLL. It is important to notice that because of the zero in the closed-loop

FIGURE 10.6 PLL closed-loop frequency response.

response, there is a small amount of phase noise amplification at phase noise frequencies of  $\omega_N$  for all values of  $\zeta$ . However, for values of  $\zeta$  less than 0.7, the amplification gain starts to become significant.

The closed-loop transient step response of the PLL for different values of  $\zeta$  and for times normalized to  $1/\omega_N$  is shown in Fig. 10.7. The step response is generated by instantaneously advancing the phase of the reference input by one radian and observing the output for different damping levels in the time domain. For damping factors below one, the system is underdamped as the PLL output overshoots the final phase and rings at the frequency  $\omega_N$ . The amplitude of the overshoot increases and the rate of decay for the ringing decreases as the damping factor is decreased below one. The fastest settling response is generated with a damping factor of one, where the system is critically damped. For damping factors

FIGURE 10.8 Typical PLL block diagram with  $C_2$  (clock distribution omitted).

greater than one, the system is overdamped as the PLL output initially responds rapidly but then takes a long time to reach the final phase. The rate of the initial response increases and the rate of the final response decreases as the damping factor is increased above one.

### PLL with Higher-Order Roll-Off

It is very common for an actual PLL implementation to contain an extra capacitor,  $C_2$ , in shunt with the loop filter, as shown in Fig. 10.8. This capacitor may have been introduced intentionally for filtering or may result from parasitic capacitances within the resistor or at the input of the VCO.

Because the charge pump and phase detector are activated once every reference frequency cycle, they can cause a periodic disturbance on the control voltage node. This disturbance is usually not an issue for loops with  $N$  equal to one because the disturbance will occur in every VCO cycle. However, the disturbance can cause a constant shift in the duty cycle of the VCO output. When  $N$  is greater than one, the disturbance will occur once every  $N$  VCO cycles, which could cause the first one or two of the  $N$  cycles to be different from the others, leading to jitter in the PLL output period. In the frequency domain, this periodic disturbance will cause sidebands on the fundamental peak of the VCO frequency spaced at intervals of the reference frequency.

Capacitor  $C_2$  will help filter out this reference frequency noise by introducing a pole at  $\omega_C$ . It will decrease the magnitude of the reference frequency sidebands by the ratio of  $\omega_{REF}/\omega_C$ . However, the introduction of  $C_2$  can also cause stability problems for the PLL since it converts the PLL into a third-order system. In addition,  $C_2$  makes the analysis of the PLL much more difficult.

The PLL is now characterized by the four loop parameters  $\omega_N$ ,  $\omega_C$ ,  $\zeta$ , and  $N$ . The damping factor,  $\zeta$ , is changed by  $C_2$  as follows:

$$\zeta = 1/2 \cdot (1/N \cdot I_{CH} \cdot K_V \cdot R^2 \cdot C^2 / (C + C_2))^{0.5}$$

The loop bandwidth,  $\omega_N$ , is changed by  $C_2$  through its dependency on  $\zeta$ . The added pole in the open-loop response is at frequency  $\omega_C$  given by

$$\omega_C = (C + C_2) / (R \cdot C \cdot C_2)$$

This pole can reduce the stability of the loop if it is too close to the loop bandwidth frequency. Typically, it should be set at least a factor of ten above the loop bandwidth so as not to compromise the stability loop.

Because the stability of the loop is now established by both  $\zeta$  and  $\omega_C/\omega_N$ , a figure of merit can be defined that represents the potential stability of the loop as

$$\zeta \cdot \omega_C / \omega_N = (C / C_2 + 1) / 2$$

This definition is useful because it actually defines the maximum possible phase margin given an optimal choice for the loop gain magnitude.

Consider the normalized loop gain magnitude and phase plots for the PLL with different ratios of  $C$  to  $C_2$  shown in Fig. 10.9. From these plots, it is clear that the added pole at  $\omega_C$  causes the loop gain magnitude slope to increase to  $-40$  dB per decade and the loop gain phase to “increase” to  $-180^\circ$  above the frequency of the pole. Between the zero at  $1/(R \cdot C)$  and the pole at  $\omega_C$  there is a region where the

FIGURE 10.9 PLL loop gain magnitude and phase with  $C_2$ .

loop gain magnitude slope is  $-20$  dB per decade and the loop gain phase approaches  $-90^\circ$ . It is in this region where a unity gain crossing would provide the maximum possible phase margin. As the ratio of  $C$  to  $C_2$  increases, this region becomes wider and the maximum phase becomes closer to  $-90^\circ$ . Thus, the ratio of  $C$  to  $C_2$ , and, therefore, the figure of merit for stability, defines the maximum possible phase margin.

Based on the frequency response results for the PLL we can make a number of observations about its behavior. First, the continuous time analysis used assumes that the reference frequency is about a decade above all significant frequencies in the response. Second, both the second-order and third-order response are independent of operating frequency, as long as  $K_V$  remains constant. Third, the resistor  $R$  introduces a zero in the open-loop response, which is needed for stability. Finally, capacitor  $C_2$  can decrease the phase margin if larger than  $C/20$  and can reduce the reference frequency sidebands by  $\omega_{REF}/\omega_C$ .

### PLL Design Issues

With a good understanding of the PLL frequency response, we can consider issues related to the design of the PLL. The design of the PLL involves first establishing the loop parameters that lead to desirable control dynamics and then establishing device parameters for the circuits that realize those loop parameters.

The loop parameters  $\omega_N$ ,  $\omega_C$ , and  $\zeta$  are often set by the application. The desired value for  $\zeta$  is typically near unity for the fastest overdamped response and about  $76^\circ$  of phase margin, or at least  $0.707$  for minimal ringing and about  $65^\circ$  of phase margin.  $\omega_N$  must be about one decade below the reference frequency for stability. For frequency synthesis or clock recovery applications, where input jitter filtering is desirable,  $\omega_N$  is typically set relatively low. For input tracking applications, such as clock de-skewing,  $\omega_N$  is typically set as high as possible to minimize jitter accumulation, as discussed in the sub-section on “PLL Supply/Substrate Noise Response.” When reference sideband filtering is important,  $\omega_C$  is typically set as low as possible at about a decade above  $\omega_N$  to maximize the amount of filtering.

The values of the loop parameters must somehow be mapped into acceptable values for the device parameters  $R$ ,  $C$ ,  $C_2$ ,  $I_{CH}$ , and  $K_V$ . The values of these parameters are typically constrained by the implementation. The value for capacitor  $C_2$  is determined by all capacitances on the control voltage node if the zero is implemented directly with a resistor. If capacitor  $C$  is implemented on chip, which is desirable

to minimize jitter, its size is constrained to less than about 1nF. The charge pump current  $I_{CH}$  is constrained to be greater than about 10  $\mu A$  depending on the level of charge pump charge injection offsets.

The problem of selecting device parameters is made more difficult by a number of constraining factors. First,  $\omega_N$  and  $\zeta$  both depend on all of the device parameters. Second, the maximum limit for C and minimum limit for  $I_{CH}$  will impose a minimum limit on  $\omega_N$ , which already has a maximum limit due to  $\omega_{REF}$  and other possible limits due to jitter and reference sideband issues. Third and most important, all worst-case combinations of device parameters due to process, voltage, and temperature variability must lead to acceptable loop dynamics.

Handling the interdependence between the loop parameters and device parameters is simplified by observing some proportionality relationships and scaling rules that directly result from the equations that relate the loop and device parameters. They are summarized in Table 10.4 and Table 10.5, respectively. The constant frequency scaling rules can transform one set of device parameters to another without changing any of the loop parameters. The proportional frequency scaling rules can transform one set of device parameters, with the resistance, capacitances, or charge pump current held constant, to another set with scaled loop frequencies and the same damping factor. These rules make it easy to make adjustments to the possible device parameters with controlled changes to the loop parameters.

With the many constraints on the loop and device parameters established by both the system environment and the circuit implementation, the design of a PLL typically turns into a compromise between conflicting design requirements. It is the job of the designer to properly balance these conflicting requirements and determine the best overall solution.

### PLL Design Strategy

Two general approaches can be used to determine the device parameters for a PLL design. The first approach is based on an open-loop analysis. This approach makes it easier to visualize the stability of the design from a frequency domain perspective. The open-loop analysis also easily accommodates more complicated loop filters. The second approach is based on a closed-loop analysis. This approach involves

FIGURE 10.10 PLL phase margin as a function of damping factor.

the loop parameters  $\omega_N$  and  $\zeta$ , which are commonly specified by higher-level system requirements. The complexity of these approaches depends on whether  $C_2$  exists and its level of significance.

If  $C_2$  does not need to be considered, a simplified version of the open-loop analysis or second-order analysis can be used. For an open-loop analysis without  $C_2$ , we need to consider the open-loop response of the PLL in Fig. 10.5. The loop gain normalization constant,  $G_O$ , for the normalized loop gain magnitude plot is directly related to the damping factor  $\zeta$  by

$$G_O = R^2 \cdot C \cdot I_{CH} \cdot K_V/N = 4 \cdot \zeta^2$$

This normalization constant is also the loop gain magnitude at the asymptotic break point for the zero at  $1/(R \cdot C)$ . An increase in the loop gain normalization constant will lead to a higher unity gain crossing, and therefore more phase margin. A plot of phase margin as a function of the damping factor  $\zeta$  is shown in Fig. 10.10. In order to adequately stabilize the design, the phase margin should be set to  $65^\circ$  or more and the unity gain bandwidth should be set no higher than  $\omega_{REF}/5$ . It is easiest to first adjust the loop gain magnitude level to set the phase margin, then to use the frequency scaling rules to adjust the unity gain bandwidth to the desired frequency. Without  $C_2$ , the second-order analysis simply depends on the loop parameters  $\omega_N$  and  $\zeta$ . To adequately stabilize the design,  $\omega_N$  should be set no higher than  $\omega_{REF}/10$  and  $\zeta$  should be set to 0.707 or greater.

If  $C_2$  exists but is not too large, an extension of the above approaches can be used.  $C$  should be set greater than  $C_2 \cdot 20$  to provide a minimum of  $65^\circ$  of phase margin at the unity gain bandwidth with the maximum phase margin. For any  $C/C_2$  ratio, the maximum phase margin is given by

$$PM_{MAX} = 2 \cdot \tan^{-1}(\sqrt{(C/C_2 + 1)}) - \pi/2$$

With the open-loop analysis, as before, the phase margin should be set to at least  $65^\circ$  or its maximum and the unity gain bandwidth should be set no higher than  $\omega_{REF}/5$ . With the second-order analysis,  $\Omega_N$  should be set no higher than  $\omega_{REF}/10$ ,  $\zeta$  should be set to 0.707 or greater, and  $\omega_C$  should be at least a decade above  $\omega_N$ .

If  $C_2$  exists and is large enough to make it difficult to guarantee adequate phase margin, then a third-order analysis must be used. This situation may have been caused by physical constraints on the capacitor sizes, or by attempts to minimize  $\omega_C$  in order to maximize the amount of reference frequency sideband filtering. In this case, it is desirable to determine the optimal values for the other device parameters that maximize the phase margin. The phase margin, PM, and unity gain bandwidth,  $\omega_o$ , where the phase margin is maximized, can be determined from the open-loop analysis as

$$\begin{aligned} \text{PM} &= 2 \cdot \tan^{-1}(\sqrt{(C/C_2 + 1)}) - \pi/2 \\ \omega_o &= \sqrt{(C/C_2 + 1)/(R \cdot C)} \end{aligned}$$

In order to realize the optimal value for  $\omega_o$ , the loop gain magnitude level must be appropriately set. This can be accomplished by determining  $I_{CH}$  given R, or R given  $I_{CH}$ , using the equations

$$\begin{aligned} I_{CH} &= N/K_V \cdot C_2/(R \cdot C)^2 \cdot (C/C_2 + 1)^{3/2} \\ R &= \sqrt{(N/(K_V \cdot I_{CH})) \cdot C_2 \cdot C^2 \cdot (C/C_2 + 1)^{3/2}} \end{aligned}$$

It is important to remember that all worst-case combinations of device parameters due to process, voltage, and temperature variability must be considered since they must lead to acceptable loop dynamics for the PLL to operate correctly under all conditions.

## Advanced PLL Architectures

PLL and DLL architectures each have their own advantages and disadvantages. PLLs are easier to use in systems than DLLs. DLLs typically cannot perform frequency multiplication and have a limited delay range. PLLs, however, are more difficult to design due to conflicting design constraints. It is difficult to assure stability while designing for a high bandwidth.

By using variations on the basic architectures many of these problems can be avoided. DLLs can be designed to perform frequency multiplication by recirculating intermediate edges around the delay line [7]. DLLs can also be designed to have an unlimited phase shift range by employing a delay line that can produce edges that completely span the clock cycle [4]. In addition, both DLLs and PLLs can be designed to have very wide bandwidths that track the clock frequency by using self-biased techniques [8], as discussed in “Self-Biased Techniques.”

## DLL/PLL Performance Issues

To this point, this chapter section presents basic issues concerning the structure and design of DLLs and PLLs. While these issues are important, a good understanding of the performance issues is essential to successfully design a DLL or PLL. Many performance parameters can be specified for a DLL or PLL design. They include frequency range, loop bandwidth, loop damping factor (PLL only), input offset, output jitter, both cycle-to-cycle (period) jitter and tracking (input-to-output) jitter, lock time, and power dissipation; however, the biggest performance problems all relate to input offset and output jitter.

Input offset refers to the average offset in the phase of the output clock from its ideal value. It typically results from asymmetries between the circuits for the reference and feedback paths of the phase detector or from charge injection or charge offsets in the charge pump. In contrast, output jitter refers to the time-varying offsets in the phase of the output clock from its ideal value or from some reference signal caused by disturbances from internal and external sources.

### Output Jitter

Output jitter can create significant problems for an interface by causing setup and hold time violations, which lead to data transmission errors. Consider, for example, the measured jitter histogram in Fig. 10.11. It shows the traces of many PLL output transitions triggered from transitions on the reference input and

**FIGURE 10.11** Measured PLL jitter histogram.

a histogram with the number of output transitions as a function of their center voltage crossing time. Most of the transition samples occur very close to the reference, while a few outlying transitions occur far to either side of the peak. These outlying transitions must be within the jitter tolerance of the interface. These few edges are typically caused by data dependent low frequency noise events with fast rise times.

Output jitter can be measured in a number of ways. It can be measured relative to absolute time, to another signal, or to the output clock itself. The first measurement of jitter is commonly referred to as absolute jitter or long-term jitter. The second is commonly referred to as tracking jitter or input-to-output jitter when the other signal is the reference signal. If the reference signal is perfectly periodic such that it has no jitter, absolute jitter and tracking jitter for the output signal are equivalent. The third is commonly referred to as period jitter or cycle-to-cycle jitter. Cycle-to-cycle jitter can be measured as the time-varying deviations in the period of single clock cycles or in the width of several clock cycles referred to as cycle-to-Nth-cycle jitter.

Output jitter can also be reported as RMS or peak-to-peak jitter. RMS jitter is interesting only to applications that can tolerate a small number of edges with large time displacements that are well beyond the RMS specification with gracefully degrading results. Such applications can include video and audio signal generation. Peak-to-peak jitter is interesting to applications that cannot tolerate any edges with time displacements beyond some absolute level. The peak-to-peak jitter specification is typically the only useful specification for jitter related to clock generation since most setup or hold time failures are catastrophic to the operation of a chip.

The relative magnitude for each of these measurements of jitter depends on the type of loop and on how the phase disturbances are correlated in time. For a PLL design, the tracking jitter can be ten or more times larger than the period jitter depending on the noise frequency and the loop bandwidth. For a DLL design, the tracking jitter can be equal to or a factor of two times larger than the period jitter. However, in the particular case when the noise occurs at half the output frequency, the period jitter can be twice the tracking jitter for either the PLL or DLL due to the correlation of output edges times.

### **Causes Of Jitter**

Tracking jitter for DLLs and PLLs can be caused by both jitter in the reference signal and by noise sources. The noise sources include thermal noise, flicker noise, and supply and substrate noise. Thermal noise is generated by electron scattering in the devices within the DLL or PLL and can be significant at low bias currents. Flicker noise is generated by mobile charge in the gate oxides of devices within the DLL or PLL and can be significant for low loop bandwidths. Supply and substrate noise is generated by on-chip sources external to the DLL or PLL, including chip output drivers and functional blocks such as adders and multipliers, and by off-chip sources. This noise can be very significant in digital ICs.

The supply and substrate noise generated by the on-chip and off-chip sources is highly data dependent and can have a wide range of frequency components that include low frequencies. Substrate noise tends not to have as large low-frequency components as possible for supply noise since no significant “DC” drops develop between the substrate and the supply voltages. Under worst-case conditions, DLLs and PLLs may experience as much as 500 mV of supply noise and 250 mV of substrate noise with a nominal 2.5 V supply. The actual level of substrate noise depends on the nature of the substrate used by the IC process. To reduce the risk of latch-up, many IC processes use lightly doped epitaxy on the same type heavily doped substrate. These substrates tend to transmit substrate noise across large distances on the chip, which make it difficult to eliminate through guard rings and frequent substrate taps.

Supply and substrate noise affect DLLs and PLLs differently. They affect a DLL by causing delay shifts in the delay line output, which lead to fixed phase shifts that persist until the noise pulses subside or the DLL can correct the delay error, at a rate limited by its bandwidth (proportional to  $\omega_{REF}/\omega_N$  cycles). They affect a PLL by causing frequency shifts in the oscillator output, which lead to phase shifts that accumulate for many cycles until the noise pulses subside or the PLL can correct the frequency error, at a rate limited by its bandwidth (proportional to  $\omega_{REF}/\omega_N$  cycles). Because the phase error caused by period shifts in PLLs accumulate over many cycles, unlike the delay shifts in DLLs, the tracking jitter for PLLs that results from supply and substrate noise can be several times larger than the tracking jitter for DLLs; however, due to the added jitter from on-chip clock distribution networks, which typically have poor supply and substrate noise rejection, the observable difference is typically less than a factor of 2 for well designed DLLs and PLLs.

**DLL Supply/Substrate Noise Response**

More insight can be gained into the noise response of DLLs and PLLs by considering how much jitter is produced as a function of frequency for supply and substrate noise. Figure 10.12 shows the output jitter sensitivity to input jitter for a DLL with a log-log plot of the absolute output jitter magnitude normalized to the absolute input jitter magnitude as a function of the input jitter frequency. Because the DLL simply delays the input signal, the jitter at the input is simply replicated with the same magnitude at the DLL output. For the same reason, the tracking jitter sensitivity to input jitter is very small at most frequencies; however, when the input jitter frequency approaches one half of the inverse of the delay line delay, the output jitter becomes 180° out-of-phase with respect to the input jitter and the observed tracking jitter can be twice the input jitter.

Figure 10.13 shows the output jitter sensitivity to sine-wave supply or substrate noise for a DLL with a log-log plot of the absolute output jitter magnitude as a function of the noise frequency. With the input jitter free, this absolute output jitter is equivalent to the tracking jitter. Also, since the DLL simply delays the input signal, the absolute output jitter is equivalent to the period jitter. This plot shows that the normalized jitter magnitude decreases at 20 dB per decade for decreases in the noise frequency below the loop bandwidth and is constant at one for noise frequencies above the loop bandwidth. This behavior results since the DLL acts as a low-pass filter to changes in its input period or, equivalently, to noise induced changes in its delay line delay. Thus, the jitter or delay error is the difference between the noise induced delay error and a low-pass filtered version of the delay error, leading to a high-pass noise response.

FIGURE 10.13 DLL output jitter sensitivity to sine-wave supply or substrate noise.

FIGURE 10.14 DLL output jitter sensitivity to square-wave supply or substrate noise.

FIGURE 10.15 PLL output jitter sensitivity to input jitter.

Figure 10.14 shows the output jitter sensitivity to square-wave supply or substrate noise for a DLL with a log-log plot of the peak absolute output jitter magnitude as a function of the noise frequency. With fast rise and fall times, the square-wave supply noise causes the delay line delay to change instantaneously. The peak jitter is then observed on at least the first output transition from the delay line after the noise signal transition, independent of the loop bandwidth. Thus, the output jitter sensitivity is independent the square-wave noise frequency. Overall, the output jitter sensitivity to supply and substrate noise for DLLs is independent of the loop bandwidth and the reference frequency for the worst-case of square-wave noise.

### PLL Supply/Substrate Noise Response

Figure 10.15 shows the output jitter sensitivity to input jitter for a PLL with a log-log plot of the absolute output jitter magnitude normalized to the absolute input jitter magnitude as a function of the input jitter frequency. This plot shows that the normalized output jitter magnitude decreases asymptotically at 20 dB per decade for noise frequencies above the loop bandwidth and is constant at one for noise frequencies below the loop bandwidth. It also shows that for underdamped loops where the damping factor is less than one, the normalized jitter magnitude can be greater than one for noise frequencies near the loop bandwidth leading to jitter amplification. This overall behavior directly results from the fact that the PLL is a low-pass filter to input phase noise as determined by the closed-loop frequency response.

Figure 10.16 shows the tracking jitter sensitivity to input jitter for a PLL with a log-log plot of the tracking jitter magnitude normalized to the absolute input jitter magnitude as a function of the input

FIGURE 10.16 PLL tracking jitter sensitivity to input jitter.

FIGURE 10.17 PLL output jitter sensitivity to sine-wave supply or substrate noise.

jitter frequency. This plot shows that the normalized tracking jitter magnitude decreases at 40 dB per decade for decreases in the noise frequency below the loop bandwidth and is constant at one for noise frequencies above the loop bandwidth. Again, it shows that for underdamped loops, the normalized jitter magnitude can be greater than one for noise frequencies near the loop bandwidth. This overall behavior occurs because the PLL acts as a low-pass filter to input jitter and the tracking error is the difference between the input signal and the low-pass filtered version of the input signal, leading to a high-pass noise response.

Figure 10.17 shows the tracking jitter sensitivity to sine-wave supply or substrate noise for a PLL with a log-log plot of the tracking jitter magnitude as a function of the noise frequency. With the input jitter free, this tracking jitter is equivalent to absolute output jitter as with the DLL. This plot shows that the tracking jitter magnitude decreases at 20 dB per decade for decreases in the noise frequency below the loop bandwidth and decreases at 20 dB per decade for increases in the noise frequency above the loop bandwidth. It also shows that for underdamped loops, the tracking jitter magnitude can be significantly larger for noise frequencies near the loop bandwidth. This overall behavior results indirectly from the fact that the PLL acts as a low-pass filter to input jitter. Because a frequency disturbance is equivalent to a phase disturbance of magnitude equal to the integral of the frequency disturbance, the tracking jitter sensitivity response to frequency noise is the integral of the tracking jitter sensitivity response to phase noise or, equivalently, input jitter. Therefore, the tracking jitter sensitivity response to sine-wave supply or substrate noise should simply be the plot in Fig. 10.15 with an added 20 dB per decade decrease over all noise frequencies, which yields the plot in Fig. 10.17.

This tracking jitter sensitivity response to sine-wave supply or substrate noise can also be explained in less quantitative terms. Because the PLL acts as a low-pass filter to noise, it tracks the input increasingly better in spite of the frequency noise as the noise frequency is reduced below the loop bandwidth. Noise frequencies at the loop bandwidth are at the limits of the PLL's ability to track the input. The PLL is not able to track noise frequencies above the loop bandwidth. However, the impact of this frequency noise is reduced as the noise frequency is increased above the loop bandwidth since the resultant phase disturbance, which is the integral of the frequency disturbance, accumulates for a reduced amount of time.

Figure 10.18 shows the tracking jitter sensitivity to square-wave supply or substrate noise for a PLL with a log-log plot of the tracking jitter magnitude as a function of the noise frequency. This plot shows that the tracking jitter magnitude is constant for noise frequencies below the loop bandwidth and

**FIGURE 10.18** PLL output jitter sensitivity to square-wave supply or substrate noise.

decreases at 20 dB per decade for increases in the noise frequency above the loop bandwidth. Again, it shows that for underdamped loops, the tracking jitter magnitude can be significantly larger for noise frequencies near the loop bandwidth. This response is similar to the response for sine waves except that square-wave frequencies below the loop bandwidth result in the same peak jitter as the loop completely corrects the frequency and phase error from one noise signal transition before the next transition occurs; however, the number of output transition samples exhibiting the peak tracking jitter will decrease with decreasing noise frequency, which can be misunderstood as a decrease in tracking jitter. Also, the jitter levels for square waves are higher by about a factor of 1.7 compared to these for sine waves of the same amplitude.

Overall, several observations can be made about the tracking jitter sensitivity to supply and substrate noise for PLLs. First, the jitter magnitude decreases inversely proportional to increases in the loop bandwidth for the worst case of square-wave noise at frequencies near or below the loop bandwidth. However, the loop bandwidth must be about a decade below the reference frequency, which imposes a lower limit on the jitter magnitude. Second, the jitter magnitude decreases inversely proportional to the reference frequency for a fixed hertz per volt frequency sensitivity, since the phase disturbance measured in radians is constant, but the reference period decreases inversely proportional to the reference frequency. Third, the jitter magnitude is independent of reference frequency for fixed %/V frequency sensitivity, since the phase disturbance measured in radians changes inversely proportional to the reference period. Finally, the jitter magnitude increases directly proportional to the square root of  $N$ , the feedback divider value, with a constant oscillator frequency and if the loop is overdamped, since the loop bandwidth is inversely proportional to the square root of  $N$ .

### Observations on Jitter

The optimal loop bandwidth depends on the application for the PLL. For frequency synthesis or clock recovery applications, where the goal is to filter out jitter on the input signal, the loop bandwidth should be as low as possible. For this application, the phase relationship between the output of the PLL and other clock domains is typically not an issue. As a result, the only jitter of significance is period jitter and possibly jitter spanning a few clock periods. This form of jitter does not increase with reductions in the loop bandwidth; however, if the phase relationship between the PLL output and other clock domains is important or if the jitter of the PLL output over a large number of cycles is significant, then the loop bandwidth should be maximized. Maximizing the loop bandwidth will minimize this form of jitter since it decreases proportional to increases in loop bandwidth.

Because of the hostile noise environments of digital chips, the peak value of the measured tracking jitter from DLLs and PLLs will likely be caused by square-wave supply and substrate noise. For PLLs, this noise is particularly significant when the noise frequencies are at or below the loop bandwidth. If a PLL is underdamped, noise frequencies near the loop bandwidth can be even more significant. In addition, a PLL can amplify input jitter at frequencies near the loop bandwidth, especially if it is underdamped. However, as previously discussed, jitter in a PLL or DLL can also be caused by a dead-band region in phase detector and charge pump characteristics.

In order to minimize jitter it is necessary to minimize supply and substrate noise sensitivity of the VCDL or VCO. The supply and substrate noise sensitivity can be separated into both static and dynamic components.

The static components relate to the sensitivity to the DC value of the supply or substrate voltage. The static noise sensitivity can predict the noise response for all but the high-frequency components of the supply and substrate noise. The dynamic components relate to the extra sensitivity to a sudden change in the supply or substrate voltage that the static components do not predict. The effect of the dynamic components increases with increasing noise edge rate. For PLLs, the dynamic noise sensitivity typically has a much smaller overall impact on the supply and substrate noise response than the static noise sensitivity; however, for DLLs, the dynamic noise sensitivity can be more significant than static noise sensitivity. Only static supply and substrate noise sensitivity are considered in this chapter.

### **Minimizing Supply Noise Sensitivity**

All VCDL and VCO circuits will have some inherent sensitivity to supply noise. In general, supply noise sensitivity can be minimized by isolating the delay elements used within the VCDL or VCO from one of the supply terminals. This goal can be accomplished by using a buffered version of the control voltage as one of the supply terminals; however, this technique can require too much supply voltage headroom. The preferred and most common approach is to use the control voltage to generate a supply independent bias current so that current sources with this bias current can be used to isolate the delay elements from the opposite supply.

Supply voltage sensitivity is directly proportional to current source output conductance. Simple current sources provide a delay sensitivity per fraction of the total supply voltage change ( $(dt/t)/(dV_{DD}/V_{DD})$ ), of about 10%, such that if the supply voltage changed by 10% the delay would change by 1%. This level of delay sensitivity is too large for good jitter performance in PLLs. Cascode current sources provide an equivalent delay sensitivity of about 1%, such that if the supply voltage changed by 10% the delay would change by 0.1%, which is at the level needed for good jitter performance, but cascode current sources can require too much supply voltage headroom. Another technique that can also offer an equivalent delay sensitivity of about 1% is replica current source biasing [9]. In this approach, the bias voltage for simple current sources is actively adjusted by an amplifier in a feedback configuration to keep some property of the delay element, such as voltage swing, constant and possibly equal to the control voltage.

Once adequate measures are taken to minimize the current source output conductance, other supply voltage dependencies may begin to dominate the overall supply voltage sensitivity of the delay elements. These effects include the dependencies of threshold voltage and diffusion capacitance for switching devices on the source or drain voltages, which can be modulated by the supply voltage. With any supply terminal isolation technique, all internal switching nodes will have voltages that track the supply terminal opposite to the one isolated. Thus, these effects can be manifested by devices with bulk terminals connected to the isolated supply terminal. These effects are always a problem for substrate devices with an isolated substrate-tap voltage supply terminal, such as for NMOS devices in an N-well process with an isolated negative supply terminal. Isolating the well-tap voltage supply terminal avoids this problem since the bulk terminals of the well devices can be connected to their source terminals, such as with PMOS devices in an N-well process with an isolated positive supply terminal. However, such an approach leads to more significant substrate noise problems. The only real solution is to minimize their occurrence and to minimize their switching diffusion capacitance. Typically, these effects will establish a minimum delay sensitivity per fraction of the total supply voltage change of about 1%.

### **Supply Noise Filters**

Another technique to minimize supply noise is to employ supply filters. Supply filters can be both passive, active, or a combination of the two. Passive supply filters are basically low-pass filters. Off-chip passive filters work very well in filtering out most off-chip noise but do little to filter out on-chip noise. Unfortunately, on-chip filters can have difficulty in filtering out low-frequency on-chip noise. Off-chip capacitors can easily be made large enough to filter out low-frequency noise, but on-chip capacitors are much more limited in size. In order for the filter to be effective in reducing jitter for both DLLs and PLLs, the filter cutoff frequency must be below the loop bandwidth.

Active supply filters employ amplifiers in a feedback configuration to buffer a desired reference supply voltage and act as high-pass filters. The reference supply voltage is typically established by a band-gap or control voltage reference. The resultant supply isolation will decrease with increasing supply filter bandwidth due to basic amplifier feedback tradeoffs. In order for the active filter to be effective, the bandwidth must exceed the inverse VCDL delay of a DLL or the loop bandwidth of a PLL. The DLL bandwidth limit originates because the VCDL delay will begin to be less affected by a noise event if it subsides before a signal transition propagates through the complete VCDL. The PLL bandwidth limit exists because, as higher-frequency noise is filtered out above the loop bandwidth, the VCO will integrate the resultant change in frequency for fewer cycles. Although the PLL bandwidth limit is achievable in a supply filter with some level of isolation, the DLL bandwidth limit is not. Thus, although active supply filters can help PLLs, they are typically ineffective for DLLs; however, the combination of passive and active filters can be an effective supply noise-filtering solution for both PLLs and DLLs by avoiding the PLL and DLL bandwidth constraints. When the low-pass filter cutoff frequency is below the high-pass filter cutoff frequency, filtering can be achieved at both low and high frequencies so that tracking bandwidths and inverse VCDL delays are not an issue.

Other common isolation approaches include using separate supply pins for a DLL or PLL. This approach should be used whenever possible. However, the isolated supplies will still experience noise from coupling to other supplies through off-chip paths and coupling to the substrate through well contacts and diffusion capacitance, requiring that supply noise issues be addressed. Also, having separate supply pins at the well tap potential can lead to increased substrate noise depending on the overall conductivity of the substrate.

### **Minimizing Substrate Noise Sensitivity**

Substrate noise sensitivity like supply noise sensitivity can create jitter problems for a PLL or DLL. Substrate noise can couple into the delay elements by modulating device threshold voltages. Substrate noise can be minimized by only using well-type devices for fixed-biased current sources, only using well-type devices for the loop filter capacitor, only connecting the control voltage to well-type devices, and only using the well-tap voltage as the control voltage reference. These constraints will insure that substrate noise does not modulate fixed-bias current source outputs or the conductance of devices connected to the control voltage, both through threshold modulation. In addition, they will prevent supply noise from directly summing into the control voltage through a control voltage reference different from the loop filter capacitor reference. Even with these constraints, substrate noise can couple into switching devices, as with supply noise, through the threshold voltage and diffusion capacitance dependencies on the substrate potential.

Substrate noise can be converted to supply noise by connecting the substrate-potential supply terminals of the delay elements only to the substrate [10]. This technique insures that the substrate and the substrate-potential supply terminals are at the same potential, however, it only works with low operating currents, because otherwise voltage drops will be generated in the substrate and excessive minority carriers will be dumped into the substrate.

### **Other Performance Issues**

High loop bandwidths in PLLs make it possible to minimize tracking jitter, but they can lead to problems during locking. PLLs based on phase-frequency detectors cannot tolerate any missing clock pulses in the feedback path during the locking process. If a clock pulse is lost in the feedback path because the VCO output frequency is too high, the phase-frequency detector will detect only reference edges, causing a continued increase in the VCO output frequency until it reaches its maximum value. At this point the PLL will never reach lock. To avoid losing clock pulses, which results in locking failure, all circuits in the feedback path, which might include the clock distribution network and off-chip circuits, must be able to pass the highest frequency the PLL may generate during the locking process. As the loop bandwidth is increased to its practical maximum limit, however, the amount that the PLL output frequency may overshoot its final value will increase. Thus, overshoot limits may impose an additional bandwidth limit on the PLL beyond the decade below the reference frequency required for stability.

A more severe limit on the loop bandwidth beyond a decade below the reference frequency can result in both PLLs and DLLs if there is considerable delay in the feedback path. The decade limit is based on the phase detector adding one reference period delay in the feedback path since it only samples clock edges once per reference cycle. This single reference period delay leads to an effective pole near the reference frequency. The loop bandwidth must be at least a decade below this pole to not affect stability. This bandwidth limit can be further reduced if extra delay is added in the feedback path, by an amount proportional to one plus the number of reference periods additional delay.

## DLL/PLL Circuits

Prior sections discussed design issues related to DLL and PLL loop architectures and low output jitter. With these issues in mind, this section discusses the circuit level implementation issues of the loop components. These components include the VCDL and VCO, phase detector, charge pump, and loop filter.

### VCDLs and VCOs

The VCDL and VCO are the most critical parts of DLL and PLL designs for achieving low output jitter and good overall performance. Two general types of VCDLs are used with analog control. First, a VCDL can interpolate between two delays through an analog weighted sum circuit. This approach only leads to linear control over delay, if the two interpolated delays are relatively close, which restricts the overall range of the VCDL. Second, a VCDL can be based on an analog delay line composed of identical cascaded delay elements, each with a delay that is controlled by an analog signal. This approach usually leads to a wide delay range with nonlinear delay control. A wide delay range is often desired in order to handle a range of operating frequencies and process and environmental variability. However, nonlinear delay control can restrict the usable delay range due to undesirable loop dynamics.

Several types of VCOs are used. First, a VCO can be based on an LC tank circuit. This type of oscillator has very high supply noise rejection and low phase noise output characteristics. However, it usually also has a restricted tuning range, which makes it impractical for digital ICs. Second, a VCO can be based on a relaxation oscillator. The frequency in this circuit is typically established by the rate a capacitor can be charged and discharged over some established voltage range with an adjustable current. This approach typically requires too much supply headroom to achieve good supply noise rejection and can be extra sensitive to sudden changes in the supply voltage. Third, and most popular for digital ICs, a VCO can be based on a phase shift oscillator, also known as a ring oscillator. A ring oscillator is a ring of identical cascaded delay elements with inverting feedback between the two elements that close the ring. A ring oscillator can typically generate frequencies over a wide range with linear control over frequency.

The delay elements, also known as buffer stages, used in a delay line or ring oscillator can be single-ended, such that they have only one input and one output and invert the signal, or differential, such they have two complementary inputs and outputs. Single-ended delay elements typically lead to reduced area and power, but provide no complementary outputs. Complementary outputs provide twice as many output signals with phases that span the output period compared to single-ended outputs, and allow a 50% duty cycle signal to be cleanly generated without dividing the output frequency by two. Differential delay elements typically have reduced dynamic noise coupling to their outputs and provide complementary outputs.

A number of factors must be considered in the design of the delay elements. The delay of the delay elements should have a linear dependence on control voltage when used in a VCDL and an inverse linear dependence on control voltage when used in a VCO. These control relationships will make the VCDL and VCO control gains constant and independent of the operating frequency, which will lead to operating frequency independent loop dynamics. The static supply and substrate noise sensitivity should be as small as possible, ideally less than 1% delay sensitivity per fraction of the total supply voltage change. As previously discussed, this reduced level of supply sensitivity can be established with current source isolation.

Figure 10.19 shows a single-ended delay element circuit for an N-well CMOS process. This circuit contains a PMOS common-source device with a PMOS diode clamp and a simple NMOS current source. The diode clamp restricts the buffer output swing in order to keep the NMOS current source device in saturation.

FIGURE 10.19 Single-ended delay element for an N-well CMOS process.

FIGURE 10.20 Differential delay element with symmetric loads for an N-well CMOS process.

In order to achieve high static supply and substrate noise rejection, the bias voltage for the simple NMOS current source is dynamically adjusted with changes in the supply or substrate voltage to compensate for its finite output impedance.

Figure 10.20 shows a differential delay element circuit for an N-well CMOS process [9]. This circuit contains a source-coupled pair with resistive load elements called symmetric loads. Symmetric loads consist of a diode-connected PMOS device in shunt with an equally sized biased PMOS device. The PMOS bias voltage  $V_{BP}$  is nominally equal to  $V_{CTRL}$ , the control input to the bias generator.  $V_{BP}$  defines the lower voltage swing limit of the buffer outputs. The buffer delay changes with  $V_{BP}$  because the effective resistance of the load elements also changes with  $V_{BP}$ . It has been shown that these load elements lead to good control over delay and high dynamic supply noise rejection. The simple NMOS current source is dynamically biased with  $V_{BN}$  to compensate for drain and substrate voltage variations, achieving the effective static supply noise rejection performance of a cascode current source without the extra supply voltage required by cascode current sources.

A block diagram of the bias generator for the differential delay element is shown in Fig. 10.21 and the detailed circuit is shown in Fig. 10.22. A similar bias generator circuit is used for the single-ended delay element. This circuit produces the bias voltages  $V_{BN}$  and  $V_{BP}$  from  $V_{CTRL}$ . Its primary function is to continuously adjust the buffer bias current in order to provide the correct lower swing limit of  $V_{CTRL}$  for the buffer stages. In so doing, it establishes a current that is held constant and independent of supply and substrate voltage since the I-V characteristics of the load element does not depend on the supply or substrate voltage. It accomplishes this task by using a differential amplifier and a half-buffer replica. The amplifier adjusts  $V_{BN}$ , so that the voltage at the output of the half-buffer replica is equal to  $V_{CTRL}$ , the lower swing limit. If the supply or substrate voltage changes, the amplifier will adjust to keep the swing and thus the bias current constant.

FIGURE 10.21 Replica-feedback current source bias circuit block diagram.

FIGURE 10.22 Replica-feedback current source bias circuit schematic.

The bandwidth of the bias generator is typically set close to the operating frequency of the buffer stages or as high as possible without compromising its stability, so that the bias generator can track all supply and substrate voltage disturbances at frequencies that can affect the DLL and PLL designs. The bias generator also provides a buffered version of  $V_{CTRL}$  at the  $V_{BP}$  output using an additional half-buffer replica, which is needed in the differential buffer stage. This output isolates  $V_{ctrl}$  from potential capacitive coupling in the buffer stages and plays an important role in self-biased PLL designs [8].

Figure 10.23 shows the static supply noise sensitivity of a ring oscillator using the differential delay element and bias generator in a  $0.5 \mu\text{m}$  N-well CMOS process. With this bias generator, the buffer stages can achieve static frequency sensitivity per fraction of the total supply voltage change of less than 1% while operating over a wide delay range with low supply voltage requirements that scale with the operating delay. Buffer stages with low supply and substrate noise sensitivity are essential for low-jitter DLL and PLL operation.

## Differential Signal Conversion

PLLs are typically designed to operate at twice the chip operating frequency so that their outputs can be divided by two in order to guarantee a 50% duty cycle [2]. This practice can be wasteful if the delay elements already generate differential signals since the differential signal transitions equally subdivide

**FIGURE 10.23** Frequency sensitivity to supply voltage for a ring oscillator with differential delay elements and a replica-feedback current source bias circuit in a 0.5  $\mu\text{m}$  N-well CMOS process.

the clock period. Thus, the requirement for a 50% duty cycle can be satisfied without operating the PLL at twice the chip operating frequency, if a single-ended CMOS output with 50% duty cycle can be obtained from a differential output signal. This conversion can be accomplished using an amplifier circuit that has a wide bandwidth and is balanced around the common-mode level expected at the inputs so that the opposing differential input transitions have roughly equal delay to the output. Such circuits will generate a near 50% duty cycle output without dividing by two provided that device matching is not a problem; however, on-wafer device mismatches for nominally identical devices will tend to unbalance the circuit and establish a minimum signal input and internal bias voltage level below which significant duty-cycle conversion errors may result. In addition, as the device channel lengths are reduced, device mismatches will increase. Therefore, using a balanced differential-to-single-ended converter circuit instead of a divider can relax the design constraints on the VCO for high-frequency designs but must be used with caution because of potential device mismatches.

## Phase Detectors

The phase detector detects the phase difference between the reference input and the feedback signal of a DLL or PLL. Several types of phase detectors can be used, each of which will allow the loop achieve a different phase relationship once in lock. An XOR or mixer can be used as a phase detector to achieve a quadrature lock on input signals with a 50% duty cycle. The UP and DN outputs are complementary, and, once in lock, each will generate a 50% duty cycle signal at twice the reference frequency. The 50% duty cycle will cause the UP and DN currents to cancel out leaving the control voltage unchanged. An edge-triggered SR latch can be used as the phase detector for an inverted lock. The UP and DN outputs are also complementary, and, once in lock, each will generate a 50% duty cycle signal at the reference frequency. If differential inputs are available, an inverted lock can be easily interchanged with an in-phase lock. A sampling flip-flop can be used to sample the reference clock as the phase detector in a digital feedback loop, where the flip-flop is used to match the input delay for digital inputs also sampled by identical flip-flops. The output state of the flip-flop will indicate if the feedback clock is early or late. Finally, a phase-frequency detector (PFD) can be used as a phase detector to achieve an in-phase lock. PFDs are commonly based on two SR latches or two D flip-flops. They have the property that only UP pulses are generated if the frequency is too low, only DN pulses are generated if the frequency is too high, and to first order, no UP or DN pulses are generated once in lock. Because of this property, PLLs using PFDs will slew their control voltage with, on

FIGURE 10.24 Phase-frequency detector based on NAND gates.

average, half of the charge pump current until the correct frequency is reached, and will never falsely lock at some harmonic of the reference frequency. PFDs are the most common phase detectors used in DLLs and PLLs.

Phase detector can have several potential problems. The phase detector can have an input offset caused by different edge rates between the reference and feedback signals or caused by asymmetric circuits or device layouts between the reference and feedback signal paths. In addition, the phase detector can exhibit nonlinearity near the locking point. This nonlinearity can include a dead-band, caused by an input delay difference where the phase detector output remains zero or unchanged, or a high-gain region, caused by an accelerated sensitivity to transitions on both the reference and feedback inputs. In order to properly diagnose potential phase detector problems, the phase detector must be simulated or tested in combination with the charge pump.

A PFD based on SR latches [2], as shown in Fig. 10.24, can be implemented with NAND or NOR gates. However, the use of NAND gates will lead to the highest speed. The input sense polarity can be maintained as positive edge sensitive if inverters are added at both inputs. The layout for the PFD should be constructed from two identical pieces for complete symmetry. The basic circuit structure can be modified in several ways to improve performance.

One possible modification to the basic PFD structure is to replace the two-input NAND gates at the inputs with three-input NAND gates. The extra inputs can serve as enable inputs to the PFD by gating out positive pulses at the reference or feedback inputs. For the enable inputs to function properly, they must be low for at least the entire positive pulse in order to properly ignore a falling transition at the reference or feedback inputs.

### Charge Pumps

The charge pump, which is driven by the phase detector, can be structured in a number of ways. The key issues for the structure are input offset and linearity. An input offset can be caused by a mismatch in charge-up or charge-down currents or by charge injection. The nonlinearity near the lock point can be caused by edge rate dependencies and current source switching.

A push-pull charge pump is shown in Fig. 10.25. This charge pump tends to have low output ripple because small but equal UP and DN pulses, produced by a PFD once in lock, generate equal current pulses at exactly the same time that cancel out with an insignificant disturbance to the control voltage.

FIGURE 10.25 Push-pull charge pump.

FIGURE 10.26 Current mirror charge pump.

The switches for this charge pump are best placed away from the output toward the supply rails in order to minimize charge injection from the supply rails to the control voltage. The opposite configuration can inject charge from the supply rails through the capacitance at the shared node between the series devices.

A current mirror charge pump is shown in Fig. 10.26. This charge pump tends to have the lowest input offset due to balanced charge injection. In the limit that a current mirror has infinite output impedance, it will mirror exact charge quantities; however, because the DN current pulse is mirrored to the output, it will occur later and have a longer tail than the UP current pulse, which is switched directly to the output. This difference in current pulse shape will lead to some disturbance to the control voltage.

Another combined approach for the charge pump and loop filter involves using an amplifier-based voltage integrator. This approach is difficult to implement in most IC processes because it requires floating capacitors. Any of the above approaches can be modified to work in a “bang-bang” mode, where the output charge magnitude is fixed independent of the phase error. This mode of operation is sometimes used with digital feedback loops when it is necessary to cancel the aperture offset of a high-speed interface receiver [11]; however, it makes the loop control very nonlinear and commonly produces dither jitter, where the output phase, once in lock, alternates between positive and negative errors.

## Loop Filters

The loop filter directly connects to the charge pump to integrate and filter the detected phase error. The most important detail for the loop filter is the choice of supply terminal to be used as the control voltage reference. As discussed in the section on “Supply Noise Filters,” substrate noise can couple into delay elements through threshold modulation of the active devices. The substrate noise sensitivity can be minimized by using well-type devices for the loop filter capacitor and for fixed-biased devices. Also, care must be taken to insure that the voltage reference used by the circuitry that receives the control voltage is the same as the supply terminal to which the loop filter capacitor connects. Otherwise, any supply noise will be directly summed with the control voltage.

Some designs employ level shifting between the loop filter voltage and the control voltage input to the VCDL or VCO. Such level shifting is often the cause of added supply noise sensitivity and should be avoided whenever possible. Also, some designs employ differential loop filters. A differential loop filter is useful only if the control input to the VCDL or VCO is differential, as is often the case with a delay interpolating VCDL. If the VCDL or VCO has a single-ended control input, a differential loop filter adds no value because its output must be converted back to a single-ended signal. Also, the differential loop filter needs some type of common-mode biasing to establish the common-mode voltage. The common-mode bias circuit will add some differential mode resistance that will cause the loop filter to leak charge and will lead to an input offset for the DLL or PLL.

For PLLs, the loop filter must implement a zero in order to provide phase margin for stability. The zero can be implemented directly with a resistor in series with the loop filter capacitor. In this case, the charge pump current is converted to a voltage through the resistor, which is added to the voltage across the loop filter capacitor to form the control voltage. Alternatively, this zero can be formed by summing an extra copy of the charge pump current directly with a bias current used to control the VCO, possibly inside a bias generator for the VCO. This latter approach avoids using an actual resistor and lends itself to self-biased schemes [8].

## Frequency Dividers

A frequency divider can be used in the feedback path of a PLL to enable it to generate a VCO output frequency that is a multiple of the reference frequency. Since the divider is in the feedback path to the phase detector, care must be taken to insure that the insertion delay of the divider does not upset any clock de-skewing to be performed by the PLL. As such, an equivalent delay may need to be added in the reference path to the phase detector in order to cancel out the insertion delay of the divider. The best approach for adding the divider is to use it as a feedback clock edge enable input to the phase detector. In this scheme, the total delay of the feedback path, from the VCO to the phase detector, is not affected by the divider. As long as the divider output satisfies the setup and hold requirements for the enable input to the phase detector, it can have any output delay and even add jitter. As previously noted, an enable input can be added to both the reference and feedback inputs of an SR latch PFD by replacing the two-input NAND gates at the inputs with three-input NAND gates.

## Layout Issues

The layout for a DLL or PLL can have significant impact on its overall performance. Supply independent biasing uses many matched devices that must match when the circuit is fabricated. Typical device matching problems originate from different device layouts, different device orientations, different device geometry surroundings leading to device etching differences, and sensitivity to process gradients. In general, the analog devices should be arrayed in identical common denominator units at the same orientation so that the layers through polysilicon for and around each device appear identical. The common denominator units should use folding at a minimum to reduce the sensitivity to process gradients. Bias voltages, especially the control voltage, and switching nodes within the VCO or VCDL should be carefully routed to minimize coupling to the supply terminal opposite the one referenced. In addition, connecting the control voltage to a pad in a DLL or PLL with an on-chip loop filter should be avoided. At a minimum, it should only be bonded for testing but not production purposes.

## Circuit Summary

In general, all DLL and PLL circuits must be designed from the outset with supply and substrate noise rejection in mind. Obtaining low noise sensitivity requires careful orchestration among all circuits and cannot be added as an after thought. Supply noise rejection requires isolation from one supply terminal, typically with current source isolation. Substrate noise rejection requires all fixed-biased devices to be well-type devices to minimize threshold modulation. However, the best circuits to use depend on both the loop architecture and the IC technology.

## Self-Biased Techniques

Achieving low tracking jitter and a wide operating frequency range in PLL and DLL designs can be difficult due to a number of design trade-offs. To minimize the amount of tracking jitter produced by a PLL, the loop bandwidth should be set as high as possible. However, the loop bandwidth must be set at least a decade below the lowest desired operating frequency for stability with enough margin to account for bandwidth changes due to the worst-case process and environmental conditions. Achieving a wide operating frequency range in a DLL requires that the VCDL work over a wide range of delays. However, as the delay range is increased, the control becomes increasingly nonlinear, which can undermine the stability of the loop and lead to increased jitter. These different trade-offs can cause both PLLs and DLLs to have narrow operating frequency ranges and poor jitter performance.

Self-biasing techniques can be applied to both PLLs and DLLs as a solution to these design trade-off problems [8]. Self-biasing can remove virtually all of the process technology and environmental variability that affect PLL and DLL designs, and provide a loop bandwidth that tracks the operating frequency. This tracking bandwidth sets no limit on the operating frequency range and makes wide operating frequency ranges spanning several decades possible. This tracking bandwidth also allows the bandwidth to be set aggressively close to the operating frequency to minimize tracking jitter. Other benefits of self-biasing include a fixed damping factor for PLLs and input phase offset cancellation. Both the damping factor and the bandwidth to operating frequency ratio are determined completely by a ratio of capacitances giving effective process technology independence. In general, self-biasing can produce very robust designs.

The key idea behind self-biasing is that it allows circuits to choose the operating bias levels in which they function best. By referencing all bias voltages and currents to other generated bias voltages and currents, the operating bias levels are essentially established by the operating frequency. The need for external biasing, which can require special band-gap bias circuits, is completely avoided. Self-biasing typically involves using the bias currents in the VCO or VCDL as the charge pump current. Special accommodations are also added for the feed-forward resistor needed in a PLL design.

## Characterization Techniques

A good DLL or PLL design is not complete without proper simulation and measurement characterization. Careful simulation can uncover stability, locking, and jitter problems that might occur at the operating, environment, and process corners. Alternatively, careful laboratory measurements under the various operating conditions can help prevent problems in manufacturing.

## Simulation

The loop dynamics of the DLL or PLL should be verified through simulation using one of several possible modeling techniques. They can be modeled at the circuit level, at the behavioral level, or as a simplified linear system. Circuit-level modeling is the most complete, but can require a lot of simulation time because the loops contain both picosecond switching events and microsecond loop bandwidth time constants. Behavioral models can simulate much faster, but are usually restricted to transient simulations. A simplified linear system model can be constructed as a circuit from linear circuit elements and voltage-controlled current sources, where phase is modeled as voltage. This simple model can be analyzed not just with transient simulations, but also with AC simulations and other forms of analysis possible for linear circuits. Such models can include supply and substrate noise sensitivities and actual loop filter and bias circuitry.

Open-loop simulations at the circuit level should be performed on individual blocks within the DLL or PLL. The VCDL and VCO should be simulated using a transient analysis as a function of control voltage, supply voltage, and substrate voltage in order to determine the control, supply, and substrate sensitivities. The phase detector should be simulated with the charge pump, by measuring the output charge as a function of input phase different and possibly control voltage, to determine the static phase offset and if any nonlinearities exist at the locking point, such as a dead-band or high-gain region. The results of these simulations can be incorporated into the loop dynamics simulation models.

Closed-loop simulations at the circuit level should also be performed on the complete design in order to characterize the locking characteristics, overall stability, and jitter performance. The simulations should be performed from all possible starting conditions to insure that the correct locking result can be reliably established. The input phase step response of the loop should be simulated to determine if there are stability problems manifested by ringing. Also, the supply and substrate voltage step response of the loop should be simulated to give a good indication of the overall jitter performance. All simulations should be performed over all operating conditions, including input frequencies and divider ratios, and environmental conditions including supply voltage and temperature as well as process corners.

### Measurement

Once the DLL or PLL has been fabricated, a series of rigorous laboratory measurements should be performed to insure that a problem will not develop late in manufacturing. The loop should first be characterized under controlled conditions. Noise-free supplies should be used to insure that the loop generally locks and operates correctly. Supply noise steps at sub-harmonic of the output frequency can be used to allow careful measurement of the loop's response to supply steps. If such a supply noise signal is added synchronously to the output signal, it can be used as a trigger to obtain a complete time averaged response to the noise steps. The step edge rates should be made as high as possible to yield the worst-case jitter response. Supply noise steps swept over frequency, especially at low frequencies, should be used to determine the overall jitter performance. Also, supply sine waves swept over frequency will help determine if there are stability problems with the loop manifested by a significant increase in jitter when the noise frequency approaches the loop bandwidth.

The loop should then be characterized under uncontrolled conditions. These conditions would include worst-case I/O switching noise and worst-case on-chip core switching noise. These experiments will be the ultimate judge of the PLL's jitter performance assuming that the worst-case data patterns can be constructed. The best jitter measurements to perform for characterizations will depend on the DLL or PLL application, but they should include both peak cycle-to-cycle jitter and peak input-to-output jitter.

### Conclusions

DLLs and PLLs can be used to relax system-timing constraints. The best loop architecture strongly depends on the system application and the system environment. DLLs produce less jitter than PLLs due to their inherently reduced noise sensitivity. PLLs provide more flexibility by supporting frequency multiplication and an unlimited phase range. Independent of the chosen loop architecture, supply and substrate noise will likely be the most significant cause of output jitter. As such, all circuits must be designed from the outset with supply and substrate noise rejection in mind.

## 10.2 Latches and Flip-Flops

---

*Fabian Klass*

### Introduction

This chapter section deals with latches and flip-flops that interface to complementary static logic and are built in CMOS technology. Two fundamental types of designs are discussed: (1) design based on *transparent latches* and (2) designs based on *edge-triggered flip-flops*. Because conceptually flip-flops are built from transparent latches, the analysis of timing requirements is focused primarily on the former. Flip-flop-based designs are then analyzed as a special case of a latch-based design. Another type of latch, known as a *pulsed latch*, is treated in a special section also. This is because while similar in nature to a transparent latch, its usage in practice is similar to a flip-flop, which makes it a unique and distinctive type.

The chapter section is organized as follows. The first half deals with the timing requirements of latch- and flip-flop-based designs. It is generic and the concepts discussed therein are applicable to other technologies as well. The second half of the chapter presents specific circuit topologies and is exclusively focused on CMOS technology. Various latches and flip-flops are described and their performance is analyzed. A subsection on scan design is also provided. A summary and a historical perspective is finally presented.

### Historical Trends

In discussing latch and flip-flop based designs, it is important to review the fundamental concept behind them, which is *pipelining*. Pipelining is a technique that achieves parallelism by segmenting long sequential logical operations into smaller ones. At any given time, each stage in the pipeline operates concurrently on a different data set. If the number of stages in the pipeline is  $N$ , then  $N$  operations are executed in parallel. This parallelism is reflected in the clock frequency of the system. If the clock frequency of the unsegmented pipeline is  $F_{req}$ , a segmented pipeline with  $N$  stages can operate *ideally* at  $N \times F_{req}$ . It is important to understand that the increase in clock rate does not necessarily translate linearly into increased performance. Architecturally, the existence of data dependencies, variable memory latencies, interruptions, and the type of instructions being executed, among other factors, contribute to reducing the effective number of operations executed per clock cycle, or the effective parallelism [1]; however, as a historical trends show, pipelines are becoming deeper, or correspondingly, the stages are becoming shorter. For instance, the design reported in [2] has a pipeline 15-stage deep. From a physical perspective, the theoretical speedup of segmentation is not attainable either. This is because adjacent pipeline stages need to be isolated, so independent operations, which execute concurrently, do not intermix. Typically, synchronous systems use *latches* or *flip-flops* to accomplish this. Unfortunately, these elements are not ideal and add overhead to each pipeline stage. This *pipeline overhead* depends on the specific latching style and the clocking scheme adopted. For instance, if the pipeline overhead in an  $N$ -stage design is 20%

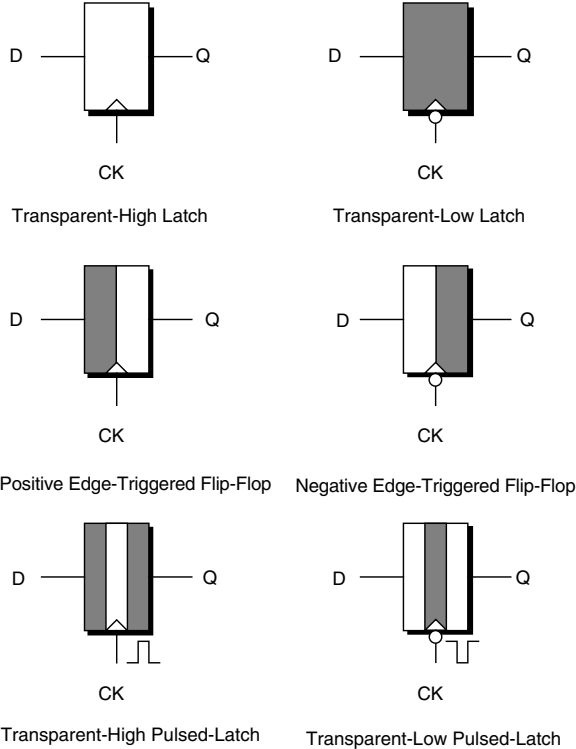

of the cycle time, the effective parallelism achieved is only  $N \times 0.8$ . If the clock rate were doubled by making the pipeline twice as deep, e.g., by inserting one additional latch or flip-flop per stage, then the pipeline overhead would become 40% of the cycle time, or correspondingly, the achieved parallelism  $2 \times N \times 0.6$ . So in such a case, a doubling of the clock rate translates into a 50% only increase in performance ( $2 \times 0.6/0.8 = 1.50$ ). In practice, other architectural factors, some of them mentioned above, would reduce the performance gain even further.

From the above discussion, it becomes clear that in selecting a latch type and clocking scheme, the minimization of the pipeline overhead is key to performance; however, as discussed in detail throughout this chapter section, performance is not the only criterion that designers should follow in making such a selection. In addition to the pipeline overhead, latch- and flip-flop-based designs are prone to *races*. This term refers to fast signals propagating through contiguous pipeline stages within the same clock cycle, resulting in data corruption. Although this problem does not reflect directly in performance, it is the nightmare of designers because it is usually fatal. If it appears in silicon, it is extremely hard to debug, and therefore it is generally detrimental to the design cycle. Furthermore, since most of the design time is spent on verification, particularly timing verification, a system that is susceptible to races takes longer to design.

Other design considerations, such as layout area, power dissipation, power-delay product, design robustness, clock distribution, and timing verification, some of which are discussed in this chapter section, must also be carefully considered in selecting a particular latching design.

**Nomenclature and Symbols**

The nomenclature and symbols used throughout this chapter are shown in Fig. 10.27. The polarity of the clock is indicated with a conventional bubble. The presence of the bubble means the latch is *transparent-low* or that the flip-flop samples with the *negative edge* of clock. Conversely, the lack of the bubble means the latch is *transparent-high*, or that the flip-flop samples with the *positive edge* of clock. The term *opaque*,

**FIGURE 10.27** Symbols used for latches, flip-flops, and pulsed latches.

introduced in [3], is used to represent the opposite to transparent. It is considered unambiguous in contrast to on/off or open/close. A color convention is also adopted to indicate the transparency of the latch. *White* means transparent-high (or opaque-low), while *shaded* means transparent-low (or opaque-high) (Fig. 10.27, top). Because most flip-flops are made from two transparent latches, one transparent-high and one transparent-low, a half-white half-shaded symbol is used to represent them (Fig. 10.27, middle). The symbol adopted for pulsed flops has a white band on a shaded latch, or vice versa, to indicate a short transparency period (Fig. 10.27, bottom).

To make timing diagrams easy to follow, relevant timing dependencies are indicated with light arrows, as shown in Fig. 10.28. Also, a coloring convention is adopted for the timing diagrams. Signal waveforms that are timing dependent are shaded. This eases the identification of the timing flow of signals and helps better visualizing the timing requirements of the different latching designs.

### Definitions

The following definitions apply to a transparent-high latch; however, they are generic and can be applied to transparent-low pulsed latches, regular latches, or flip-flops. Most flip-flops are made from back-to-back latches, as will be discussed later on.

#### Blocking Operation

A *blocking* operation results when the input  $D$  to the latch arrives during the *opaque* period of the clock (see Fig. 10.29). The signal is “blocked,” or delayed, by the latch and does not propagate to the output  $Q$  until clock  $CK$  rises and the latch becomes transparent. Notice the dependency between the timing edges, in particular, the *blocking* time from the arrival of  $D$  until the latch opens. The delay between the rising edge of  $CK$  and the rising/falling edge of  $Q$  is commonly called the *Clock-to-Q* delay ( $T_{CKQ}$ ).

#### Nonblocking Operation

A *nonblocking* operation is the opposite to a blocking one and results when the input  $D$  arrives during the *transparent* period of the clock (see Fig. 10.30). The signal propagates through the latch without being delayed by clock. The only delay between  $D$  and  $Q$  is the combinational delay of the latch, or latency, which is denoted as  $T_{DQ}$ .

In general, slow signals should not be blocked by a latch. As soon as they arrive they should transfer to the next stage with the minimum possible delay. This is equivalent to say that the latch must become

FIGURE 10.28 Timing diagram convention.

FIGURE 10.29 A blocking operation.

FIGURE 10.30 A nonblocking operation.

transparent before the slowest signal arrives. Fast signals, on the other hand, can be blocked by a latch since they do not affect the cycle time of the circuit. These two are the basic principles of latch-based designs. A detailed timing of latches will be presented later on.

### The Setup and Hold Time

Besides latency, setup and hold time are the other two parameters that characterize the timing of a latch. Setup and hold can be defined using the blocking and nonblocking concepts just introduced. The time reference for such definition can be either edge of the clock. For convenience, the falling edge is chosen when using a transparent-high latch, while the rising edge is chosen when using a transparent-low latch. This makes the definitions of these parameters independent of the clock period.

#### Setup Time

It is the latest possible arrival of signal  $D$  that guarantees nonblocking operation and optimum  $D$ -to- $Q$  latency through the latch.

#### Hold Time

It is the earliest possible arrival of signal  $D$  that guarantees a safe blocking operation by the latch.

Notice that the previous definitions are quite generic and that a proper criterion should be established in order to measure these parameters in a real circuit. The condition for *optimum latency* in the setup definition is needed because as the transition of  $D$  approaches or exceeds a certain value, while the latch may still be transparent, its latency begins to increase. This can lead to a metastable condition before a complete blockage is achieved. The exact definition of optimum is implementation dependent, and is determined by the latch type, logic style, and the required design margins. In most cases, a minimum or near-minimum latency is a good criterion. Similarly, the definition of *safe blocking operation* is also implementation dependent. If the transition of  $D$  happens too soon, while the latch is neither transparent nor opaque, small glitches may appear at  $Q$ , which may be acceptable or not. It is up to the designer to determine the actual criterion used in the definition.

The timing diagrams depicted in Fig. 10.31 show cases of signal  $D$  meeting and failing setup time, and meeting and failing hold time. The setup and hold region of the latch is indicated by the shaded area.

### The Sampling Time

Although the setup and hold time seem to be independent parameters, in reality they are not. Every signal in a circuit must be valid for a minimum amount of time to allow the next stage to sample it safely. This is true for latches and for any type of sampling circuit. This leads to the following definition.

#### Sampling Time

It is the minimum pulse width required by a latch to sample input  $D$  and pass it safely to output  $Q$ .

The relationship between setup, hold, and sampling time is the following:

$$T_{\text{setup}} + T_{\text{hold}} \geq T_{\text{sampling}} \quad (10.1)$$

FIGURE 10.31 Setup and hold time timing diagrams.

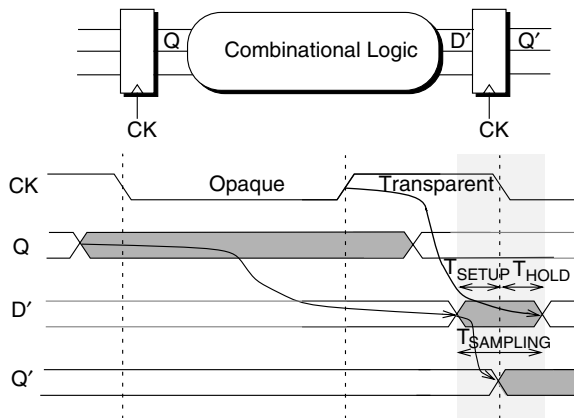

FIGURE 10.32 Relationship between setup, hold, and sampling time.

For a properly designed latch,  $T_{\text{setup}} + T_{\text{hold}} = T_{\text{sampling}}$

In contrast to the setup and hold time, which can be manipulated by the choice of latch design, the sampling time is an independent parameter, which is determined by technology. Setup and hold times may have positive or negative values, and can increase or decrease at the expense of one another, but the sampling time has always a positive value. Figure 10.32 illustrates the relationship between the three parameters in a timing diagram. Notice the lack of a timing dependency between the trailing edge of  $D'$  and  $Q'$ . This is because this transition happens during the opaque phase of the clock. This suggests that the hold time does not define the maximum speed of a circuit. This will be discussed more in detail later on.

## Timing Constraints

Most designers tend to think of latches and flip-flops as memory elements, but few will think of traffic lights as memory elements. However, this is the most appropriate analogy of a latch: the latch being transparent equals to a green light, being opaque to a red light; the setup time is equivalent to the duration of the yellow light, and the latency to the time to cross the intersection. The hold time is harder to visualize, but if the road near the intersection is assumed to be slippery, it may be thought of as the minimum time after the light turns red that allows a moving vehicle to come to a full stop. Slow and fast signals may be thought of as slow and fast moving vehicles, respectively. Now, when electrical signals are stopped, i.e.,

blocked by a latch, their values must be preserved until the latch opens again. The preservation of the signal value, which may be required for a fraction of a clock cycle or several clock cycles, requires a form of storage or memory built into a latch. So in this respect a latch is both a synchronization and a memory element. Memory structures (SRAMs, FIFOs, registers, etc.) built from latches or flip-flops, use them primarily as memory elements. But as far as timing is concerned, the latch is a synchronization element.

**The Latch as a Synchronization Element**

Pipelined designs achieve parallelism by executing operations concurrently at different pipeline stages. Long sequential operations are divided into small steps, each being executed at one stage. The shorter the stage, the higher the clock frequency and the throughput of the system. From a timing perspective, the key to such design approach is to prevent data from different stages from intermixing. This might happen because different computations, depending on complexity and data dependency, produce results at different times. So within a single stage, signals propagate at different speeds. A fast-propagating signal can catch up with a slow-propagating signal from a contiguous stage, resulting in data corruption. This observation leads to the following conclusion: if signals were to propagate all at the same speed (e.g., a FIFO), there would be no race through stages and therefore no need for synchronization elements. Designs based on this principle were actually built and the resulting ‘latch-less’ technique is called *wave-pipelining* [4]. A good analogy for wave-pipelining is the rolling belt of a supermarket: groceries are the propagating signals and sticks are the synchronization elements that separate a set of groceries belonging to one customer from the next; however, since all groceries move at the same speed, as long as sufficient space is left between sets, no sticks are needed.

**Single-Phase, Latch-Based Design**

In viewing latches as synchronization elements, there are two types of timing constraints that define a latch-based design. One deals with the slow-propagating signals and determines the maximum speed at which the system can be clocked. The second deals with fast-propagating signals and determines race conditions through the stages. These timing constraints are the subject of this section. To make the analysis more generic, the clock is assumed to be asymmetric: the high time and the low time are not the same. As will be explained later on in the chapter, timing constrains for all other latching designs are derived from the generic case discussed below.

**Max-Timing Constraints**

The max-timing problem can be formulated in the two following ways:

1. Given the maximum propagation delay within a pipeline state, determine the maximum clock frequency the circuit can be clocked at, or conversely,
2. Given the clock frequency, determine the maximum allowed propagation delay within a stage.

The first formulation is used when the logic partition is predefined, while the second is preferred when the clock frequency target is predefined. The analysis that follows uses the second formulation.

The circuit model used to derive the timing constraints is depicted in Fig. 10.33. It consists of a sending and receiving latch and the combinational logic between them. The logic corresponds to one pipeline stage.

FIGURE 10.33 Single-phase, latch-based design.

FIGURE 10.34 Max-timing diagrams for single-phase, latch-based design.

The model shows explicitly the slowest path, or *max path*, and the fastest path, or *min path*, through the logic. The two paths need not be independent, i.e., they can converge, diverge or intersect, although for simplicity and without losing generality they are assumed to be independent.

As mentioned earlier, the first rule of a latch-based design is that signals propagating through max paths must not be blocked. A timing diagram for this case is shown in Fig. 10.34.  $T_{CYC}$  represents the clock period, while  $T_{ON}$  represents the length of the transparent period. If max path signals  $D_1$  and  $D_1'$  arrive at the latch when it is transparent, the only delay introduced in the critical path is the latch latency ( $T_{DQ}$ ). So, assuming that subsequent pipeline stages are perfectly balanced, i.e., the logic is equally partitioned at every stage, the maximum propagation delay  $T_{max}$  at any given stage is determined by

$$T_{max} < T_{CYC} - T_{DQ} \quad (10.2)$$

So the pipeline overhead of a single-phase latch design is  $T_{DQ}$ .

Using the traffic light analogy, this would be equivalent to a car driving along a long road with synchronized traffic lights, and moving at a constant speed equal to the speed of the green light wave. In such a situation, the car would never have to stop at a red light.

### Min-Timing Constraints

Min-timing constraints, also known as *race-through* constraints, are not related to the cycle time, therefore they do not affect speed performance. Min-timing has to do with correct circuit functionality. This is of particular concern to designers because failure to meet min-timing in most cases means a nonfunctional chip regardless of the clock frequency. The min-timing problem is formulated as outlined below.

Assuming latch parameters are known, determine the minimum propagation delay allowed within a stage.

The timing diagram shown in Fig. 10.35 illustrates the problem. Signal  $D_2$  is blocked by clock, so the transition of  $Q_2$  is determined by the *CK-to-Q* delay of the latch ( $T_{CKQ}$ ). The minimum propagation delay ( $T_{min}$ ) is such that  $D_2'$  arrives when the receiving latch is still transparent and before the setup time. Then,  $D_2'$  propagates through the latch creating a transition at  $Q_2'$  after a *D-to-Q* delay. Although the value of  $Q_2'$  is logically correct, a timing problem is created because two pipeline stages get updated in the same clock cycle (or equivalently, a signal “races through” two stages in one clock cycle). The color convention adopted in the timing diagram helps identifying this type of failure: notice that when the latches are opaque,  $Q_2$  and  $Q_2'$  have the same color, which is not allowed.

To condition to avoid a min-timing problem now becomes apparent. If  $T_{min}$  is long enough such that  $D_2'$  arrives after the receiving latch has become opaque, then  $Q_2'$  will not change until the latch becomes transparent again. This is the second rule of a latch-based design and says that a signal propagating

**FIGURE 10.35** Min-timing diagrams for single-phase, latch-based design showing a min-timing (or race-through) problem.

**FIGURE 10.36** Min-timing diagrams for single-phase, latch-based design showing correct operation.

through a min-path must be blocked. A timing diagram for this case is illustrated in Fig. 10.36 and is formulated as

$$T_{CKQ} + T_{min} > T_{ON} + T_{hold} \quad (10.3)$$

or equivalently

$$T_{min} > T_{hold} - T_{CKQ} + T_{ON} \quad (10.4)$$

Using the traffic light analogy again, a fast moving vehicle stopping at every red light on the average moves at the same speed as the slow moving vehicle.

Having defined max and min timing constrains, the valid timing window for a latch-based design is obtained by combining Eqs. (10.2) and (10.4). If  $T_D$  is the propagation delay of a signal, the valid timing window for such signal is given by

$$T_{ON} + T_{hold} - T_{CKQ} < T_D < T_{CYC} - T_{DQ} \quad (10.5)$$

Equation (10.5) must be used by a timing analyzer to verify that all signals in a circuit meet timing requirements. Notice that this condition imposes a strict requirement on min paths. If  $T_{ON}$  is half clock cycle (i.e., 50% duty cycle clock), then the minimum delay per stage must be approximately equal to that value, depending on the value of  $(T_{hold} - T_{CKQ})$ . In practice, this is done by padding the short paths of the circuit with buffers that act as delay elements. Clearly, this increases not only area and power, but

FIGURE 10.37 Time borrowing for single-phase, latch-based design.

also design complexity and verification effort. Because of these reasons, single latch-based designs are rarely used in practice.

Notice that the latch setup time is not part of Eq. (10.5). Consequently, it can be concluded that the setup time does not affect the timing of a latch-based design (although the latency of the latch does). This is true except when *time borrowing* is applied. This is the subject of the next subsection.

### Time Borrowing

Time borrowing is the most important aspect of a latch-based design. So far it has been said that in a latch-based design critical signals should not be blocked, and that the max-timing constraint is given by Eq. (10.2); however, depending on the latch placement, the nonblocking requirement can still be satisfied even if Eq. (10.2) is not. Figure 10.37 illustrates such a case. With reference to the model in Fig. 10.33, input  $D_1$  is assumed to be blocked. So the transition of  $Q_1$  happens a  $CK$ -to- $Q$  delay after clock ( $T_{CKQ}$ ) and starts propagating through the max path. As long as  $D'_1$  arrives to the receiving latch before the setup time, the  $D$ -to- $Q$  transition is guaranteed to be nonblocking. In this way, the propagation of  $D'_1$  is allowed to “borrow” time into the next clock cycle without causing a timing failure.

The maximum time that can be borrowed is determined by the setup time of the receiving latch. The timing requirement for such condition is formulated as follows:

$$T_{CKQ} + T_{max} < T_{CYC} + T_{ON} - T_{setup} \quad (10.6)$$

and rearranged as:

$$T_{max} < T_{CYC} + T_{ON} - (T_{setup} + T_{CKQ}) \quad (10.7)$$

By subtracting Eq. (10.2) from Eq. (10.7), the maximum amount of time borrowing,  $T_{borrow}$  can be derived and it is given by

$$T_{borrow} = T_{ON} - (T_{setup} + T_{CKQ}) + T_{DQ} \quad (10.8)$$

Assuming that  $T_{CKQ} \approx T_{DQ}$ , Eq. (10.8) reduces to

$$T_{borrow} = T_{ON} - T_{setup} \quad (10.9)$$

So the maximum time that can be borrowed from the next clock cycle is approximately equal to the length of the transparent period minus the latch setup time.

Because time borrowing allows signal propagation across a clock cycle boundary, timing constraints are no longer limited to a single pipeline stage. Using the timing diagram of Fig. 10.37 as a reference,

and assuming that  $T'_{\max}$  is the maximum propagation delay from  $Q'_1$ , the following timing constraint, besides Eq. (10.7), must be met across two adjacent stages:

$$T_{\max} + T'_{\max} < 2T_{\text{CYC}} + T_{\text{ON}} - T_{\text{setup}} + T_{\text{CKQ}} - T_{\text{DQ}} \quad (10.10)$$

which again if  $T_{\text{CKQ}} \approx T_{\text{DQ}}$ , reduces to

$$T_{\max} + T'_{\max} < 2(T_{\text{CYC}} - T_{\text{DQ}}) + T_{\text{ON}} - T_{\text{setup}} \quad (10.11)$$

For  $n$  stages, Eq. (10.11) can be generalized as follows:

$$\sum_n T_{\max} < n(T_{\text{CYC}} - T_{\text{DQ}}) + T_{\text{ON}} - T_{\text{setup}} \quad (10.12)$$

where  $\sum_n T_{\max}$  is the sum of the maximum propagation delays across  $n$  stages.

Equation (10.12) seems to suggest that the maximum allowed time borrowing across  $n$  stages is limited to  $T_{\text{ON}} - T_{\text{setup}}$  (see Eq. (10.9)); however, this is not the case. If the *average*  $T_{\max}$  across two or more stages is such that Eq. (10.2) is satisfied, then maximum time borrowing can happen more than once.

Although time borrowing is conceptually simple and gives designers more relaxed max-timing constraints, and thus more design flexibility, in practice timing verification across clock cycle boundaries is not trivial. Few commercial timing tools have such capabilities, forcing designers to develop their own in order to analyze such designs. A common practice is to disallow time borrowing as a general rule and only to allow it in exceptional cases, which are then verified individually by careful timing analysis.

The same principle that allows time borrowing gives transparent latches another very important property when dealing with clock skew. This is the topic of the next subsection.

## The Clock Skew

Clock skew refers to the misalignment of clock edges at the end of a clock distribution network due to manufacturing process variations, load mismatch, PLL jitter, variations in temperature and voltage, and induced noise. The *sign* of the clock skew is relative to direction of the data flow, as illustrated in Fig. 10.38. For instance, if the skew between the clocks is such that CK arrives after CK', data moving from left to right see the clock arriving *early* at the destination latch. Conversely, data moving in the opposite direction see the clock arriving *late* at the destination latch. The remainder of this chapter section assumes that the data flow is not restricted to a particular direction. Thus, the worst-case scenario of clock skew is assumed for each case: early skew for max-timing, and late skew for min-timing. How clock skew affects the timing of a single-phase latch design is discussed next.

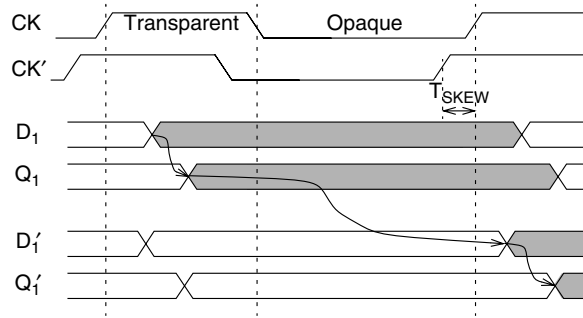

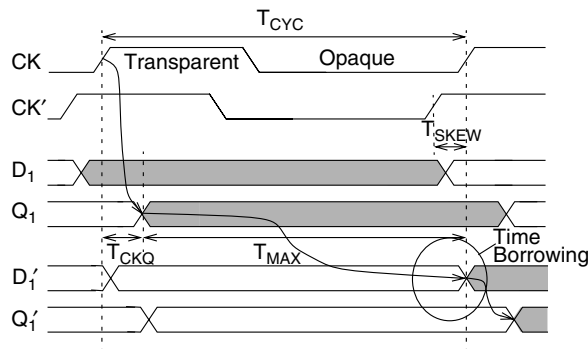

FIGURE 10.38 Clock skew.

**FIGURE 10.39** Max-timing for single-phase, latch-based design under the presence of *early* clock skew.  $D_1$  transition is not blocking.

**FIGURE 10.40** Max-timing for single-phase, latch-based design under the presence of *early* clock skew.  $D_1$  transition is blocking.

### Max-timing

The max-timing of a single-phase latch-based design is, to a large extent, immune to clock skew. This is because signals in a max-path are not blocked. The timing diagram of Fig. 10.39 illustrates this case. Using Fig. 10.33 as a reference, the skew between clocks CK and CK' is  $T_{skew}$ , with CK' arriving earlier than CK. The transition of signals  $D_1$  and  $D_1'$ , assumed to be critical, occur when latches are transparent or nonblocking. As observed, the receiving latch becoming transparent earlier than expected has no effect on the propagation delay of  $Q_1$ , as long as the setup time requirement of the receiving latch is satisfied. Therefore, Eq. (10.2) still remains valid.

Other scenarios where clock skew might affect max-timing can be imagined. However, none of these invalidates the conclusion arrived at in the previous paragraph. One of such scenarios is illustrated in the timing diagram of Fig. 10.40. In contrast to the previous example, here the input to the sending latch ( $D_1$ ) is blocked. If the maximum propagation delay is such that  $T_{CKQ} + T_{max} = T_{CYC}$ , the earlier arrival of CK' results in *unintentional* time borrowing. Although this reduces the maximum available of *intentional* time borrowing from the next cycle (as defined earlier), from a timing perspective, no violation has occurred. Another scenario is illustrated in Fig. 10.41. Similar to the previous example,  $D_1$  is blocked and  $T_{CKQ} + T_{max} = T_{CYC}$ , but in this case the arrival of the receiving clock CK' is late. The result is that signal  $D_1'$  gets blocked for the period of length equal to  $T_{skew}$ . Depending on whether the next stage receives a late clock or not, this blocking has either no effect on timing or leads to time borrowing in the next clock cycle.

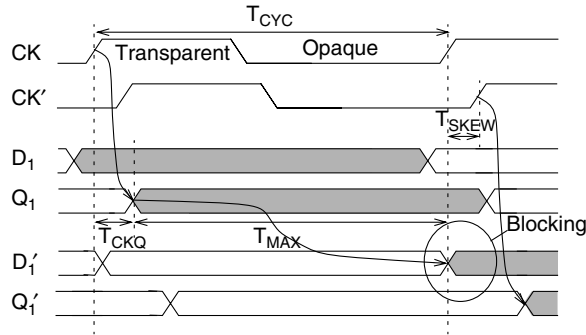

FIGURE 10.41 Max-timing for single-phase, latch-based design under the presence of *late* clock skew.  $D_1$  transition is blocked.

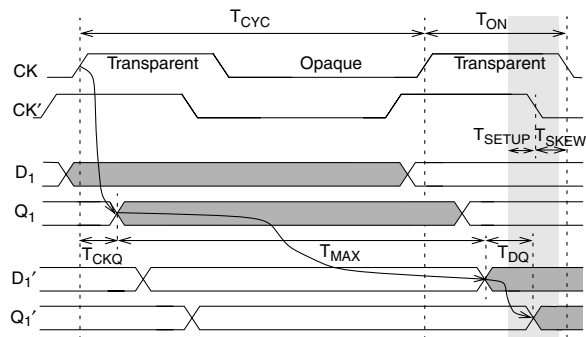

FIGURE 10.42 Time borrowing for single-phase, latch-based design under the presence of *early* clock skew.

### Time Borrowing

The preceding max-timing discussion has indicated that the presence of clock skew may result in unintentional time borrowing. The timing diagram shown Fig. 10.42 illustrates how this could happen. Using Fig. 10.33 as a reference, the input to the sending latch ( $D_1$ ) is assumed blocked. After propagating through the max path, the input to the receiving latch ( $D_1'$ ) must arrive before its setup time to meet the max-timing requirement. The early arrival of clock  $CK'$  may be interpreted as if the setup time boundary *moves* forward by  $T_{skew}$ , thus reducing the available borrowing time by an equivalent amount.

The condition for maximum time borrowing in this case is formulated as follows:

$$T_{CKQ} + T_{max} < T_{CYC} + T_{ON} - (T_{setup} + T_{skew}) \quad (10.13)$$

Again assuming that  $T_{CKQ} \approx T_{DQ}$ , in the same manner as Eq. (10.9) was derived, it can be shown that maximum time borrowing in this case is given by

$$T_{borrow} = T_{ON} - (T_{setup} + T_{skew}) \quad (10.14)$$

By comparing Eq. (10.14) against Eq. (10.9) (zero clock skew), it is concluded that the presence of clock skew reduces the amount of time borrowing by  $T_{skew}$ .

### Min-Timing

In contrast to max-timing, min-timing is not immune to clock skew. Figure 10.43 provides a timing diagram illustrating this case. With reference to Fig. 10.33, clock CK' is assumed to arrive late. In order to insure that  $D'_2$  gets blocked, it is required that:

$$T_{CKQ} + T_{min} > T_{ON} + T_{skew} + T_{hold} \quad (10.15)$$

After rearranging terms, the min-timing requirement is expressed as

$$T_{min} > T_{hold} - T_{CKQ} + T_{ON} + T_{skew} \quad (10.16)$$

Equation (10.16) shows that in addition to  $T_{ON}$ ,  $T_{skew}$  is added now. The clock skew presence makes the min-timing requirement even more strict than before, yielding a single-phase latch design nearly useless in practice.

### Nonoverlapping Dual-Phase, Latch-Based Design

As pointed out in the preceding subsection, the major drawback of a single-phase, latch-based design is in its rigorous min-timing requirement. The presence of clock skew makes matters worse. Unless the transparent period can be made very short, i.e., a narrow pulse, a single-phase, latch-based design is not very practical. The harsh min-timing requirement of a single-phase design is due to the sending and receiving latch being both transparent simultaneously, allowing fast signals to race through one or more pipeline stages. A way to eliminate this problem is to intercept the fast signal with a latch operating on a complementary clock phase. The resulting scheme, referred to as a dual-phase, latch-based design, is shown in Fig. 10.44. Because the middle latch operates on a complementary clock, at no point in time

FIGURE 10.43 Min-timing diagrams for single-phase, latch-based design under the presence of late clock skew.

FIGURE 10.44 Nonoverlapping dual-phase, latch-based design.

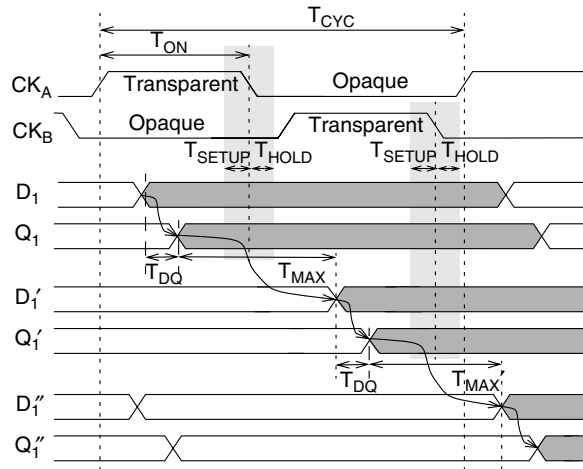

FIGURE 10.45 Max-timing diagrams for nonoverlapping dual-phase, latch-based design.

a transparent period is created between adjacent pipeline stages, eliminating the possibility of races. Notice that the insertion of a complementary latch, while driven by the need to slow fast signals, ends up slowing down max paths also. Although, in principle, a dual-phase design is race free, clock skew may still cause min-timing problems. The clock phases may be nonoverlapping or fully complementary. The timing requirement of a nonoverlapping dual-phase, latch-based design is discussed below. A dual-phase complementary design is treated later on as a special case.

### Max-timing

Because a signal in a max path has to go through two latches in a dual-phase latch-based design the  $D$ -to- $Q$  latency of the latch is paid twice in the cycle. This is shown in the timing diagram of Fig. 10.45. The max-timing constraint in a dual-phase design is therefore given by

$$T_{\max} < T_{\text{CYC}} - 2T_{DQ} \quad (10.17)$$

The above equation remains still valid under the presence of clock skew. By comparing it against Eq. (10.2), it is evident that as a result of the middle latch insertion the pipeline overhead ( $2T_{DQ}$ ) becomes twice as large as in the single-latch design.

### Time Borrowing

Time borrowing does not get affected either by the insertion of the complementary latch. Maximum time borrowing is still given by Eq. (10.9), or by Eq. (10.14) in the presence of clock skew.

### Min-timing

Min-timing is the most affected by the introduction of the complementary latch. As pointed out earlier, the complementary latch insertion is a solution to relax the min-timing requirement of a latch-based design. Figure 10.46 provides a timing diagram illustrating how a dual-latch design prevents races. Clock  $CK_A$  and  $CK_B$  are nonoverlapping clock phases, with  $T_{\text{NOV}}$  being the nonoverlapping time. With reference to Fig. 10.44, the input  $D_2$  to the sending latch is assumed to be blocked. After a  $CK$ -to- $Q$  and a  $T_{\text{min}}$  delay, signal  $D_2'$  arrives at the middle latch while it is still opaque. Therefore,  $D_2'$  gets blocked until  $CK_B$  transitions and the latch becomes transparent. A  $CK$ -to- $Q$  delay later, signal  $Q_2'$  transitions. If the nonoverlapping time is long enough, the  $Q_2'$  transition satisfies the hold time of the sending latch. The same phenomenon happens in the second half of the stage.

FIGURE 10.46 Min-timing diagrams for nonoverlapping dual-phase, latch-based design.

FIGURE 10.47 Min-timing diagrams for nonoverlapping dual-phase, latch-based design under the presence of late clock skew.

The presence of clock skew in this design makes min-timing worse also, as expected. The effect of late clock skew is to increase the effective hold time of the sending latch. This is illustrated in Fig. 10.47, where clock  $CK'_B$  is late with respect to  $CK_A$ .

The min-timing condition is given by

$$T_{NOV} + T_{CKQ} + T_{min} > T_{skew} + T_{hold} \quad (10.18)$$

which can be rearranged as

$$T_{min} > T_{hold} - T_{CKQ} + T_{skew} - T_{NOV} \quad (10.19)$$

Comparing with Eq. 10.16, notice that the transparent period ( $T_{ON}$ ) is missing from the right-hand side of Eq. (10.19), reducing the requirement on  $T_{min}$ , and that the nonoverlap time ( $T_{NOV}$ ) gets subtracted from the clock skew ( $T_{skew}$ ). The latter gives designers a choice to trade-off between  $T_{ON}$  and  $T_{NOV}$  by increasing  $T_{NOV}$  at the expense of  $T_{ON}$  (so the clock cycle remains constant), min-timing problems can be minimized at the cost of reducing time borrowing. For a sufficiently long  $T_{NOV}$ , the right hand side of Eq. 10.19 becomes negative. Under such assumption, this type of design may be considered *race free*. Furthermore, by making the nonoverlap time a function of the clock frequency, a manufactured chip is

FIGURE 10.48 Complementary dual-phase, latch-based design.

guaranteed to work correctly at some lower than nominal frequency, even in the event that unexpected min-timing violations are discovered on silicon. This is the most important characteristic of this type of latching design, and the main reason why such designs were so popular before automated timing verification became more sophisticated.

Although min-timing constraints are greatly reduced in a two-phase, nonoverlapping latch-based design, designers should be aware that the introduction of an additional latch per stage results in twice as many potential min-timing races that need to be checked in contrast to a single latch design. This becomes a more relevant issue in a two-phase, complementary latch-based design, as discussed next.

### Complementary Dual-Phase, Latch-Based Design

A two-phase, complementary latch-based design (Fig. 10.48) is a special case of the generic nonoverlapping design, where clock  $CK_A$  is a 50% duty cycle clock, and clock  $CK_B$  is complementary to  $CK_A$ . In such a design, the nonoverlapping time between the clock phases is zero. The main advantage of this approach is the simplicity of the clock generation and distribution. In most practical designs, only one clock phase needs to be globally distributed to all sub-units, generating the complementary clock phase locally.

#### Max-timing

Similar to a nonoverlapping design, the maximum propagation delay is given by Eq. (10.17), and it is unaffected by the clock skew. The pipeline overhead is  $2T_{DQ}$ .

#### Time Borrowing

Time borrowing is similar to a single-phase latch, except that  $T_{ON}$  is half clock cycle. Therefore, maximum time borrowing is given by

$$T_{\text{borrow}} = T_{\text{CYC}}/2 - (T_{\text{setup}} + T_{\text{skew}}) \quad (10.20)$$

So complementary clocks maximizes time borrowing.

#### Min-timing

The min-timing requirement is similar to the nonoverlapping scheme, except that  $T_{\text{NOV}}$  is zero. Therefore,

$$T_{\text{min}} > T_{\text{hold}} - T_{\text{CKQ}} + T_{\text{skew}} \quad (10.21)$$

The simplification of the clocking scheme comes at a price though. Although Eq. (10.21) is less stringent than Eq. (10.16) (no  $T_{\text{ON}}$  in it), it is not as good as Eq. (10.19). Furthermore, a min-timing failure in such a design cannot be fixed by slowing down the clock frequency, making silicon debugging in such a situation more challenging. This is a clear example of a design trade-off that designers must face when picking a latching and clocking scheme.

The next section discusses how a latch-based design using complementary clock phases can be further transformed into an edge-triggered-based design.

### Edge-Triggered, Flip-Flop-Based Design

The major drawback of a single-phase latch based design is min-timing. The introduction of dual-phase-latch-based designs greatly reduces the risk of min-timing failure; however, from a physical implementation perspective, the insertion of a latch in the middle of a pipeline stage is not free of cost. Each

FIGURE 10.49 Edge-triggered, flip-flop-based design.

FIGURE 10.50 Max-timing diagrams for edge-triggered, flip-flop-based design.

pipeline stage has to be further partitioned in half, although time borrowing helps in this respect. Clock distribution and clock skew minimization becomes more challenging because clocks need to be distributed to twice as many locations. Also, timing verification in a latch-based design is not trivial. First, latches must be properly placed to allow maximum time borrowing and maximum clock skew hiding. Second, time borrowing requires multi-cycle timing analysis and many timing analyzers lack this capability. A solution that overcomes many of these shortcomings is to use flip-flops. This is discussed in the rest of this subsection.

Most edge-triggered flip-flops, also known as *master-slave* flip-flops, are built from transparent latches. Figure 10.49 shows how this is done. By collapsing the transparent-high and transparent-low latches in one unit, and rearranging the combinatorial logic so that it is all contained in one pipeline segment, the two-phase, latch-based design is converted into a positive-edge, flip-flop-based design. If the collapsing order of the latches were reverted, the result would be a negative-edge flip-flop. In a way, a flip-flop-based design can be viewed as an unbalanced dual-phase, latch-based design where all the logic is confined to one single stage. The timing analysis of flip-flops, therefore, follows the same steps as applied to latches.

### Max-timing

The max-timing diagram for flip-flops is shown in Fig. (10.50). Two distinctive characteristics are observed in this diagram: (1) the transparent-high latches ( $L_2$  and  $L_4$ ) are blocking, and (2) the transparent-low latches ( $L_1$  and  $L_3$ ) provide maximum time borrowing. The opposite is true for negative-edge flip-flops. The first condition results from the fact that the complementary latches are never transparent simultaneously, so a transparent operation in the first latch leads to a blockage in the second. The second condition is necessary to maximize the time allowed for logic in the stage. Because  $L_2$  is blocking, unless time borrowing happens in  $L_3$ , only half a cycle would be available for logic.

The max-timing constraint is formulated as a maximum time borrowing constraint (see Eq. (10.13) for comparison), but confining it to one clock cycle because the sending latch ( $L_2$ ) is blocking. With reference to Fig. 10.50, the constraint is formulated as follows:

$$T_{\text{CKQ}} + T_{\text{max}} < T_{\text{CYC}} - (T_{\text{setup}} + T_{\text{skew}}) \quad (10.22)$$

which after rearranging terms gives

$$T_{\text{max}} < T_{\text{CYC}} - (T_{\text{CKQ}} + T_{\text{setup}} + T_{\text{skew}}) \quad (10.23)$$

To determine the pipeline overhead introduced by flip-flops and compare it against a dual latch based design, Eq. (10.23) is compared against Eq. (10.17). To make the comparison more direct, observe that  $T_{\text{setup}} + T_{\text{CKQ}} < 2T_{DQ}$ . This is because as long as signal  $D_1''$  meets the setup time of latch  $L_3$ ,  $Q_1''$  is allowed to *push* into the transparent period of  $L_4$ , adding one latch delay ( $T_{DQ}$ ), and then go through  $L_4$ , adding a second latch delay. Therefore, Eq. (10.23) can be rewritten as

$$T_{\text{max}} < T_{\text{CYC}} - (2T_{DQ} + T_{\text{skew}}) \quad (10.24)$$

By looking at Eq. (10.17), it becomes clear that the pipeline overhead is larger in flip-flops than in latches, and it is equal to  $2T_{DQ} + T_{\text{skew}}$ . In addition to the latch delays, the clock skew is now also subtracted from the cycle time, this being a major drawback of flip-flops. It should be noticed, however, that faster flip-flops with less than two latch delays can be designed.

### Min-timing

The min-timing requirement is essentially equal to a dual latch-based design and it is given by Eq. (10.21). An important observation is that inside the flip-flop this condition may be satisfied *by construction*. Since the clock skew is zero, it is only required that  $T_{\text{min}} > T_{\text{hold}} - T_{\text{CKQ}}$ . If the latch parameters are such that  $T_{\text{CKQ}} > T_{\text{hold}}$  then this condition is always satisfied since  $T_{\text{min}} \geq 0$ . Timing analyzers still need to verify that min-timing requirements between flip-flops are satisfied according to Eq. (10.21), although the number of potential races is reduced to half in comparison to the dual latch scheme.

Timing verification is easier in flip-flop-based designs because most timing paths are confined to a single cycle boundary. Knowing with precision the departing time of signals may also be advantageous to some design styles, or may reduce iterations in the design cycle, resulting eventually in a simpler design (In an industrial environment, where design robustness is paramount, in contrast to the academia, nearly 90% of the design cycle is spent on verification, including logic and physical verification, timing verification, signal integrity, etc.)

As discussed earlier, time borrowing in a flip-flop-based design is confined to the boundary of a clock cycle. Therefore, time borrowing from adjacent pipeline stages is not possible. In this respect, when choosing flip-flops instead of latches, designers have a more challenging task at partitioning the logic to fit in the cycle—a disadvantage. An alternative solution to time borrowing is *clock stretching*. The technique consists of the adjustment of clock edges (e.g., by using programmable clock buffers) to allocate more timing in one stage at the expense of the other. It can be applied in cases when logic partitioning becomes too difficult, assuming that timing slack in adjacent stages is available. When applied correctly, e.g., guaranteeing that no min-timing violation get created as by-product, clock stretching can be very useful.

### Pulsed Latches

Pulsed latches are conceptually identical to transparent latches, except that the length of the transparent period is designed to be very short (i.e., a *pulse*), usually a few gate delays. The usage of pulsed latches is different from conventional transparent latches though. Most important of all, the short transparency makes single pulsed latch-based design practical, see Fig. 10.51, contributing to the reduction of the pipeline overhead yet retaining the good properties of latches. Each timing aspect of pulsed latch-based design is discussed below.

FIGURE 10.51 Pulsed latch-based design.

FIGURE 10.52 Pulsed latch-based design combining single- and dual-pulsed latches.

### Max-timing

Pulsed latches are meant to be used as one per pipeline stage, as mentioned earlier, so the pipeline overhead is limited to only one latch delay (see Eq. (10.2)). This is half the overhead of a dual-phase, latch-based design. Furthermore, logic partitioning is similar to a flip-flop-based design, simplifying clock distribution.

### Time Borrowing

Although still possible, the amount of time borrowing is greatly reduced when using pulsed latches. From Eq. (10.14),  $T_{\text{borrow}} = T_{\text{ON}} - (T_{\text{setup}} + T_{\text{skew}})$ . If  $T_{\text{ON}}$  is chosen such that  $T_{\text{ON}} = T_{\text{setup}} + T_{\text{skew}}$ , then time borrowing is reduced to zero; however, the clock skew can still be hidden by the latch, i.e., it is not subtracted from the clock cycle for max-timing.

### Min-timing

This is the biggest challenge designers face when using pulsed latches. As shown by Eq. (10.16), the minimum propagation delay in a latch-based system is given by  $T_{\text{min}} > T_{\text{hold}} - T_{\text{CKQ}} + T_{\text{ON}} + T_{\text{skew}}$ . Ideally, to minimize min-timing problems,  $T_{\text{ON}}$  should be as small as possible. However, if it becomes too small, the borrowing time may become negative (see above), meaning that some of the clock skew gets subtracted from the cycle time for max-timing. Again, this represents another trade-off that designer must face when selecting a latching strategy. In general, it is good practice to minimize min-timing at the expense of max-timing. Although max-timing failures affect the speed distribution of functional parts, min-timing failures are in most cases fatal.

From a timing analyzer perspective, pulsed latches can be treated as flip-flops. For instance, by redefining  $T'_{\text{hold}} = T_{\text{hold}} + T_{\text{ON}}$ , min-timing constraints look identical in both cases (see Eqs. (10.16) and (10.21)). Also, time borrowing in practice is rather limited with pulsed latches, so the same timing tools and methodology used for analyzing flip-flop based designs can be applied.

Last but not least, it is important to mention that designs need not to adhere to one latch or clocking style only. For instance, latches and flip-flops can be intermixed in the same design. Or single and dual-phase latches can be combined also, as depicted in Fig. 10.52. Here, pulsed latches are utilized in max paths in order to minimize the pipeline overhead, while dual-phase latches are used in min paths to eliminate, or minimize, min-timing problems. In this example, the combination of transparent-high and transparent-low pulsed latches works as a dual-phase nonoverlapping design. Clearly, such combinations require a good understanding of the timing constraints of latches and flip-flops not only by designers but also by the adopted timing tools, to ensure that timing verification of the design is done correctly.

## Summary of Latch and Flip-Flop-Based Designs

Table 10.6 summarizes the timing requirements of the various latch and flip-flop-based designs discussed in the preceding sections. In terms of pipeline overhead, the single latch and the pulsed latch appear to be the best. However, because of its prohibitive min-timing requirement, a single-phase design is of little practical use. Flip-flops appear the worst, primarily because of the clock skew. Although, as mentioned earlier, a flip-flop can be designed to have latency less than two equivalent latches. In terms of time borrowing, all latch-based designs allow some degree of it, in contrast to flip-flop based designs. From a min-timing perspective, nonoverlapping dual-phase is the best, although clock generation is the more complex. It is followed by the dual-phase complementary design, which uses a simpler clocking scheme, and by the flip-flop design with an even simpler single-phase clocking scheme. The min-timing requirement of the both designs is the same, so the number of potential races in the dual-phase design is twice as large as in the flip-flop design.

## Design of Latches and Flip-Flops

This sub-section covers the fundamentals of latch and flip-flop design. It starts with the most basic transparent latch: the pass gate. Then, it introduces more elaborated latches and flip-flops made from latches, and discusses their features. Next, it presents a sample of advanced designs currently used in the industry. At the end of the sub-section, a performance analysis of the different circuits described is presented.

Because many designers tend to use the same terminology to refer to different circuit styles or properties, to avoid confusion, this sub-section adheres to the following nomenclature. The term *dynamic* refers to circuits with *floating* nodes only. By definition, a floating node does not see a DC path to either  $V_{\text{DD}}$  or GND during a portion of the clock cycle, and it is, therefore, susceptible to discharge by leakage current, or to noise. The term *precharge logic* is used to describe circuits that operate in precharge and evaluation phase, such as Domino logic [5]. The term *skewed logic* refers to a logic style where only the propagation of one edge is relevant, such as Domino [5, 6], Self-Reset [7], or Skewed Static logic [8]. Such logic families are typically monotonic.

### Design of Transparent Latches

This sub-section explains the fundamentals of latch design. It covers pass and transmission gate latches, tristate latches, and true-single-phase-clock latches. A brief discussion of feedback circuits is also given.

#### Transmission-Gate Latches

A variety of transparent-high latches built from pass gates and transmission gates is shown in Fig. 10.53. Transparent-low equivalents, not shown, are created by inverting the clock. The most basic latch of all is the pass gate (Fig. 10.53(a)). Although it is the simplest, it has several limitations. First, being an NMOS transistor, it degrades the passage of a high signal by a threshold voltage drop, affecting not only speed but also noise immunity, especially at low  $V_{\text{DD}}$ . Second, it has dynamic storage: output Q is floating when CK is low, being susceptible to leakage and output noise. Third, it has limited fanout, especially if input D is driven through a long interconnect, or if Q drives a long interconnect. Last, it is susceptible to input

FIGURE 10.53 Transparent-high latches built from pass gates and transmission gates.

FIGURE 10.54 Feedback structures for latches.

noise: a noise spike can turn momentarily the gate on, or can inject charge in the substrate by turning the parasitic diode on, leading to a charge loss. To make this design more robust, each of the variants in Fig. 10.53 (b-f) attempts to overcome at least one of the limitations just described. Figure 10.53(b) uses a transmission gate to avoid the threshold voltage drop, at the expense of generating a complementary clock signal [12,13]. Figure 10.53(c) buffers the output to protect the storage node and to improve the output drive. Figure 10.53(d) uses a back-to-back inverter to prevent the storage node from floating. Avoiding node Q in the feedback loop, as shown, improves robustness by completely isolating the output from the storage node, at the expense of a small additional inverter. Figure 10.53(e) buffers the input in order to: (1) improve noise immunity, (2) ensure the writability of the latch, and (3) bound the *D-to-Q* delay (which depends on the size of input driver). Conditions 2 and 3 are important if the latch is to be instantiated in unpredictable contexts, e.g., as a library element. Condition 2 becomes irrelevant if a clocked feedback is used instead. It should be noted that the additional input inverter results in increased *D-to-Q* delay; however, it need not be an inverter, and logic functionality may be provided instead with the latch. Figure 10.53(f) shows such an instance, where a NAND2 gate is merged with the latch. A transmission gate latch, where both input and output buffers can be logic gates, is reported in [11].

### Feedback Circuits

A feedback circuit in latches can be built in more than one way. The most straightforward way is the back inverter, adopted in Fig. 10.53(d-f), and shown in detail in Fig. 10.54(a). Clock CKB is the complementary of clock CK. The back inverter is sized to be *weak*, in general by using minimum size transistors, or increasing channel length. It must allow the input driver to overwrite the storage node, yet it must provide enough charge to prevent it from floating when the latch is opaque. Although simple and compact layout-wise, this type of feedback requires designers to check carefully writability, especially in skewed process corners (e.g., fast PMOS, slow NMOS) and under different temperature and voltage conditions. A more robust approach is shown in Fig. 10.54(b). The feedback loop is open when the storage node is driven, eliminating all contention. It requires additional devices, although not necessarily more area since the input driver may be downsized. A third approach is shown in Fig. 10.54(c) [12]. It uses a back inverter but connecting the rails to the clock signals CK and CKB. When the latch is opaque, CK is low and CKB

FIGURE 10.55 Transparent latches built from tristate gates.

FIGURE 10.56 Complementary TSPC transparent-high and transparent-low latches.

is high, so it operates as a regular back inverter. When the storage node is being driven, the clock polarity is reverted, resulting in a *weakened* back inverter. For simplicity, the rest of circuits discussed in this section assumes a back inverter.

### Tristate Gate

Transparent-high latches built from tristate gates are shown in Fig. 10.55. The dynamic variant is shown in Fig. 10.55(a). By driving a FET gate as opposed to source/drain, this latch is more robust to input noise than the plain transmission gate of Fig. 10.55(b). The staticized variant with the output buffer is shown in Fig. 10.55(b). Similar to the transmission-gate case, transparent-low latches are created by inverting the clock.

### True Single-Phase Clock (TSPC) Latches

Transmission gate and tristate gate latches are externally supplied with a single clock phase, but in reality they use *two clock* phases, the second being the internally generated clock CKB. The generation of this complementary clock becomes critical when building flip-flops with these type of latches. For instance, unexpectedly large delay in CKB might lead to min-timing problem inside the flip-flop, as explained later on in the sub-section on “Design of Flip-Flops.” To eliminate the need for a complementary clock, true single phase clock (TSPC) latches were invented [13, 14]. The basic idea behind TSPC is the complementary property of CMOS devices in combination with the inverting nature of CMOS gates.

A complementary transparent-high TSPC latch is shown in Fig. 10.56(a). The latch operates as follows. When CK is high (latch is transparent), the circuit acts as a two-stage buffer, so output Q

**FIGURE 10.57** Complementary TSPC transparent-high latch with direct feedback from storage node Q.

**FIGURE 10.58** Precharged TSPC transparent-high and transparent-low blocking latches.

follows input  $D$ . When  $CK$  is low (latch is opaque), devices  $N_1$  and  $N_2$  are turned off. Since node  $X$  can only transition monotonically high, (1)  $P_1$  is either on or off when  $Q$  is high, or (2)  $P_1$  is off when  $Q$  is low. In addition to node  $Q$  being floating if  $P_1$  is off, also node  $X$  is floating if  $D$  is high. So the latch has two dynamic nodes that need to be staticized with back-to-back inverters for robustness. This is shown in Fig. 10.56(b), where the output is buffered also.

Contrary to the latches described in the previous sub-sections, a transparent-low TSPC latch cannot be generated by just inverting the clock. Instead, the complementary circuit shown in Fig. 10.56 (c and d) is used (Fig. 10.56(c) is dynamic, Fig. 10.56(d) is static). The operation of the latch is analogous to the transparent-high case. A dual-phase complementary latch based design using TSPC was reported in [15].

As Fig. 10.56 shows, the conversion of TSPC latches into static ones takes several devices. A way to save at least one feedback device is shown in Fig. 10.57. If  $D$  is low and  $Q$  is high when the latch is opaque, this feedback structure results in no contention. The drawback is that node  $X$  follows input  $D$  when  $CK$  is low, resulting in additional toggling and increased power dissipation.

Another way to build TSPC latches is shown in Fig. 10.58. The number of devices remains the same as in the previous case but the latch operates in a different mode. With reference to Fig. 10.58(a), node  $X$  is precharged high when  $CK$  is low (opaque period), while  $Q$  retains its previous value. When  $CK$  goes high (latch becomes transparent), node  $X$  remains either high or discharges to ground, depending on the value of  $D$ , driving output  $Q$  to a new value. The buffered version of this latch, with staticizing back-to-back inverters, is shown in Fig. 10.58(b).

Because of its precharge nature, this version of the TSPC latch is faster than the static one. The clock load is higher also (3 vs. 2 devices), contributing to higher power dissipation, although the input loading is lower (1 vs. 2 devices).  $X$  switches only monotonically during the transparent phase, so the input to the latch must either: (1) be monotonic, or (2) change during the opaque phase only (i.e., a blocking latch).

**FIGURE 10.60** A positive, edge-triggered flip-flop built from transmission gate latches.

One of the advantages of the precharged TSPC latch is that, similar to Domino, relatively complex logic can be incorporated in the precharge stage. An example of a latch with an embedded NOR2 is given in Fig. 10.59.

Although this latch cannot be used generically because of its special input requirement, it is the base of a TSPC flip-flop (discussed next) and of pulsed flip-flops described later on in this chapter section.

## Design of Flip-Flops

This sub-section explains the fundamentals of flip-flop design. It covers three types of flip-flops based on the transmission gate, tristate, and TSPC latches presented earlier. The sense-amplifier based flip-flop, with no latch equivalence, is also discussed. Design trade-offs are briefly mentioned.

### Master-Slave Flip-Flop

The master-slave flip-flop, shown in Fig. 10.60, is perhaps the most commonly used flip-flop type [6]. It is made from a transparent-high and a transparent-low transmission gate latch. Its mode of operation is quite simple: the master section writes into the first latch when CK is low, and the value is passed onto the slave section and propagated to the output when CK is high. As pointed out earlier, a flip-flop made this way has to satisfy the internal min-timing requirement. Specifically, the delay from CK to X has to be greater than the hold time of the second latch. Notice that the second latch turns completely opaque only after CKB goes low. The inverter delay between CK and CKB creates a short period of time where both latches are transparent. Therefore, designers must pay careful attention to the timing of signals X and CKB to make sure the design is race free. Setting the min-timing requirement aside, the master-slave flip-flop is simple and robust; however, for applications requiring very high performance, its long *D-to-Q* latency might be unacceptable.

A flip-flop made from tristate latches (see Fig. 10.55), that is, free of internal races, yet uses complementary clocks, is shown in Fig. 10.61 [16]. The circuit, also known as  $C^2$ MOS flip-flop, does not require the internal inverter at node X because: (1) node X drives transistor gates only, so there is no fight with a feedback inverter, and (2) there is no internal race: a pull up(down) path is followed by a pull down(up) path, and both paths see the same clock. The *D-to-Q* latency of the  $C^2$ MOS flip-flop is about equal or better than the master-slave flip-flop of Fig. 10.60; however, because of the stacked PMOS devices, this circuit dissipates more clock power and is less area efficient. For the same reason, also the input load is higher.

FIGURE 10.62 Positive, edge-triggered TSPC flip-flop built from complementary and precharged TSPC latches.

FIGURE 10.63 Sense-amplifier, edge-triggered flip-flop.

### TSPC Flip-Flop

TSPC flip-flops are designed by combining the TSPC latches of Figs. 10.57 and 10.58. There are several possible combinations. In an effort to reduce  $D$ -to- $Q$  delay, which is inherently high in this type of latches, a positive-edge flip-flop is constructed by combining a half complementary transparent-low latch (see Fig. 10.56(d)) and a full precharged transparent-high latch (see Fig. 10.58(b)). The resulting circuit is shown in Fig. 10.62. Choosing a precharged latch as the slave portion of the flip-flop helps reduce  $D$ -to- $Q$  delay, because (1) the precharged latch is faster than the complementary one, and (2)  $Y$  switches monotonically low when  $CK$  is high, so the master latch can be reduced to half latch because  $X$  switches monotonically low also when  $CK$  is high. The delay reduction comes at a cost of a hold time increase: to insure node  $Y$  is fully discharged, node  $X$  must remain high long enough, increasing in turn the hold time of input  $D$ .

### Sense-Amplifier Flip-Flop

The design of a sense-amplifier flip-flop [10, 17] is borrowed from the SRAM world. A positive-edge triggered version of the circuit is shown in Fig. 10.63. It consists of a dual-rail precharged stage, followed by a static SR latch built from back-to-back NAND2 gates. The circuit operates as follows. When  $CK$  is low, nodes  $X$  and  $Y$  are precharged high, so the SR latch holds its previous value. Transistors  $N_1$  and  $N_2$  are both on. When  $CK$  is high, depending on the value of  $D$ , either  $X$  or  $Y$  is pulled low, and the SR latch latches the new value. The discharge of node  $X$  ( $Y$ ) turns off  $N_2$  ( $N_1$ ), preventing node  $Y$  ( $X$ ) from

discharging if, during evaluation, DB(D) transitions low-to-high. Devices  $P_1$ ,  $P_2$ , and  $N_3$  are added to staticize nodes  $X$  and  $Y$ . Transistor  $N_3$  is a small device that provides a DC path to ground, since either  $N_1|N_4$  or  $N_2|N_3$ , and the clock footer device are all on when CK is high. While the  $D$ -to- $Q$  latency of the flip-flop appears to comprise two stages only, in the worst-case it is four: the input inverter, the precharged stage, and two NAND2 delays. It should be noted that the precharge stage allows the incorporation of logic functionality. But it is limited by the dual-rail nature of the circuit, which required  $2N$  additional devices to implement an  $N$ -input logic function. In particular, XOR/XNOR gates allow device sharing, minimizing the transistor count and the increase in layout area.

### Design of Pulsed Latches

This subsection covers the design of pulsed latches. It first discusses how this type of latch can be easily derived from a regular transparent latch, by clocking it with a pulse instead of regular clock signal. It then looks at specific circuits that embed the pulse generation inside the latch itself, allowing better control of the pulse width.

#### Pulse Generator and Pulsed Latch

A pulsed latch can be designed by combining a pulse generator and a regular transparent latch, as suggested in Fig. 10.64 [18, 19]. While the pulse generator adds latency to the path of the clock, this is not an issue from a timing perspective. As long as all clock lines see the same delay, or as long as the timing tool includes this delay in the timing analysis, the timing verification of a pulsed latch-based design should not be more complex than that of a latch or flip-flop-based designs.

A simple pulse generator consists of the ANDing two clock signals: the original clock and a delayed and inverted version of it, as illustrated in Fig. 10.65. The length of the clock pulse is determined by the delay of the inverters used to generate CKB. In practice, it is hard to generate an acceptable pulse width less than three, although more inverters can be used.

This pulse generator can be used with any of the transparent latches described previously to design pulsed latches. Figure 10.66 shows two examples of such designs. The design in Fig. 10.66(a) uses the transmission gate latch of Fig. 10.53(e) [20], while the design Fig. 10.66(b) uses the TSPC latch of Fig. 10.56(b). As mentioned previously, designers should pay close attention to ensure that the pulse

FIGURE 10.68 Hybrid latch flip-flop (HLFF).

width is long enough under all process corners and temperature/voltage conditions, so safe operation is guaranteed. On the other hand, a pulse that is too wide might create too many min-timing problems (see Eq. (10.4)). This suggests that the usage of pulsed latches should be limited to the most critical paths of the circuit.

### Pulsed Latch with Embedded Pulse Generation

A different approach to building pulsed latches is to embed the pulse generation within the latch itself. A circuit based on this idea is depicted in Fig. 10.67. It resembles the flip-flop of Fig. 10.60, with the exception that the second transmission gate is operated with a delayed CKB. In this way, both transmission gates are transparent simultaneously for the length of three inverter delays. The structure of Fig. 10.67 has longer  $D$ -to- $Q$  delay compared to the pulsed latch of Fig. 10.66(a); however, this implementation gives designers a more precise control over the pulse width, resulting in slightly better hold time and more robustness. Compared with the usage of the circuit as a master slave flip-flop, this latch allows partial or total clock skew hiding, therefore, its pipeline overhead is reduced.

The hybrid latch flip-flop (HLFF) reported in [21] is based on the idea of merging a pulse generator with a TSPC latch (see Fig. 10.66(b)). The proposed circuit is shown in Fig. 10.68. The design converts the first stage into a fully complementary static NAND3 gate, preventing node  $X$  from floating. The circuit operates as follows. When  $CK$  is low, node  $X$  is precharged high. Transistors  $N_1$  and  $P_1$  are both off, so  $Q$  holds its previous value. When  $CK$  switches low-to-high, node  $X$  remains high if  $D$  is low, or gets discharged to ground if  $D$  is high. If  $X$  transitions high-to-low, node  $Q$  gets pulled high. Otherwise, it gets pulled down. After three inverter delays, node  $X$  is pulled back high while  $N_3$  is turned off, preventing  $Q$  from losing its value. The NAND3 pull-down path and the  $N_1 - N_3$  pull-down path are

**FIGURE 10.69** Semi-dynamic flip-flop (SDFF).

both transparent for three inverter delays. This must allow node  $X$  or node  $Q$  to be fully discharged. If input  $D$  switches high-to-low after  $CK$  goes high, but before  $CKB'$  goes low (during the transparent period of the latch), node  $X$  can be still pulled back high allowing node  $Q$  to discharge. A change in  $D$  after the transparent period has no effect on the circuit. To allow transparency and keep the  $D$ -to- $Q$  delay balanced, all three stages of the latch should be designed to have balanced rise and fall delays. If the circuit is used instead as a flip-flop as opposed to a pulsed latch (i.e., not allowing  $D$  to switch during the transparent period), then the  $D$ -to- $Q$  latency can be reduced by skewing the logic in one direction.

A drawback of HLFF being used as a pulsed latch is that it generates glitches. Because node  $X$  is precharged high, a low-to-high glitch is generated on  $Q$  if  $D$  switches high-to-low during the transparent period. Instead, a high-to-low glitch is generated on  $Q$  if  $D$  switches low-to-high during the transparent period. Glitches, when allowed to propagate through the logic, create unnecessary toggling, which results in increased dynamic power consumption.

The semi-dynamic flip-flop of Fig. 10.69 (SDFF), originally reported in [22] and used in [23], is based on a similar concept (here the term “dynamic” refers to “precharged” as defined in this context). It merges a pulse generator with a *precharged* TSPC latch instead of a static one. A similar design, but using an external pulse generator, is reported in [24]. Although built from a pulse generator and a latch, SDFF does not operate strictly as a pulsed latch. The first stage is precharged, so the input is not allowed to change during the transparent period anymore. Therefore, the circuit behaves as an edge-triggered flip-flop (it is included in this subsection because of its similar topology with other pulsed designs). The circuit operates as follows. When  $CK$  is low, node  $X$  is precharged high, turning  $P_1$  off. Since  $N_1$  is also off, node  $Q$  holds its previous value. Transistor  $N_3$  is on during this period. When  $CK$  switches low-to-high, depending on the value of  $D$ , node  $X$  remains either high or discharges to ground, driving  $Q$  to a new value. If  $X$  remains high,  $CKB'$  switches high-to-low after three gate delays, turning off  $N_3$ . Further changes in  $D$  after this point have no effect on the circuit until the next clock cycle. If  $X$  discharges to ground instead, the NAND2 gate forces  $CKB'$  to remain high, so the pull-down path  $N_3 - N_5$  remains on. Changes in  $D$  cannot affect  $X$ , which has discharged already. This feature is called *conditional shut-off* and it is added to reduce the effective width of the pulse without compromising the design safety. Having the characteristics of a flip-flop, the circuit does not allow time borrowing or clock skew hiding; however, by being precharged, transistors can be skewed resulting in a very short  $D$ -to- $Q$  delay. Another major advantage of this design is that complex logic functions can be embedded in the precharge stage, which is similar to a Domino gate. Typical logic include NAND/NOR, XOR/XNOR, and AND-OR functions [25]. The merging of a complex logic stage, at the expense of a slight increase in  $D$ -to- $Q$  delay, contributes to reducing the pipeline overhead of the design.

## Performance Analysis

This subsection attempts to provide a performance comparison of the diverse latching and flip-flop structures described in the previous sections. Because transistor sizing can be chosen to optimize delay, area, power, or power-delay product, and different fanout rules can be applied in the optimization process, a fair performance comparison based on actual transistor sizing and SPICE simulation results is not trivial. The method adopted here is similar to counting transistors in the critical paths, but it does so by breaking the circuit into source-drain interconnected regions. Each subcircuit is identified and a delay number is

assigned, based on the subcircuit topology and the relative position of the driving transistor in the stack. The result, which is rather a measure of the logical effort of the design, reflects to a first order the actual speed of the circuit. Table 10.7 shows the three topologies used to match subcircuits. It corresponding to single-, double-, and triple-transistor stack. Each transistor in the stack is assigned a propagation delay normalized to a FO4 inverter delay, with increasing delays toward the bottom of the stack (closest to  $V_{DD}$  or  $V_{SS}$ ). The table provide NMOS versus PMOS delay (PMOS stack are 20% slower) and also skewed versus complementary static logic. Details on the delay computation for each design is provided in the “Appendix.”

Table 10.8 provides a summary of the timing characteristics for most of the flip-flops and latches studied in this chapter section. The clocking scheme for latches is assumed to be complementary dual-phase. Values are normalized to a FO4 inverter delay, unless otherwise indicated. The first column is the maximum *D-to-Q* delay and is the value used to compute the pipeline overhead. The second and third column contain the minimum *CK-to-Q* delay and the hold time, respectively. The fourth column represents the overall pipeline overhead, which is determined according to Table 10.6. This establishes whether the latch delay is paid once or twice or whether the clock skew is added or not to the pipeline overhead. The overhead is expressed as a percentage of the cycle time, assuming that the cycle is 20 FO4 inverter delay, and that the clock skew is 10% of the cycle. The fifth column represents the minimum propagation delay between latches, or between flip-flops, required to avoid min-timing problems. It is computed according to Table 10.6, and assuming that the clock skew is 5% of the cycle time. A smaller clock skew is assumed

for min-timing because the PLL jitter, a significant component in max-timing, is not part of the clock skew in this case. From a max-timing perspective, Table 10.8 shows that pulsed latches have the minimum pipeline overhead, the winner being the pulsed transmission gate. The unbuffered transmission gate latch is a close second. But as pointed out earlier, unbuffered transmission gates are rarely allowed in practice. In the flip-flop group, SDFP is the best, while the buffered master-slave flip-flop is the worst. Merging a logic gate inside the latch or flip-flop may result in additional 5% or more reduction in the pipeline overhead, depending on the relative complexity of the logic function. Precharged designs such as SDFP or the sense-amplifier flip-flop are best suited to incorporate logic efficiently. From a min-timing perspective, pulsed latches with externally generated pulses are the worst, while the buffered master-slave flip-flop is the best. If the pulse is embedded in the circuit (like in SDFP or HLFF), min-timing requirements are more relaxed. It should be noticed that because of manufacturing tolerances, the minimum delay requirement is usually larger than what Table 10.8 (fifth column) suggests. One or two additional gate delays is in general sufficient to provide enough margin to the design.

Although pulsed latches are the best for max-timing, designers must keep in mind that max-timing is not the only criterion used when selecting a latching style. The longer hold time of pulsed latches may result in too many race conditions, forcing designers to spend a great deal of time in min-timing verification and min-timing fixing, which could otherwise be devoted to max-timing optimization. Ease of timing verification is also of great importance, especially in an industry where a simple and easily understood methodology translates into shorter design cycles. With the advancement of design automation, min-timing fixing (i.e., buffer insertion) should not be a big obstacle to using pulsed latches. Finally, notice that the selection of a latching technique can affect the cycle time of a design by 10–20%. It is important that designers look into all design trade-offs discussed throughout this chapter section in making the right selection of the latching scheme.

For a similar analysis of some of the designs included in this section but based on actual transistor sizing and SPICE simulation, including a power-delay analysis, the reader is referred to [26].

## Scan Chain Design

The previous sub-section covered the design of latches and flip-flops and presented a performance analysis of each of the circuits. In practice, however, these circuits are rarely implemented as shown. This is because in many cases, to improve testability, a widely accepted practice is to add scan circuitry to the design. The addition of scan circuitry alters both the circuit topology and the performance of the design. The design of scannable latches and flip-flops is the subject of this sub-section.

As mentioned previously, a widely accepted industrial practice to efficiently test and debug sequential circuits is the use of scan design techniques. In a scan-based design, some or all of the latches or flip-flops in a circuit are linked into a single or multiple scan chains. This allows data to be serially shifted into and out of the scan chain, greatly enhancing controllability and observability of internal nodes in the design. After the circuit has been tested, the scan mechanism is disabled and the latches or flip-flops operate independently of one another. So a scannable latch or flip-flop must operate in two modes: a *scan mode*, where the circuit samples the scan input, and a *data mode*, where the circuit samples the data input. Conceptually, this may be implemented as a 2:1 multiplexer inserted in the front of the latch, as suggested in Fig. 10.70. A control signal SE selects the scan input if asserted (i.e., scan mode) or the data input otherwise.

A straightforward implementation of the scan design of Fig. 10.70 consists of adding, or merging, a 2-to-1 multiplexer to the latch. Unfortunately, this would result in higher pipelining overhead because of the additional multiplexer delay, even when the circuit operates in data mode, or would limit the embedding of additional logic. It becomes apparent that a scan design should affect as little as possible the timing characteristic of the latch or flip-flop when in data mode, specifically its latency and hold time. In addition, it is imperative that the scan design be robust. A defective scan chain will prevent data

FIGURE 10.70 A scannable latch.

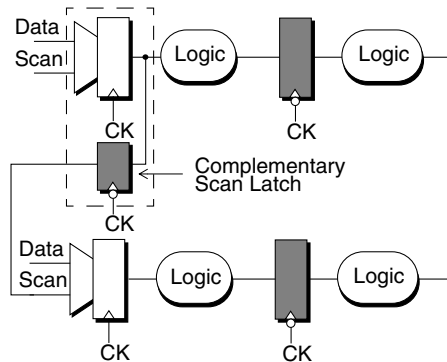

FIGURE 10.71 Scan chain for dual-phase, latch-based design.

FIGURE 10.72 Scan chain for flip-flop-based design.

from being properly shifted through the chain and, therefore, invalidate the testing of some parts of the circuit. Finally, at current integration levels, chips with huge number of latches or flip-flops (>100 K) will become common in the near future. Therefore, a scan design should attempt to maintain the area and power overhead of the basic latch design at a minimum. The remainder of this section describes how to incorporate scan into the latches and flip-flops presented earlier.

Figure 10.71 shows a scan chain in a dual-phase, latch-based design. In such design, a common practice is to link only the latches on one phase of the clock. In order to prevent min-timing problems, the scan chain typically includes a complementary latch, as indicated in Fig. 10.71. The complementary latch, although active during scan mode only, adds significant area overhead to the design. Instead, in a flip-flop-based design, the scan chain can be directly linked, as shown in Fig. 10.72.

Similar to any regular signal in a sequential circuit, scan related signals are not exempt from races. To ensure data is shifted properly, min-timing requirements must be satisfied in the scan chain. Max-timing is not an issue because: (1) there is no logic between latches or flip-flops in the scan chain, and (2) the shifting of data may be done at low frequencies during testing.

To minimize the impact on latency, a common practice in scan design is to prevent the *data clock* from toggling during scan mode. The latch storage node gets written through a scan path controlled by a *scan clock*. In data mode, the scan clock is disabled instead and the data clock toggles, allowing the data input to set the value of the storage node. Figure 10.73(a) shows a possible implementation of a scannable transmission gate latch. For clarity, a dotted box surrounds all scan related devices. Either the data clock (DCK) and the scan clock (SCK) are driven low during scan and data mode, respectively. The scan circuit is a master-slave flip-flop, similar to Fig. 10.60, that shares the master storage node with the latch. To ensure scan robustness, the back-to-back inverter of the slave latch is decoupled from its output, and

FIGURE 10.73 Latches and flip-flops with scan circuitry.

both transmission gates are buffered. The circuitry that controls the DCK and SCK is not shown for simplicity. In terms of speed, drain/source and gate loading is added to nodes X and Q. This increases delay slightly, although less substantially than adding a full multiplexor at the latch input. A similar approach to the one just described may be used with the TSPC latch, as suggested in Fig. 10.73(b). Since transistor P<sub>1</sub> is not guaranteed to be off when DCK is low, transistor P<sub>2</sub> is added to pull-up node X during scan mode. Control signal SEB is the complement of SE and is set low during scan operation.

Figure 10.73(c) shows the scannable version of the master-slave flip-flop. This design uses three clocks: CK (free running clock), DCK (data clock), and SCK (scan clock). DCK and SCK, when enabled, are complementary to CK. Under data or scan mode, CK is always toggling. In scan mode, DCK is driven low and SCK is enabled. In data mode, SCK is driven low and DCK is enabled. While this approach minimizes the number of scan related devices, its drawback is the usage of three clocks. One clock may be eliminated at the expense of increased scan complexity. If CK and DCK are made fully complementary, and CK is set low during scan mode (DCK is set high), the same approach used in Fig. 10.73(a) may be used.

Figure 10.73(d) shows a possible implementation of an scannable sense amplifier flip-flop (see Fig. 10.63). In scan mode, DCK is set low forcing nodes X and Y to pull high. The output latch formed by the cross coupled NANDs is driven by the scan flip-flop. To ensure the latch can flip during scan, the NAND gate driving QB must either be weak or be disabled by SCK. Also for robustness, node QB should be kept internal to the circuit.

Figure 10.73(e) shows the scannable version of the transmission gate pulsed latch of Fig. 10.66(a). The circuit requires the generation of two pulses, one for data (DPCK) and one for scan (SPCK). It should be noticed that having pulsed latches in the scan chain might be deemed too risky because of min-timing problems. To make the design more robust, a full scan flip-flop like in Fig. 10.73(a) shall be used instead.

The disabling of the data (or scan) path in a pulsed latch during scan (or data) mode does not require the main clock to be disabled. Instead, the delayed clock phase used in the pulse generation can be disabled. This concept is used in the implementation of scan for the pulsed latch of Fig. 10.67, and it is shown in Fig. 10.73(f). As previously explained, this latch uses embedded pulse generation. Signals SE

and SEB, which are complementary, control the mode of operation. In data mode, SE is set to low (SEB high), so SCKB is driven low disabling the scan path, and DCKB is enable. In scan mode, SE is set to high (SEB low), so DCKB is driven low, which disables the data path, and SCKB is enabled. The advantage of this approach is in the simplified clock distribution: only one clock needs be distributed in addition to the necessary scan control signals.

The disabling of the delayed clock is used in SDFF (see Fig. 10.69) to implement scan [27]. The implementation is shown in Fig. 10.73(g). For simplicity, the NAND gate that feeds back from node  $X$  is not shown. Control signal SE and SEB determines whether transistor  $N_1$  or  $N_2$  is enabled, setting the flip-flop into data mode (when  $N_1$  is on and  $N_2$  is off) or scan mode (when  $N_1$  is off and  $N_2$  is on). Besides using a single clock, the advantage of this approach is in the small number of scan devices required.

For HLFF (see Fig. 10.68), the same approach cannot be used because node  $X$  would be driven high when CKB is low. Instead, an approach similar to Fig. 10.73(d) may be used.

## Historical Perspective and Summary

Timing requirements of latch and flip-flop-based designs were presented. A variety of latches, pulsed latches, flip-flops, and hybrid designs were presented, and analyzed, taking into account max- and min-timing requirements.

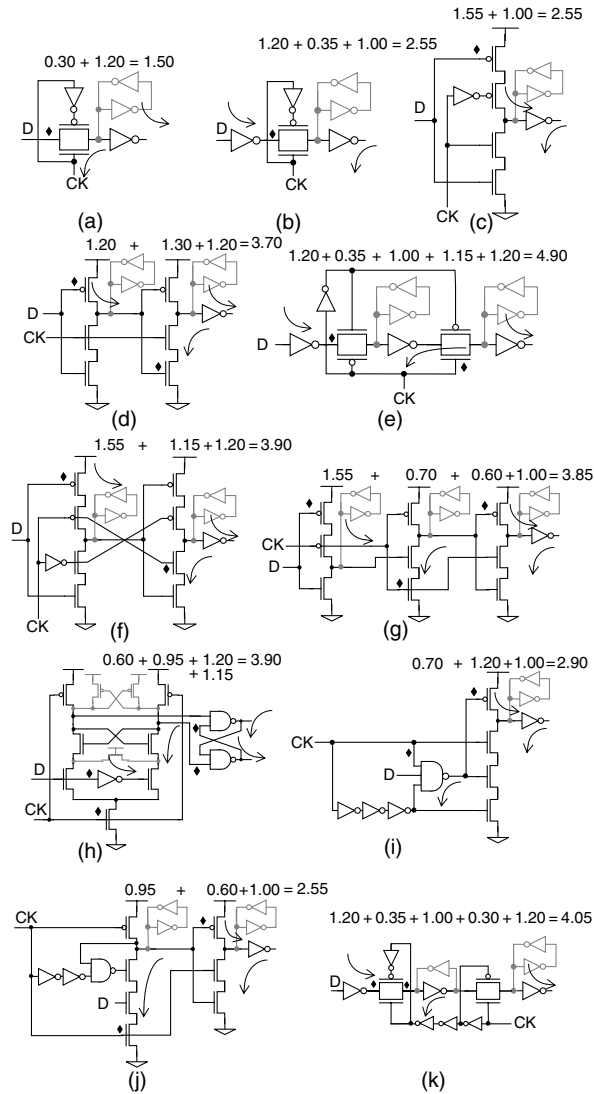

Historically, the number of gates per pipeline stage has kept decreasing. This increases the pipeline clock frequency, but does not necessarily translate into higher performance. The pipeline overhead becomes larger as the pipeline stages get shorter. Clock skew, which is becoming more difficult to control as chip integration keeps increasing, is part of the overhead in flip-flop based designs. Instead, latch-based systems can absorb some or all of the clock skew, without affecting the cycle time. If clock skew keeps increasing, as a percentage of the cycle time, at some point in time latch based designs will perform better than flip-flop-based designs.

Clock skew cannot increase too much without affecting the rest of the system. Other circuits such as sense-amplifiers in SRAMs, which operate in blocking mode, get affected by clock skew also. The goal of a design is to improve overall performance, and access to memory is usually critical in pipelined systems. Clock skew has to be controlled also, primarily because of min-timing requirements. While some of it can be absorbed by transparent latches for max-timing, latches are as sensitive as flip-flops to clock skew for min-timing (with the exception of the nonoverlapping dual-phase design). While the global clock skew is most likely to increase as chips get bigger, local skews are not as likely to do so. PLL jitter, which is a component of clock skew for max-timing, may increase or not depending on advancements in PLL design. Because cycle times are getting so short, on-chip signal propagation in the next generation of complex integrated circuits (e.g., system on-chip) will take several clock cycles to traverse from one side of the die to the other, seeing mostly local clock skews along the way. Clocking schemes in such complex chips are becoming increasingly more sophisticated also, with active on-chip de-skewing circuits becoming common practice [28, 29].

As for the future, flip-flops will most likely continue to be part of designs. They are easy to use, simple to understand, and timing verification is simple also. Even in the best designs, most paths are not critical and therefore can be tackled with flip-flops. For most critical paths, the usage of fast flip-flops, such as SDFF/HLFF will be necessary. Pulsed latches will become more common also, as they can absorb clock skew yet provide smaller overhead than dual-phase latches. A combination of latches and flip-flops will become more common in the future also. In all these scenarios, the evolvement of automated timing tools will be key to verifying such complex designs efficiently and reliably.

## Appendix

A stage-by-stage  $D$ -to- $Q$  delay analysis of the latches and flip-flops included in Table 10.8 is shown in Fig. 10.74. The values per stage are normalized to a FO4 inverter delay. The delay per stage, which is defined as a source-drain connected stack, is determined by the depth of the stack and the relative position of the switching device, following Table 10.7. The delay per stage is indicated on the top of each circuit, with the total delay on the top high right-hand side. Transmission gates are added to the stack of the

**FIGURE 10.74** Normalized delay (FO4 inverter) of various latches and flip-flops: (a) unbuffered transmission gate latch, (b) buffered transmission gate latch, (c)  $C^2$ MOS latch, (d) TSPC latch, (e) master-slave flip-flop, (f)  $C^2$ MOS flip-flop, (g) TSPC flip-flop, (h) sense-amplifier flip-flop, (i) hybrid latch flip-flop, (j) semi-dynamic flip-flop, and (k) pulsed transmission gate flip-flop.

driver to compute delay. For instance, a buffered transmission where CK is switching (Fig. 10.74(b)) is considered as a two-stack structure switching from top. If  $D$  switches instead, it is considered as a two-stack structure switching from bottom. For each design, the worst-case switching delay is assumed. In cases where the high-to-low and low-to-high delays are unbalanced, further speed optimization could be accomplished by equalizing both delays. A diamond is used to indicate the transistor in the stack that is switching. In estimating the total delay of each design, the following assumptions are made. Precharged stages (e.g., sense-amplifier flip-flop, TSPC flip-flop, SDF) are skewed and therefore faster (see Table 10.7, skewed logic). Output inverters are complementary static in all cases. The input inverter in the sense-amplifier flip-flop (Fig. 10.74(h)) is skewed, favoring the low-to-high transition, because its speed is critical in that direction only. The SR latch is complementary static. In the case of HLFF (Fig. 10.74(i)),

when used as a flip-flop, the NAND3 is skewed favoring the high-to-low transition, while the middle stack is complementary. This is because if the middle stack were skewed, favoring the low-to-high transition, the opposite transition would become critical. When the circuit is used as a transparent latch, all stages are static. (i.e., both transitions are balanced). The worst-case transition in this case is opposite to that shown in Fig. 10.74: input  $D$  is switching and the total delay is equal to  $1.2 + 1.5 + 1.2 = 3.9$ . In the case of SDFF (Fig. 10.74(j)), since the middle stack is shorter, both the first stage (precharged) and the middle stack are skewed.

A similar procedure to the one described above is followed to compute the minimum  $CK$ -to- $Q$  delay. An additional assumption is that the output buffer has FO1 as opposed to FO4 as in max-timing, which results in shorter delay. The normalized FO1 pull-up delay of a buffer is 0.6 (PMOS), and the pull-down is 0.5 (NMOS).

To compute hold time the following assumptions are made. The inverters used in inverting or delaying clock signals, with the exception of external pulse generators (see Fig. 10.65), have FO1, so their delays are those of the previous paragraph. External pulse generators use three FO4 inverters instead (i.e., slower), because in practical designs it is very hard to create a full-rail pulse waveforms with less delay. For transparent-high latches, the hold time is defined as the time from  $CK$  switching high-to-low until all shutoff devices are *completely* turned off. To insure the shutoff device is completely off, 50% delay is added to the last clock driver. For instance, the hold time of the transparent-low transmission gate latch is  $0.5$  (FO1 inverter delay)  $\times 1.5 = 0.75$ . For a positive edge-triggered flip-flop, the hold time is defined as the time from  $CK$  switching low-to-high until all shutoff devices are *completely* turned off. If there is one or more stages before the shutoff device, the corresponding delay is subtracted from the hold time. This is the case of the buffered master-slave flip-flop (Fig. 10.74(e)), which results in a negative hold time. An exception to this definition is the case of HLFF or SDFF. Here, the timing of the shutoff device must allow that the stack gets *fully* discharged. Therefore, the hold time is limited by the stack delay, which is again defined as 1.5 times the stage delay. For instance, for HLFF, the middle stage pull-down delay is 1.3, so the hold time is  $1.5 \times 1.3 = 1.95$ . SDFF, instead, has its hold time determined by the timing of the shutoff device because the precharged stage is fast.

## 10.3 High-Performance Embedded SRAM

---

Cyrus (Morteza) Afghahi

### Introduction

Systems on-chip (SoC) are integrating more and more functional blocks. Current trend is to integrate as much memories as possible to reduce cost, decrease power consumption, and increase bandwidth. Embedded memories are the most widely used functional block in SoC. A unified technology for the memory and logic brings about new applications and new mode of operations. A significant part of almost all applications such as networking, multimedia, consumer, and computer peripheral products is memory. This is the second wave of memory integration. Networking application is leading this second

FIGURE 10.75 Integrated memory for some networking products (Mbit).

FIGURE 10.76 Integrated memory for some consumer products (Mbit).

wave of memory integration due to bandwidth and density requirements. Very high system contribution by this adoption continues to slow other solutions like ASIC with separated memories.

Integrating more memories extends the SoC applications and makes total system solutions more cost effective. Figure 10.75 shows a profile of integrated memory requirements for some networking applications. Figure 10.76 shows the same profile for some consumer product applications.

To cover memory requirements for these applications, tens of megabits memory storage cells needs to be integrated on a chip. In  $0.18 \mu\text{m}$  process technology, 1 Mbits SRAM occupies around  $6 \text{ mm}^2$ . The area taken by integrating 32 Mbits memory in  $0.18 \mu\text{m}$ , for example, alone will be  $\sim 200 \text{ mm}^2$ . Adding logic gates to the memory results in very big chips. That is why architect of these applications are pushing for more dense technologies ( $0.13 \mu\text{m}$  and beyond) and/or other memory storage cell circuits.

In pursuing higher density, three main alternatives are usually considered, dense SRAM, embedded DRAM (eDRAM), and more logic compatible DRAM. We call this last alternative 2T-DRAM for the reason that soon becomes clear.

The first memory cell consists of two cross-couple inverters forming a static flip-flop equipped with two access transistors, see Fig. 10.77(a). This cell is known as 6T static RAM (SRAM) cell. Many other cells are derived from this cell by reducing the number of circuit elements to achieve higher density and bits per unit area. The one transistor cell (1T)-based dynamic memory, Fig. 10.77(b), is the simplest and also the most complex of all memories. To increase the cell density 1T-DRAM cell fabrication technology

has become more and more specialized. As a consequence, adaptation of 1T-DRAM technology with mainstream logic CMOS technology is decreasing with each new generation. Logic CMOS are available earlier than technologies with embedded 1T-DRAM. 1T-DRAM is also slow for most applications and has a high standby current. For these and other reasons market for chips with embedded 1T-DRAM has shrunk and is limited to those markets, which have already adopted the technology. Major foundries have stopped their embedded 1T-DRAM developments. Another memory cell that has recently received attention for high density embedded memory uses a real MOS transistor as the storage capacitor, Fig. 10.77(c). This cell was also used in the first generation stand alone DRAM (up to 16 kbit). This cell is more compatible with logic process. Thus, availability will be earlier than 1T-DRAM, it is more flexible and can be used in many applications. This volume leverage helps in yield improvements and support from logic technology development.

Table 10.9 compares main performance parameters for these three embedded memory solutions. 2T-DRAM needs continuous refreshing to maintain the stored signal. This is a major contributor to the high 2T-DRAM standby power. SRAM and 2T-DRAM also differ in the way they scale with technology. To see this, consider again the Fig. 10.77.

The following equation summarizes the design criteria for a 2T-cell:

$$\Delta V + V_n = C_s V_s / 2(C_s + C_{BL}) \quad (10.25)$$

where  $\Delta V$  is the minimum required voltage for reliable sensing ( $\sim 100$  mV);  $V_n$  is the total noise due to different leakage, voltage drop, and charge transfer efficiency;  $C_s$  is the storage capacitance;  $C_{BL}$  is the total bit line capacitance; and  $V_s$  is the voltage on the  $C_s$  when a “1” is stored in the cell,  $V_{cc} - V_{tn}$ . Now the effect of process development on each parameter will be examined.  $V_n$  includes sub-threshold current, gate leakage, which is becoming significant in  $0.13 \mu\text{m}$  and beyond, the charge transfer efficiency, and voltage noises on the voltage supply. All these components degrade from one process generation to another.  $V_s$  also scales down with technology improvements. We assume that  $C_s$  and  $C_{BL}$  scale in the same way. Then for a fixed  $\Delta V$ , for each new process generation, fewer numbers of cells must be connected to the bit line. This will decrease memory density and increase power consumption.

For SRAM the following equation may be used to study the effect of technology scaling:

$$\Delta V = (I_{\text{sat}}/C_{BL})T \quad (10.26)$$

FIGURE 10.78 A basic column in a memory array.

New process generations are designed such that the current per unit width of transistor does not change significantly. So, although scaling reduces the size of the driving transistor  $ND_1$ ,  $I_{sat}$  remains almost the same.  $C_{BL}$  consists mainly of two components, metal line capacitance and diffusion contact capacitance. Contact capacitance does not scale linearly with each process generation, but the metal bit lines scale due to smaller cell. This applies to Eq. (10.25) as well. To get the same access time, the number of cells connected to a column must be reduced. However, this trend is much more drastic for 2T-DRAM because  $\square V$  is proportional to  $V_s$ . For example, in a typical  $0.18 \mu\text{m}$  technology to achieve access time  $<10 \text{ ns}$ , the number of cells in a SRAM column is 256–512, while it is only 32 for 2T-DRAM. In  $0.13 \mu\text{m}$  these numbers are reduced much slower for SRAM than for 2T-DRAM. Other factors like testing, experience and ease of design, standby current, soft error rate, foundry support, etc. are in favor of SRAM. For these reasons we concentrate on SRAM design.

## Embedded SRAM Design

To achieve high access and cycle time, low power and better noise immunity SRAM design is normally applied. To get the same speed and power performance, SRAM also results in more compact memory than 2T-DRAM. In this section we start with studying circuits involved in a column of memory cells. A memory column is used to build a memory array. Then we study the peripheral circuits for a memory array. Then techniques used to design a high-capacity memory with memory arrays will be presented. Embedded memories have different failure and testing requirements than commodity memories. Finally, these requirements and some techniques to increase yield will be discussed.

### A Memory Cell Column

Figure 10.78 shows the basic column of a SRAM memory array. For high-speed memory in  $0.18 \mu\text{m}$  technology, usually 128–256 cells are hooked to Bit and Bit# lines. More memory cell per column improves the area efficiency of the memory. Area efficiency is the ratio of the cell array to the total array area.

#### Memory Cell

The SRAM memory cell is a cross-coupled CMOS inverter pair. The read and write to the cell is through N-pass transistors ( $NP_1$  and  $NP_2$ ). The absolute and relative sizes of the transistors in the cell must satisfy different, mostly conflicting, requirements. The general goal is to keep the transistors as small as possible to achieve high density. This may then conflict with high-speed requirements and radiation hardness. To explain the design guidelines in selecting the transistor sizes, write and read operations are presented briefly. Later these operations are presented in more details.

To write a data into the cell, Bit and Bit# are driven to the data and its complement. Then the LWL is activated for the selected row. The access transistors  $NP_1$ ,  $NP_2$  and the write drivers must be able to

**FIGURE 10.79** Static noise margin of the memory cell.

provide sufficient current to flip the cell and latch the new data. Since access transistor is a single N-pass transistor, the bit line (Bit or Bit#), which is a logic “0”, is most effective in the write (and read) operation. Inside the cell the logic “1” must be restore by the P-transistors. During read, Bit and Bit# are first pre-charged to “1” then the LWL is activated again for the selected row. Depending on the data stored in the cell, ND<sub>1</sub> (or ND<sub>2</sub>) will pull the bit line down. The read operation must not destroy the stored data.

The NP transistor must be sized correctly with respect to driving ND transistor and restoring P-transistor. During the write a logic “0” on the bit line must be able to flip the cell. This means that NP transistor must be large enough to overcome the P-transistor. This transistor must also be large enough to decay the bit line for a fast read time; however, its size with respect to driver transistor ND<sub>1</sub> (ND<sub>2</sub>) must be small enough such that during a read the internal node holding a “0” does not rise sufficiently to flip the cell. Other considerations, like sub-threshold leakage and glitches during a LWL transition, suggest to keep this transistor small.

The ND transistor drives the bit line down during a read. Since the bit line capacitance is high, for high-speed read this transistor must be large. Also it must be large enough to maintain the logic “0” in the cell while pulling down the pre-charged bit line during a read. However, to have some write margin this transistor must not be too large. When writing a “0” to one side of the memory cell (for example, S<sub>1</sub>), the ND<sub>2</sub> transistor is fighting to maintain the old value. A large ND size requires the bit line to be pulled too close to V<sub>ss</sub>. This limits the write margin. A large ND size also increases the standby current of the memory.

The restoring P-transistor pull up the high side of the cell to a logic “1” and maintain it at that level. Since the P-transistor only drives the internal cell nodes, it could be small. Smaller P-transistor also reduces the sub-threshold current. However, the P-transistor must be large enough to quickly restore a partially logic “1” written through N-pass transistor to a full level. Otherwise a read immediately following a write may not meet the access time. The P-transistor must also be large enough to reduce soft error rate.

These conflicting requirements on the absolute and relative size of transistors in the cell are summarized in a graphical analysis of the transfer curve of the memory latch, Fig. 10.79. To set up this graph, normalized transfer function of the inverter in the cell is overlapped with its mirror curve. The maximum square that fits these two characteristics defines the noise margin for read and write. This square is also an indication of the cell stability. This graph must be analyzed across the voltage, temperature, and process variations. In the next section some guidelines are given for these simulations.

### **Memory Cell Stability and Noise Margin Analysis**

Some parameters of a transistor are subject to variations during fabrication. These variations can be lumped and modeled in the transistor length and threshold. Figure 10.80(a) shows an ideal transistor that has a width of  $W$  and length  $L$ . In a typical process, the transistor threshold voltage is  $V_t$ . A weak transistor is modeled by increasing the  $L$  and threshold by  $\Delta L$  and  $\Delta V_p$ , respectively.  $\Delta V_t$  must be represented by a correct battery polarity in the schematic. A strong transistor is modeled by decreasing the  $L$  and threshold by  $\Delta L$  and  $\Delta V_t$ .

FIGURE 10.80 Modeling process variations in schematic.

FIGURE 10.81 Schematic model to simulate stability, read and write noise margin.

To estimate  $\Delta L$  and  $\Delta V_t$ , use the 3-sigma figures for the specific process. These figures are usually obtainable from the process foundry. For example, in a typical  $0.18 \mu\text{m}$  technology, 3-sigma for  $L$  and  $V_t$  are  $\pm 0.01 \mu\text{m}$  and  $\pm 20 \text{ mV}$ . If 1 Mb memory is embedded in a die and you allow 1/1000 die to fail, the failure rate is  $1\text{E-}9$ . This corresponds to 6.1-sigma.  $\Delta V_t$  will be 40.6 mV. This mismatching is between two supposedly matched transistors in the same circuits. All  $N$  and/or  $P$  transistors on a die may shift from their typical characteristics to slower or faster corners. When simulating a circuit, all combination of process corners must be considered for the worst case.

The schematic model shown in Fig. 10.81 is used to study the memory cell stability, read and write margins. To initialize the cell, write a data into the cell and turn the word line (LWL) low. Then ramp the  $V_{cc}$  from, say,  $V_{cc} - 0.25V_{cc}$  to  $V_{cc} + 0.25V_{cc}$ . If the cell changes state, it is not stable. The lower and upper  $V_{cc}$  levels used in this test are application dependent. For upper level the burn-in voltage may be used. This simulation must be carried out in all process corners. To improve stability, increase the width of the ND or/and decrease the width of the pass transistor.

A read operation starts with pre-charging the bit lines. During this phase no word line (LWL) is selected. Then a row will be selected for read. This will cause a charge sharing between the bit line and the low side of the cell. The memory cell read margin determines how far the upset side of the cell is from corrupting the stored data. To replicate a read operation, a current source is ramped up on the low side of the cell. The voltage at which the cell is flipped is called the trip point of the cell. The read margin is the trip point voltage minus 5–10% of  $V_{cc}$ . The percentage depends on the memory environment. This simulation must be carried out in all process corners. For good noise immunity, the read margin needs to be between 5–10% of  $V_{cc}$ . The same measures used to improve cell stability can also be used to improve the read noise margin.

As in the read operation a write also starts with pre-charging the bit lines. Then a row is selected and the bit line to write a “0” is driven low by the write circuitry. The write operation must be finished in a pre-specified time. The write margin is an indication of the write driver strength in writing an opposite data into a cell. For this purpose a transient simulation of the write driver, bit line, and a cell under test is required. A weak transistor must be used for the pass transistor (NP). Then the write margin is the trip point voltage (measured in the read operation) minus the bit line voltage at the end of the write period. For a good noise margin the write margin must be  $\sim 10\%$   $V_{cc}$ . Again, simulation must be carried

FIGURE 10.82 Bit-line, pre-charge circuit.

out in all process corners. To improve the write noise margin the write driver strength or/and the width of the pass transistor can be increased.

### Bit Line Pre-Charge Circuit

As mentioned earlier pre-charging precedes the read and write operations. If the write circuit drives both bit lines to full “0” and “1” logical level, pre-charging the bit lines before the write is not necessary; however, pre-charging the bit lines prior to write makes the write time more predictable and the write circuit less complex. Figure 10.82 shows a pre-charge circuit. P transistors pre-charge the bit lines to full  $V_{cc}$ . Static sense amplifiers used in some designs for read operation have very low gain at  $V_{cc}$ . In these designs either  $N$  transistors is used to pre-charge the bit lines or level shifter is used to lower the voltage at the sense amplifier circuit. Using  $N$  transistor results in unpredictable pre-charged level and variable read time. If a column is not selected for a long time,  $N$  transistor leakage gradually raises the pre-charge level closer to  $V_{cc}$ .

The  $P_1$  and  $P_2$  transistors must be large enough to pre-charge the bit lines in the available time. But they must not be larger than required due to excessive gate to drain capacitance coupling and charge injection into the bit lines.  $P_3$  is used to equalize the bit lines. Equalization is particularly important after a write as one of the bit lines is driven to “0”. Any voltage mismatch between bit lines will reduce the read margin and slows down the read time if a static sense amplifier is used. In case of a sense amplifier with positive feedback, bit line voltage mismatch can cause wrong result.

### Column Select Circuit

The next element in the memory column to be considered is the column select circuit. In embedded applications, the number of bits per word can vary from as low as 3 bits to 512 or even higher. Column multiplexing gives some flexibility to handle this wide range of requirements. Multiplexing can vary from 1:1 to 1:32 or higher. Narrower multiplexing (1:1) creates difficulties in layout as the sense amplifier and write circuits must fit in a cell pitch. When the word is short, narrow multiplexing results in low memory area efficient. Wide multiplexing creates difficulties in matching Bit and Bit# lines. 1:4 and 1:8 are the usual ratio used.

In many designs read and write multiplexing are separated. This may be due to some system requirements. Figure 10.83 shows a 2:1 multiplexing with separated read/write column selects. In this circuit a single  $N$  pass transistor is used for read select and a single P pass transistor is used for read. This circuit exploit the fact that the “0” is the most active in the write operation and pre-charge circuit have already charged the bit lines to “1”. One must make sure that the “1” is not decayed below  $V_{cc} - V_{tn}$  due to coupling, sub-threshold currents of nonselected memory cells in the column, and the charge sharing with the selected memory cell. During a read operation the bit line decays only a fraction of  $V_{cc}$  (say ~100 mV). Thus, a single P transistor, instead of complementary gates, will be sufficient to transfer the bit line value to the sense amplifier input. In the Fig. 10.83 a simple write circuit is also shown. In more complex write circuit, explained later, the single multiplexing  $N$  pass transistor should be replaced with a complementary transmission gate to pass both “0” and “1.” It is also possible to use the same column select for both read and write. In this case the write circuit must be tri-stated during the read operation. In some systems, it is required to write or read only a part of a word. In these cases masking or two levels of decoding is may be used.

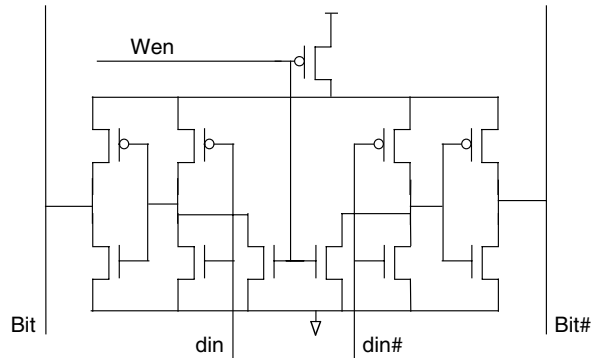

FIGURE 10.83 A column circuit.

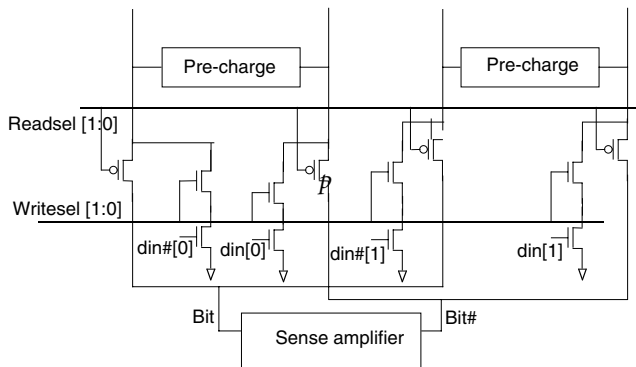

FIGURE 10.84 A write circuit.

### Write Circuit

In the previous sub-section, a simple and fast circuit was presented. The write  $N$  transistor (and write select transistor) are large enough to drive the highly capacitive bit line down and overcome the  $P$  pull-up transistor inside the memory cell in the available write time. In that circuit the bit line is not driven to “1”. This is because the bit line can not write a “1” to the memory cell and the bit line is already pre-charged to “1”. To make sure that the bit line maintains the pre-charge value or if the pre-charge is not complete prior to write, to save time, the write circuit must drive the “1” side also. Figure 10.84 is a more complex write circuit that has only one  $N$  transistor (in series with the  $N$  column select transistor) and drives the high side as well. During the read cycle, this circuit is in tri-state, so same column select might be used for both read and write.  $Wen$  signal is either the write enable signal or a derivation of it.

### Sense Amplifier

The sense amplifier is the last element considered in the column. In a read operation the bit lines are pre-charged first. Then a word line is activated to let the  $ND$  transistor in the cell pull either  $Bit$  or  $Bit\#$ , depending on the data stored in the cell, down. The bit line is highly capacitive and the transistors in the memory cell are small for density purpose, so it may take a long time for the cell to completely discharge the bit line. The common practice is to let the cell develop only a limited differential voltage, about  $\sim 100$  mV, on the bit lines and amplify it by a sense amplifier. Thus, reducing and matching the bit line capacitance is important for a fast and correct read. Power consumption of a memory is also mainly determined by the bit line capacitance.

Bit line capacitance components, contributed by each memory cell, include junction capacitance, bit line to bit line coupling, bit line to word line, and bit line to substrate capacitance. Thus, each cell connected

FIGURE 10.85 Bit line twisting to reduce coupling capacitans and read time data dependency.

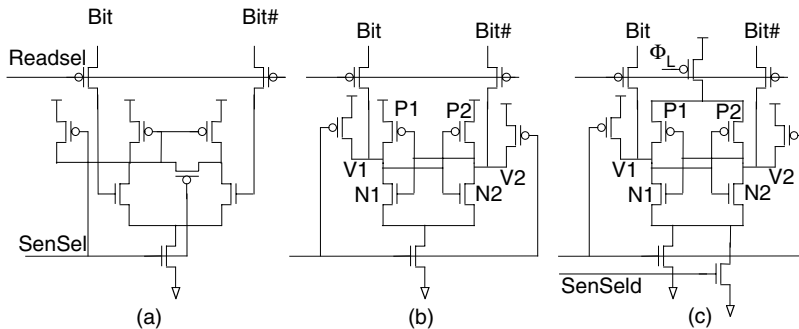

FIGURE 10.86 Three popular sense amplifiers: (a) Current mirror based, (b) Latch with positive feedback, and (c) Dual slope or/clocked  $V_{cc}$ .

to the bit line adds a certain amount of capacitance to the bit line. Junction capacitance is the main source of bit line capacitance. Choosing the number of cells per column is an important design decision as it determines the speed, power consumption, area efficiency, and hence, the architect of the memory. In a typical  $0.18 \mu\text{m}$  technology 256–512 cells per bit line is a good compromise. Bit line to bit line coupling is a major source of mismatching. Its contribution to bit line capacitance is also significant and is the only component that circuit designers can influence.

Coupling capacitance between bit lines has two consequences. It increases the total capacitance and makes the read time data dependent. Adjacent cells to a cell may have different data for two reads of the same cell. The strategy to reduce the bit line coupling capacitance is to twist the bit line along long run of bit lines. Figure 10.85(a) shows a simple strategy in which the coupling between bit lines is completely cancelled; however, the coupling between Bit and Bit# of the same cell is not cancelled. But signal shifting due to this coupling is deterministic and limited. In modern CMOS process technologies, it is possible to use higher level of metals for bit lines to lower the line to substrate capacitance. It is also made possible that to run, in addition to bit lines, a supply line through the cell. This supply line not only helps to have a power mesh in the memory, it also can be used to cancel the Bit to Bit# coupling, see Fig. 10.85(b). Twisting the bit lines degrades the area efficiency of the memory. If the supply line is drawn outside the bit lines, the strategy in Fig. 10.85(c) may be used to increase the area efficiency and live with the known Bit to Bit# coupling capacitance.

Many different sense amplifiers circuits are used in memory design. Two most popular circuits are considered here. The miller current mirror sense amplifier, Fig. 10.86(a), is used in more conservative and slow designs. The SenSel signal is asserted after enough differential signals are developed on the bit lines. The main

advantage of this circuit, compared to a circuit with positive feedback, is that it always resolves to right direction regardless of the initial amount of differential signals at the inputs. Thus it is not sensitive to the minimum delay of SenSel signal to word line. However, this circuit has many disadvantages. It is slow and consumes more power. The gain and speed of the circuit is very sensitive to the pre-charge value of the bit line. Because of the diode connected transistor in the circuit it is not suitable for low voltage operation and has structural offset. For these reasons the differential sense amplifier with positive feedback circuit, Fig. 10.86(b), is used in many designs.

This circuit is fast and consumes less power. The only disadvantage of this circuit is that it may latch in a wrong state. To avoid this, the SenSel signal must be activated after sufficient different voltage is developed on bit lines to overcome all worst-case offsets of the circuit. To calculate the worst-case offset, the schematic model in Fig. 10.81 can be used.  $\Delta L$  and  $\Delta V_t$  are smaller for sense amplifiers because bigger devices are used here. To reduce the offset, transistors used in the circuit must have at least 10–20% longer than the minimum length in the technology.

After sufficient differential voltage is developed between  $V_1$  and  $V_2$ , the SenSel signal is activated. Initially, only two input N transistors,  $N_1$  and  $N_2$ , are in saturation and two loading P transistors are off. This is a favorable case because N transistors normally have better matching characteristics than P transistors. Two cross-coupled N transistors increase the differential voltages further. Both  $V_1$  and  $V_2$  drop below pre-charge  $V_{cc}$  voltage. When  $V_1$  or  $V_2$  are below  $V_{cc} - V_{tp}$ , the P transistors further increase the positive feedback and restore a full  $V_{cc}$  on the side that is supposed to be a logic “1”. To make the initial part of the operation longer, one may use a dual slope scheme or/and clock the  $V_{cc}$  connection, Fig. 10.86(c). In the dual slope scheme first the weaker tail transistor is activated. This will cause the  $V_1$  and  $V_2$  to sink slowly. After a short delay the strong tail transistor is turned on by SenSel. In the clocked  $V_{cc}$  connection the  $\Phi_L$  is delayed with respect to SenSel. In some design the Bit and Bit# are not disconnected from the sense amplifier during sensing. This results in slower response and increased power consumption. Bit and Bit# can be disconnected by a column select transistors to increase speed and reduce power consumption.

### Memory Array

Now that main circuits comprising a column are presented, we can construct an array of columns. The goal is to organize  $n \times n$  cells in such a way to meet the required access time, power budget, and high-area efficiency. In a flat organization, Fig. 10.87(a), all the cells are included in a single array. This architecture has many disadvantages for large memories. The main contributor to the power consumption

FIGURE 10.87 Memory organizations: (a) flat, (b) hierarchical, and (c) a hierarchical circuit solution.

is the bit line capacitance. The effect of bit line capacitance on the read access time is significant. It is thus desirable to have less number of cells per column. Having less number of cells per column also make the row decoder simpler. Row decoder time performance is also crucial for a fast access time because it is in the critical delay path; however, in a flat organization less number of rows means larger number of columns. This will increase the word lines delay, requires big word line drivers, and high column multiplexing ratio.

Partitioning of the memory array has been the subject of very creative challenges for many years. This challenge will continue, as the metal lines are becoming more resistive and new generation CMOS technologies offer multilayers of metals. This provides possibilities to introduce many layers of hierarchy in the memory organization to combat parasitics reduce power, access time, and to increase area efficiency. [Figure 10.87\(b\)](#) is an example of partitioning the array into sub-arrays and introducing hierarchy into the decoding and word lines. Assume you have 256 rows per sub-array. You need eight address bits to select each row. Out of these 8 bits, 6 bits are coded and driven across all the sub-arrays. These are global word lines, GWL. Although global word lines are long, they are not heavily loaded, as they are strapped only once per sub-array. The remaining 2 bits are pre-decoded in each sub-array. A sub-array is selected through sub-array decoder (block decoder). Block decoder is normally fast, as it has a smaller number of address bits to decode. The local decoder in each sub-array is a simple circuit that decodes GWL, pre-decoded signal, and block select. [Figure 10.87\(c\)](#) is a static circuit for the row decoder chain. For faster decoding pre-charge dynamic circuits may be used instead.

Column decoding is not as time critical as row decoder, as row decoding and bit sensing can be completed before the column decoder is finish. However, in a write operation there may be a race between row decoder and column decoder.

## Testing and Reliability

High-density and high-capacity memory cores are more vulnerable to physical defects than logic blocks. The higher defect is mainly caused by SRAM denser layout. Wafer yield can be assumed to be (SRAM yield)  $\times$  (logic yield). In a logic chip with high density and capacity embedded SRAM, it is essential to enhance the SRAM yield to achieve better overall chip yield. In commodity SRAM redundancy is used to increase yield. This same methodology can be used to compensate for higher defect density of embedded SRAM. Redundancy is to replace a defected element by a redundant element. A pair of row(s) and column(s) are designed redundant to a memory block for this purpose. If any single memory block is denser than 0.5 Mbits, it is recommended to have redundant row and column. Columns fail more often than rows as they are more complex and include sense amplifier. At least use one redundant column per each 0.5 Mbits. For memories denser than 2 Mbits, both row and column redundancy is recommended.

Testing of embedded memories is more difficult than commodity memories due to the limitation in direct access, increase in data bus width, and increase in speed and flexibility in embedded memories configurations and specifications. It is, therefore, necessary to use a BIST for each memory block to run all standard test patterns. Address and data signals to embedded SRAMs may go through a long run. This can cause timing and signal integrity issues. Power supply voltage drop, flatuation and noise are another source of embedded memory failure. A well-designed power mesh together with sufficient and well-placed de-coupling capacitance is normally used in robust memory designs.

### 11.1 Introduction

---

Multiple-valued logic (MVL) is a hybrid of binary logic and analog signal processing: some of the noise advantages of a single binary signal are retained, and some of the advantages of a single analog signal's ability to provide greater informational content are used. Much work has been done on many of the theoretical aspects of MVL. The theoretical advantages of MVL in reducing the number of interconnections required to implement logical functions have been well established and widely acknowledged. Serious pinout problems encountered in some very large scale integrated (VLSI) circuit designs could be substantially influenced if signals were allowed to assume four or more states rather than only two. The same argument applies to the interconnect-limited IC design: if each signal line carries twice as much information, then only half as many lines are required. Four-valued logic signals easily interface with the binary world; they may be decoded directly into their two-binary-digit equivalent. Many logical and arithmetic functions have been shown to be more efficiently implemented with MVL, i.e., fewer operations, gates, transistors, signal lines, etc., are required. Yet, with all the theoretical advantages, MVL is not in wide use mainly because MVL circuits cannot provide these advantages without cost. The costs are typically reduced noise margins, slower raw switching speed due to increased circuit complexity and functionality, and the burden of proving MVL use improves overall system characteristics. As fabrication technologies evolve, MVL circuit designers adapt to the new technology-related capabilities and limitations and create new MVL circuit designs. Many MVL circuits have been proposed that use existing and proposed silicon and III-V fabrication technologies; that signal with flux, charge, current, voltage, and photons. A discussion of the extensive range of possible circuit-oriented MVL topics would be very

informative, but that is beyond the scope of this document. This discussion is intended to present a view of the state of the art in practical, realizable MVL circuits and of the trend expected in new MVL circuits. The reader is referred to the section on “Further Reading” below for references to additional literature and sources of information on MVL.

For most new chip designs that employ MVL to be useful and attractive, their inputs and outputs, and power supply voltages must be compatible with the signal swings and logic levels, and power supply voltages of the binary logic families with which they will be required to communicate. Looking at the potential of MVL realistically, in the near future, we expect few designers to risk using quaternary or other MVL logic signaling at the package pins (except possibly in a testing mode). The most likely situation in which MVL would be used is one in which binary signaling is done on the chip pads to be compatible with the rest of the system, some functions are realized with standard binary circuitry, and certain other functions are realized more advantageously with MVL. Rather than attempt to develop a general family of MVL circuits that is logically and computationally complete, we have examined the realization of specific MVL functions that we believe provide advantages now and may provide advantages in the future.

MVL has many theoretical advantages, but it is not widely used because MVL circuits do not provide overwhelmingly advantageous characteristics, in general. However, in many designs, overall system characteristics may be improved using specific MVL circuits in specific applications. For example, the most widely used commercial application of MVL is nonvolatile memory. The MVL nonvolatile memory provides greater memory density and decreased incremental memory cost. These circuits generate internal multiple-valued current signals that are interpreted and converted to binary voltage signals for interface out of the memory function. As system power supply voltages continue to decrease, current signaling can allow one to continue to use the advantages of MVL until subthreshold and leakage currents exceed the available noise margins. Thus, current-mode CMOS logic circuits are also seen as viable in the present and in the near future.

Several other MVL approaches may be potential candidates for MVL VLSI circuits. Current-mode, emitter-coupled, logic style circuits can be easily adapted to use multiple valued current signals and provide high-speed, high-packing-density MVL functions [1,2]. To take advantage of current-mode logic's series gating, power supply voltages must remain higher than the minimum projected for CMOS. Although the use of resonant tunneling diodes' and transistors' negative incremental resistance can be used for MVL and shows some promise [3,4], the series stacking of the multiple negative-resistance devices requires additional voltage overhead we are predicting will not be available, in general. Although interesting, these and other approaches to MVL circuits will not be discussed in detail here. Many MVL circuits that require enhancement- and depletion-mode NMOS and PMOS transistors with application-specific sets of designer-specified transistor threshold voltages have been proposed that are similar to or extend the ideas in [5,6]. We are not discussing those ideas in this document because the fabrication technologies required are too ambitious or because the circuit overhead required to maintain an MVL voltage-controlled-transistor-threshold voltage is excessive, and thus not as likely to be adopted by design engineers; however, it has been commonly observed that ideas that prove to be highly profitable can suddenly alter the vector of change in the electronics industry. If, for example, a highly capable, and highly profitable approach to photonic circuits were demonstrated that required a large power supply voltage, designers would not hesitate to reverse the power supply voltage reduction trend for the purpose of improved profit and enhanced performance. Yet, given the information now available about fabrication technology improvements and changes projected into the near future, the trend of reduced power supply voltages and minimized transistor dimensions will probably continue for some time. Under these conditions, we project current-mode MVL signals to be the most likely to be useful and advantageous.

In the next section, we discuss the use of MVL in nonvolatile memory circuits realized in CMOS technologies. Section 11.3 discusses current-mode CMOS circuits that can provide computational advantages because current summing requires no electronic components. A summary and conclusions are presented in section 11.4.

## 11.2 Nonvolatile Multiple-Valued Memory Circuits

The most widely used commercial application of MVL is in nonvolatile memory. Nonvolatile memory retains its stored information when there is no power supplied to the chip. Read only memory (ROM) is programmed in the manufacturing process and cannot be altered afterward. Programmable ROM (PROM) is programmed after manufacture only once, by the electrical means of blowing out, open circuiting, a fuse, or enabling, shorting, an “anti-fuse.” Erasable PROM (EPROM) uses a floating-gate (FG) field effect transistor (FET) that has two separate, overlapping gates, one of which is electrically isolated or floating, as shown in Fig. 11.1. The floating gate lies on the thin gate oxide between the FET’s channel and the top gate, which serves as the transistor’s gate terminal that is driven to turn on or off the transistor’s drain current. The transistor’s effective threshold voltage can be changed by changing the number of electrons, the charge, stored on the floating gate. The difference between the applied gate voltage and the effective threshold voltage determines the drain current. The drain current represents the information stored in the FG transistor. The drain current is read by a column amplifier that converts the information to voltages compatible with the interfacing circuitry. All FG transistors in the EPROM are erased simultaneously by exposing the floating gates to ultraviolet light. Electrically Erasable PROM (EEPROM) uses floating gate transistors that are programmed and erased by electrical means. The FG transistor’s effective threshold voltage, and resultant drain current, is programmed by placing charge on the floating gate. The arrangement of memory array transistors in nonvolatile memory can be in parallel as is done with a NOR gate, or in series as is done with a NAND gate, thus giving nonvolatile memory architectures NOR and NAND designations. The physical mechanism typically used in programming the floating gate is channel hot electron injection or Fowler–Nordheim tunneling, and for erasure Fowler–Nordheim tunneling [11]. Organizations of floating-gate transistors such that they can be electrically programmed one bit at a time and electrically erased a block, sector, or page simultaneously are called “Flash” memory. These nonvolatile memories usually have a single power supply, and generate the larger programming and erasure voltages on-chip. Floating gate transistors in these commercial products can typically be programmed in less than 1 ms, erased in less than 1 s, can retain data for more than 10 years, and can be erase/program cycled over 100,000 times. Binary and multiple-valued versions of flash memories can usually be realized in the same floating-gate FET fabrication technologies, and use the same memory cells. Differences are in binary and MVL read and write functions, and programming and erasure procedures.

MVL nonvolatile memory provides greater memory density and decreased incremental memory cost. In the next two sections, MVL ROM and MVL EEPROM memory, respectively, are discussed.

### Multiple-Valued Read Only Memory

Standard binary ROM circuits are programmed during the manufacturing process by making each cell transistor either operational or nonoperational. The programmed binary data is represented by either the presence or absence of drain current when the memory cell transistor is addressed. This can be accomplished in several ways. The memory cell transistor can be made nonoperational by having its

FIGURE 11.1 Floating-gate MOS FET.

drain omitted, its gate polysilicon over thin oxide omitted, and its threshold voltage increased to a value greater than the gate address voltage. For example, an additional mask and implant are used to increase the cell transistor's threshold voltage to a value large enough that the transistor remains "off" ( $I_D = 0$ ) when the address voltage is applied to its gate. Thus, with all programming approaches, when the memory cell is addressed, those cell transistors that are operational conduct drain current, and those that are not operational do not conduct drain current. The binary information is in the presence or absence of drain current. Drain current is detected by the column read amplifier, and binary output voltages are created for communication out of the memory function. The column read amplifier can be a differential amplifier or a fixed reference comparator. MVL ROM uses multiple valued drain currents to represent the stored MVL data. MVL and binary ROM architectures are essentially the same except for sensing the multiple valued currents and the creation of the equivalent binary information for output out of the memory function. Four-valued ROM [7–10] have been successfully used in commercial products.

Four-valued ROMs can be programmed during manufacture using two approaches. One approach uses two additional masks and implants to create four possible memory cell transistor threshold voltages [8,10]. Drain current is nonlinearly proportional to the difference between the applied address gate voltage and the effective threshold voltage. Cell transistors with four possible effective threshold voltage values can be of minimum size and thus produce twice the cell bit density possible with the binary version. This approach uses additional processing steps and masks, and thus a more expensive fabrication technology. Another approach uses four different cell transistor channel widths or width-to-length ratios to set the four possible drain current values [7,9]. Drain current is directly proportional to the channel width. The spacing within the array of memory cell transistors must accommodate the largest of the four possible transistor sizes, and thus must be greater than that of the threshold programmable version. This geometry-variable approach requires additional silicon area and provides a bit density less than the threshold programmable approach, but greater than the binary version; however, no additional fabrication steps or masks are necessary for this geometry-variable cell.

Detection and interpretation of the four-valued memory cell transistor's drain current is an analog-to-two-bit digital conversion problem that has many solutions. Traditional analog-to-digital conversion design issues must be considered and all conversion approaches can be used. A simple approach uses as comparator threshold references three reference currents that lie between the four logical values of the drain current. This common "thermometer" arrangement of three comparators produces simultaneously three comparison results that are easily decoded into arbitrary two-bit binary output combinations. This simultaneous comparison of the data drain current to the references is the fastest approach to detecting the stored data. These column read amplifiers are more than twice as complicated as the binary versions. Because the number of read amplifiers is much smaller than the number of memory cells, this increase in the read amplifier overhead circuitry reduces only slightly the overall density improvement provided by the bit density increase of the large array of four-valued memory cells. Overall, four-valued ROM implementations reduce chip areas 30–40%. For example, in [7], a math co-processor uses a mask-gate-area-programmable quaternary ROM that provides an approximately 31% ROM area savings compared to a binary ROM. No system speed penalty was incurred because the slower MVL ROM is fast enough to respond within the time budgeted for ROM data lookup. In [9], the 256 K four-valued ROM is said to have minimal speed loss due to careful design of the ROM architecture, the sense amp operation, and the data decoder output circuit design. Chip area savings of this four-valued ROM is approximately 30%.

Both programming approaches provide significantly increased bit density compared to binary ROM. The speed of the four-valued ROM is inherently reduced because the increased complexity of the column read amplifiers, the increased capacitance of the larger memory cell transistors, and the reduced drain current created by the memory cell transistors with large threshold voltages. Designers have minimized the speed penalty with thoughtful chip architecture design and careful transistor level circuit performance optimization. The improved capabilities demonstrated in these four-valued ROM designs motivated the use of four-valued data storage in the EEPROM and flash memories discussed next.

## Multiple-Valued EEPROM and Flash Memory

Binary and multiple-valued EEPROM [11–13] circuits are used in successful commercial products. Many of them are organized for the simultaneous electrical erasure of large blocks of cells and are called “flash memory.” Multiple-valued flash memory circuits provide greater memory density, at lower incremental cost, than the binary versions. The circuitry of multiple-valued ROM and multiple-valued EEPROM structures are very similar to each other and very similar to their binary counterparts. Development of commercially viable binary and MVL flash memory products has required extensive research in device physics and fabrication technology. That research continues and we see continual improvements in commercial flash memory products. Summary and overview discussions of flash memory [11] and multilevel flash memory [12] examine many of the inter-related effects and important tradeoffs that must be considered. Here, we discuss the principles of operation and do not attempt to explain in detail any of these evolving and complex issues.

In multiple-valued flash memory circuits, the floating gate of each EEPROM memory cell transistor is charged to one of the multiple values that creates one of the several memory cell transistor threshold voltages. Each memory cell transistor, when driven with the specified read gate voltage, generates one of the multiple logical drain current values. The multiple-valued drain currents are then decoded by a current sense amplifier column read circuit. The sense amplifier serves as an analog-to-digital converter that translates the multiple-valued drain current into an equivalent set of binary logical output signals with voltages compatible with the rest of the computing system. Four-valued signals are most commonly used. A few 16-valued EEPROM memory cells have been examined [13] and a 256-valued EEPROM “analog memory” has been used in a commercial analog audio storage product [14].

Precise control of the charge on the nonvolatile FET’s floating gate is necessary to create one of the multiple distinct effective cell transistor threshold voltage values needed. Each nominal threshold voltage value will have a distribution of voltages around that target value. Noise margins, separations between adjacent threshold voltage value distributions, diminish as the number of logical values increases. It is necessary to keep the distribution narrow and to maintain adequate distances between the adjacent threshold voltage value distributions. Research is underway to develop a self-limiting programming technique, but at the present time programming of the floating gate is usually done with an iterative program and verify procedure. A programming voltage is applied for a fixed period of time, and the resultant programmed value is read by the column sense amp. If the desired threshold voltage is reached, then programming ends. If not, then another programming voltage pulse is applied and the programmed verified. The iterative procedure ends when the verify step indicates the correct programmed threshold voltage has been created.

Reading a stored multiple valued logical signal can be accomplished with any analog to digital process, such as that described above for the four-valued ROM. This simple approach uses as comparator threshold references three reference currents that lie between the four logical values of the drain current. This common “thermometer” arrangement of three comparators produces simultaneously three comparison results that are easily decoded into arbitrary two-bit binary output combinations. This simultaneous comparison of the data drain current to the references is the fastest approach to detecting the stored data. These column read amplifiers are more than twice as complicated as the binary versions. Another approach is to drive the memory cell’s read signal from its minimum value to its maximum value with a series of steps or a ramp. Times when the read signal voltage exceeds each memory cell’s possible programmed threshold voltages are known by design. When the single read amplifier comparator senses any current at the prescribed time, the programmed logical signal value has been detected. The column read amplifier used with this approach requires only one comparator, one threshold, and thus fewer devices, but requires more time than the simultaneous conversion described previously.

Compared with binary realizations, four-valued flash memory circuits have been shown to require 50% of the memory area, about 115% of the read circuit area, and have access times from about 100% to 150%. The fabrication technology is more complicated, requiring two additional memory cell threshold voltages. These 2 additional threshold voltages can be accomplished with only one additional implant.

Thus, four-valued flash memory can provide significantly increased memory density at a moderate increase in fabrication technology complexity.

For most new chip designs to be useful and attractive, they must be compatible with the signal swings and logic levels of standard binary logic families and use compatible power supply voltages. Thus, looking at the potential of MVL realistically, we expect few designers to risk using MVL logic signaling at the package pins (except possibly in a testing mode). The most likely situation in which MVL would be used is one in which binary signaling is done on the chip pads, some functions are realized with standard binary circuitry, and certain other functional modules are realized more advantageously with MVL. Rather than attempt to develop a family of MVL circuits that are logically and computationally complete, we have examined the realization of specific MVL functions that we believe provide advantages now and may provide advantages in the future. With the predominance of CMOS fabrication technologies and the continued decline of system and chip power supply voltages, signal processing with multiple-valued currents appears to be more naturally compatible with the evolving design environment than other approaches to MVL. Thus, current-mode CMOS MVL circuits are the focus of the remaining part of this presentation.

### 11.3 Current-Mode CMOS Multiple-Valued Logic Circuits

---

Current-mode CMOS circuits in general are receiving increasing attention. Current-mode CMOS MVL circuits [15] have been studied for over two decades and may have applications in digital signal processing and computing. Introduced in 1983 [16], current-mode CMOS MVL circuits were demonstrated that are compatible with the requirements for the VLSI circuits [17]. Various approaches to realizing current-mode CMOS MVL circuits have been discussed since then, and signal processing and computing applications of current-mode MVL have been evaluated. A convincing demonstration of the advantages of current-mode CMOS MVL is the  $32 \times 32$  multiplier presented in [18]. This  $32 \times 32$  multiplier chip is half the size of an equivalent all-binary realization, dissipates half the power, and has a multiply time within 5% of the fastest reported all-binary multiply time of a comparable design of that era. These advantages arise from the combination of two ideas. The authors use a signed-digit number system ( $\pm 2, \pm 1, 0$ ) and symmetric functions [19] to streamline the multiplier algorithm and architecture, and to limit the propagation of carries. They then use multiple-valued bi-directional current-mode CMOS circuits to efficiently realize the function of addition. Addition of currents requires no components. Addition is the principal operation performed in the multiplier, so the current-mode MVL advantage in addition helps make the multiplier realization more area efficient. Thus, advantageous use of MVL usually requires finding its niche. For example, in the pipelined discrete cosine transform (DCT) chip designed using current-mode CMOS MVL circuits described in [20], it is the pipelined nature of the realization of the DCT and inverse DCT functions that makes using MVL potentially feasible. Since the maximum system clock is set by the longest delay required for any pipeline stage, as long as the slightly slower MVL current-mode CMOS adders and multipliers meet this timing requirement, then MVL circuits may be used to provide major area savings in realizing adders and multipliers.

Current-mode CMOS MVL circuits are often used to realize threshold functions. The two basic operations of a threshold function are: (1) the formation of a weighted algebraic sum-of-inputs, and (2) comparison of this sum to the multiple thresholds that define the MVL function to be realized. Current-mode CMOS MVL circuits use an analog current summing node to create the algebraic weighted-sum-or difference-of-input currents using Kirchoff's current law. This function is "free" because it requires no active or passive components. Uni- and bi-directional currents may be defined in each branch. The currents are usually defined to have logical levels that are integer multiples of a reference current. Currents may be copied, scaled, complemented, and algebraically sign changed with simple current mirror circuits realized in any MOS technology. Use of depletion-mode devices could sometimes simplify circuit design if they are available in the fabrication technology [18]. The weighted sum or difference of currents is then usually decoded into the desired MVL output function by: (1) comparing it to multiple current thresholds using some form of current comparator, and (2) using comparator-controlled switches to

direct properly scaled and logically restored currents to the outputs. The variety of current-mode MVL circuits reported by various authors over the past decade use various combinations of these three operations (algebraic sum, compare to thresholds, and switch correct logical current values to the outputs) to realize all the circuit functions reported.

Most current-mode CMOS MVL circuits have the advantage that they will operate properly at proposed reduced CMOS power supply voltages. Critics of current-mode CMOS binary and MVL circuits worry that static current-mode circuits dissipate DC power. Dynamic current-mode CMOS circuits use additional clocked pairs of transistors and additional clock signals to reduce or eliminate DC power dissipation. Current-mode CMOS circuits have a fanout of only one, yet, if the loading is known in advance as is often the case in VLSI design, circuits may be designed very easily with the appropriate number of individual outputs. Given all the possible advantages and disadvantages of current-mode CMOS circuits, it is apparent that they warrant continued study. We do not propose that current-mode CMOS MVL circuits be used, in general, as a replacement for binary voltage-mode CMOS circuits. We do, however, claim that it may be advantageous in some situations to imbed current-mode CMOS MVL circuits in a binary design. In the discussions that follow, we review several of the input/output compatible current-mode CMOS MVL circuits that we have studied over the past decade. These current-mode CMOS circuits, reviewed in [15], include a simple current threshold comparator [16], MVL encoders and decoders, quaternary threshold logic full adders (QFAs), current-mode MVL latches, latched current-mode QFA circuits, and current-mode analog-to-quaternary converter circuits. Each of these circuits is presented and its performance described. In the next section, the simple current threshold comparator circuit is described.

## CMOS Current Threshold Comparator

A key component in the design of current-mode MVL threshold circuits is the current comparator [16], or current threshold detector. Performance limitations of the current comparator will determine our MVL threshold circuits' ability to discriminate between different input current levels. The current comparator's operation is now summarized. The simplest form of the current comparator circuit, shown in Fig. 11.2, is made up of the diode-connected input NMOS transistor  $M_1$ , and NMOS transistor  $M_2$  connected to replicate this input current, a reference or threshold current generating pair of transistors  $M_3$  and  $M_4$ , and a PMOS transistor  $M_5$  that replicates the reference or threshold current. The current in the input mirror transistor  $M_2$  limits at the threshold value as the comparator switches. The drains of the PMOS replicating transistor  $M_5$  and NMOS replicating transistor  $M_2$  are connected to generate the comparator circuit's output voltage. This comparator circuit is to provide a logical HIGH output voltage when the input current is less than the threshold current and a logical LOW output voltage when the input current is greater than the threshold current. (To make a current comparator that gives a logical HIGH output voltage when the input current is greater than the threshold current and a logical LOW output voltage when the input current is less than the threshold current we can simply reverse the roles of the NMOS and PMOS transistors.) Greatest comparator discrimination is obtained by using maximum comparator gain. This current comparator configuration converts the input current to a voltage,  $V_{GS1}$ , that drives a common-source amplifier with an active load. An equivalent way to describe the operation of this circuit is to consider it a current mirror that reproduces  $I_{in}$  as  $I_D$ , and  $I_D$  then drives a high-impedance active load to convert the current difference to an output voltage. We can analyze the comparator to find the transresistance amplifier gain,  $R_o$ , to be the parallel combination of the output resistances of the NMOS driver and PMOS load devices:

$$R_o = (I_D(\lambda_p + \lambda_N))^{-1}$$

where  $\lambda$  represents the channel length modulation effect and has units of  $V^{-1}$ . A large gain is desired to provide a sharp comparator transition and greater noise margin. Lower threshold current values will increase the gain at the expense of greater comparator delay times when driving a constant load. Use of higher

FIGURE 11.2 CMOS current comparator.

output impedance current sources improves the gain, but reduces the output voltage swing and increases the comparator delay. Our characterization of test circuits with threshold currents between 5 and 100  $\mu\text{A}$  fabricated in 2- $\mu\text{m}$  p-well CMOS shows best input-current/output-voltage propagation delays of approximately 2 ns. The best reported delay performance of a similar circuit that defines the output as the difference of the two drain currents, not the drain voltage, has been reported to be 500 ps in a ring oscillator [21] realized in 2- $\mu\text{m}$  p-well CMOS.

To improve the delay performance of the comparator, we may provide a DC bias current to the input transistor to keep it biased in a conducting state. The change in input current then exceeds the bias-shifted reference threshold current. Delay improvements of more than 50% have been observed.

MVL circuits often realize threshold logic functions with several thresholds. This requires the comparison of the input current to several different threshold currents. It is possible to simply replicate the input current as many times as needed and compare these multiple copies of the input current to the set of increasingly larger threshold currents. Increased threshold current reduces the comparator gain. To keep gain higher, it is also possible to scale the input current to several different values (some of which may be smaller than the input) and then compare these scaled input currents to a set of smaller reference threshold currents. Design strategies that scale the input current and the threshold currents may be developed to optimize area, speed, and total current. For ease of explanation in this presentation, our discussions present the simplest approach: merely duplicating the input current and creating a set of linearly spaced, increasingly larger reference threshold currents.

Current comparators are a critical part of the current-mode MVL circuits presented here. This circuit with a standard CMOS inverter can also be used for current-to-voltage conversion when going from a current-mode MVL section back into a binary section of a chip. In the section that follows, we will describe the operation of CMOS current-mode binary/quaternary encoder/decoder circuits.

## Current-Mode CMOS Binary/Quaternary Encoders and Decoders

Quaternary-valued logic has the potential to increase the functional density of metal-limited digital integrated circuit layouts by reducing by almost 50% the number of signal interconnections required. The use of MVL input and output signals could also reduce the number of chip package pins required. It may be possible to use standard logical voltage swings at the package terminals during normal operation, and then use four-valued signaling during off-line testing. On-chip conversion from binary voltages to quaternary currents that would be used in a current-mode quaternary logic module can be done easily as shown below. With both on- and off-chip interfaces in mind, we have described current-mode [15] and voltage-mode CMOS circuits that perform the functions of encoding two binary signals into an equivalent four-valued (quaternary) signal for transmission to another location or use in a quaternary logic circuit like a multiplier, for example, and the decoding of this transmitted quaternary signal back into its equivalent two binary signals. Various encodings of the two binary signals are possible and several provide easier decoding. In this presentation of the encoder-decoder circuit combination we have assumed for simplicity of discussion that any two binary signals may be represented by a binary-weighted number. That two-bit number can then be encoded into a single-digit base-four equivalent number. The encoder-decoder circuit combination to be described is designed to serve both on-chip and off-chip interface functions. With proper scaling of device areas the encoder circuit can drive larger capacitive loads with reduced propagation delays and the decoder can maintain its high degree of logical discrimination.

Current-mode CMOS binary-to-quaternary encoder and quaternary-to-binary decoder circuits operate as follows. A schematic of the encoder circuit is shown in Fig. 11.3. A reference current is established and duplicated by transistors  $M_1$ – $M_4$ . The current in  $M_4$  is twice as large as that in  $M_3$ . The encoder's two binary CMOS logic signals that are to be encoded are input to the pass transistors  $M_5$  and  $M_6$ , where the signal assigned the most significance is applied to the gate of  $M_6$ , which will pass the doubly-weighted current. The pass transistor sources are tied together to form the analog sum of the currents, the four-valued output current signal,  $I_o$ .

The encoder's quaternary output current is connected either on-chip or off-chip to the compatible current comparator section of the decoder circuit shown in a schematic in Fig. 11.4. The four-valued input current is applied to the drain of the decoder's input transistor  $M_7$ .  $M_7$  then drives three current comparators [16] made up of transistor pairs  $M_8$ – $M_9$ ,  $M_{10}$ – $M_{11}$ , and  $M_{12}$ – $M_{13}$ . The common-drain connection of each current comparator transistor pair is labeled *A*, *B*, and *C*, respectively. Voltages *A*, *B*, and *C* will remain HIGH as long as the input current is less than one-half the logical output current increment, *I*. For an input current greater than  $0.5I$ , *A* will go LOW, while voltages *B* and *C* remain HIGH. For an input current greater than  $1.5I$ , *B* will also go LOW and *C* will remain HIGH. Input currents greater than  $2.5I$  will drive *C* to the LOW state and all three comparators will be LOW. The three CMOS-compatible logical voltages *A*, *B*, and *C* then drive three standard CMOS decoding logic gates shown in Fig. 11.5. The decoding logic recreates the two binary logical voltages in the same order of significance that they were applied. Obviously there is a variety of possible encodings that require decoders of more or less complexity that may be chosen to satisfy a variety of different requirements. In this presentation we are, for simplicity, using binary- and quaternary-weighted number equivalents.

Transistors  $M_{14}$  and  $M_{15}$  in the decoder circuit schematic, Fig. 11.4, establish a reference current,  $2I$ , that is mirrored by factors 0.25, 0.75, and 1.25 by transistors  $M_9$ ,  $M_{11}$ , and  $M_{13}$ , respectively, to establish the three threshold currents. For the *A* logical output, the threshold current  $I_{TH_A}$  is  $0.5I$ . For *B* and *C* outputs, the threshold currents are  $I_{TH_B} = 1.5I$  and  $I_{TH_C} = 1.5I$ , respectively. In the encoder-decoder shown in the figures, we are using logical levels of 0, 10, 20, and  $30\ \mu\text{A}$ . Current comparator *C* is to provide HIGH output voltage for input currents less than  $25\ \mu\text{A}$  and a logical LOW voltage for input currents greater than  $25\ \mu\text{A}$ . Thus, the threshold current for current comparator *C* is  $25\ \mu\text{A}$ .

**FIGURE 11.3** Current-mode CMOS binary-to-quaternary encoder.

One can increase the interface driving current,  $I_{IN}$ , by, for example, an order of magnitude to provide increased capacitive loading drive capability independently of the threshold currents and still maintain the same comparator current levels and gain by appropriately designing the width-to-length ratios of transistors  $M_7$  and transistors  $M_8$ ,  $M_{10}$ , and  $M_{12}$ . The comparators and decoder performance will be unchanged. For example, using  $10I_{IN}$  instead of  $I_{IN}$  for interfacing, we will need to increase the width of  $M_7$  by a factor of 10. This feature allows considerable design flexibility. We could apply the same technique to each comparator to give them all the same low quantity of drain current and, thus, the same high value of gain and still detect the same three input current levels selected previously. The trade-off here is the reduced load driving current available in the scaled-down current comparators. If the comparator drives only an inverter, then this is not a significant problem. These scaled-down threshold currents are not used in the circuits discussed here. Decoders may also use an input bias current to speed-up the circuit's response [16]. When a bias current is used all the thresholds must also be shifted.

A variety of current-mode CMOS encoder/decoder pairs have been fabricated and characterized. One group was fabricated in 1985 in a standard 5- $\mu\text{m}$  polysilicon-gate p-well CMOS technology. Large- and small-current current-mode, encoder–decoder circuit pairs with and without bias currents were included. Small-current, encoder–decoder pairs using nominal 10  $\mu\text{A}$  incremental currents are realized with: (1) no bias current, and (2) a 5  $\mu\text{A}$  bias current. Large-current, encoder–decoder pairs designed for driving off-chip

FIGURE 11.4 Current-mode CMOS quaternary-to-binary decoder.

loads of 100 pF that use nominal 3 mA incremental currents are realized with: (1) no bias current, and (2) a 50  $\mu$ A bias current. The encoder and decoder circuits operated exactly as predicted. Propagation delay of binary/quaternary encoder-decoder circuits has been defined as the 50–50% delay time from the incidence of the simultaneous binary encoder inputs to the generation of the last binary decoder output. Worst-case propagation delay is experienced when the encoder output changes three full increments of output current. Propagation delays of our current-mode, encoder-decoder circuit pairs have been measured with the encoder output and decoder input package pins wired together on a breadboard. Thus, the encoder circuit drives off-chip, through the package, to a board, back through the package, on-chip, and lastly the decoder circuit. Typical values of CMOS-voltage-input-to-CMOS-voltage-output propagation delay exhibited by the small-current (intended for on-chip use) encoder-decoder pairs without and with bias current driving off-chip are about 375 and 275 ns, respectively. Because the large-current, encoder-decoder circuits were designed to drive PC board loads of 100 pF, we have examined the large-current, encoder-decoder circuit pairs loaded as outlined previously with an additional capacitance load of nominal value 100 pF connected from the I/O node to ground. Under this loading condition, typical values of delay exhibited by the large-current encoder-decoder circuits without and with bias current are about 48 and 30 ns, respectively. Although the use of large signaling currents may not be attractive to many designers, the option is available and may be of value in some situations.

One might use encoder/decoder circuits to increase the information on a signal line. Current summing at a node is a “free” computation that may be exploited in circuits that realize threshold logic functions as we will see in the next section where we summarize the quaternary threshold logic full adder.

### Current-Mode CMOS Quaternary Threshold Logic Full Adder

Some operations in digital signal processing and computing are more amenable than others to implementation with quaternary threshold logic. For example, by using the summing of logical currents, adding and counting may be efficiently implemented. The quaternary threshold logic full adder (QFA) adds the values of two quaternary inputs  $A$  and  $B$ , and the value of a binary carry input,  $C$ , and produces a

FIGURE 11.5 Current-mode CMOS quaternary-to-binary decoder logic.

two-quaternary-digit output,  $CS$ , that is the base-four value of this sum of the inputs. Logical currents have been used in QFA circuits realized with integrated injection logic ( $I^2L$ ) (see, for example, [22]), current-mode logic (CML), and current-mode CMOS [15]. The well-known QFA function is summarized below.

The QFA circuit to be described implements threshold functions. The two basic operations of a threshold function are the formation of a weighted-sum-of-inputs and the comparison of that weighted-input-sum to the multiple thresholds. The QFA adds two quaternary inputs  $A$  and  $B$  and a binary input carry  $C_i$  to produce a weighted-input-sum within the range 0–7. Representing this weighted sum in base-four with the two-digit output  $CS$  requires the CARRY,  $C$ , output to assume only binary values ZERO and ONE, while the SUM,  $S$ , output will assume values ZERO, ONE, TWO, and THREE. The DC input-output transfer function for the ideal QFA is shown in Fig. 11.6. Several organizations of threshold detectors can be used to generate this two-digit output from the eight-valued weighted-sum-of-inputs. We will summarize the operation of two approaches to realizing this function with combinations of complementary MOS transistors serving as current sources and threshold detectors, and standard CMOS logic gates.

The first QFA discussed, shown in Fig. 11.7, is a direct implementation of the QFA definition. The input summing-node combines logical current inputs that are integer multiples of a reference current.

FIGURE 11.6 Current-mode CMOS quaternary threshold logic full adder I/O transfer characteristic.

FIGURE 11.7 Current-mode CMOS quaternary threshold logic full adder schematic.

The sum-of-logical-inputs must lie between ZERO and SEVEN times the reference current. This sum-of-currents,  $I_{in}$ , is received and mirrored by input transistor  $M_1$  to replicate the input current seven times by identical NMOS transistors  $M_2$ – $M_8$ . These seven identical copies of the input current are the inputs to seven current comparators [15] that compare the input weighted sum to the seven thresholds. The other halves of these comparators are PMOS transistors  $M_9$ – $M_{15}$ . The comparators generate seven binary voltage swings,  $A$ – $G$ , that are capable of driving standard CMOS logic gates. Comparator output signal  $\bar{D}$  controls the CMOS transmission gate that connects a unit value of logical current to the CARRY output line. The seven logical comparator output signals are combinationally reduced in groups of three variables with three standard CMOS logic gates to a set of control signals,  $X$ ,  $Y$ , and  $Z$  [ $\bar{X} = (A + \bar{D})E$ ,  $\bar{Y} = (B + \bar{D})F$ ,  $\bar{Z} = (C + \bar{D})G$ ], that connect three current sources of unit reference value to the SUM output line through three CMOS transmission gates. Logical currents of 10, 20, and 30  $\mu\text{A}$  are used in the QFA presented in this paper, requiring threshold currents of 5, 15, 25, 35, 45, 55, and 65  $\mu\text{A}$ . Gains of

FIGURE 11.8 Current-mode CMOS quaternary threshold logic full adder with feedback schematic.

comparators realized with simple Widlar current mirrors of four-micron channel lengths and greater have been found to be adequate to resolve the eight-valued signals used in this circuit.

One potential problem with this QFA is the possible error accumulation involved with the analog summing of seven logical currents at a node; the higher the logical value of the weighted-sum-of-inputs, the greater error possible in the sum of currents. For increasing threshold current the current comparator circuits exhibit decreasing gain, and therefore reduced ability to discriminate the threshold function. The QFA has less accuracy in discriminating the presence of the higher valued weighted sums of inputs. To compensate for this decreasing gain with increasing threshold currents, we examine a feedback technique which eliminates the need to use the three largest values of threshold currents.

A schematic of one version of this QFA modified with feedback is shown in Fig. 11.8. In the figure we see that a current of four logical units in value is combined with a copy of the weighted-sum-of-inputs to create a new input current that is  $I_{in2} = (I_{in} - 4)$  when the weighted sum of inputs exceeds logical four. The same three lowest threshold current comparators with greatest gain can now be used to generate the entire range of QFA SUM outputs. The QFA circuit with feedback operates as follows. The threshold current for the “D” comparator that controls the CARRY output is generated by PMOS transistor  $M_3$ . The input is first compared to this threshold to determine whether the input range is above or below 4. If the input is below 4, the output  $D$  is in the HIGH state.  $D$  is inverted to drive a pair of transmission gates; one controls the CARRY output current, the other controls the four units of logical current that are fed into the drain of  $M_6$ . At the drain of  $M_6$ , this feedback current is summed with a copy of the input current to form the total drain current of  $M_6$ . If the CARRY output is ZERO, no current is fed back and the  $M_6$  drain current is equal to the input current. Let us assume for this discussion that the input current is, for example, logical six. The input current will be mirrored by  $M_6$  to generate a total drain current of logical six. Since the  $D$  comparator has switched to turn on the CARRY output, the feedback current transmission gate is also conducting the logical four feedback current into the node at the drain of  $M_6$ . The excess current (logical six minus logical four = logical two) must be provided by transistor  $M_8$ .  $M_8$  is a diode connected PMOS transistor that serves as the input to the three current comparators that generate outputs  $A$ ,  $B$ , and  $C$ . These comparators operate exactly as described previously except that the roles of the PMOS and NMOS transistors and thus the  $A$ ,  $B$ , and  $C$  voltage swings have been reversed. The PMOS devices  $M_9$ – $M_{11}$  serve as the input devices while the NMOS devices  $M_{12}$ – $M_{14}$  serve as the current reference devices. This feedback technique eliminates the CMOS logic stage that encodes the comparator outputs into controls signals for the transmission gates that then switch the logical current outputs onto the SUM output line. The three largest current mirror transistors are also eliminated. The propagation delays

observed with these circuits are about 20% longer than those observed with the nonfeedback version of the QFA.

Several variations of the QFA circuits that used several different logical currents were fabricated in 1985 in a standard 5- $\mu\text{m}$  polysilicon-gate p-well CMOS technology and others using 10  $\mu\text{A}$  logical currents in MOSIS 2- $\mu\text{m}$  p-well technology. These simple current-mode test circuits are intended to drive each other on-chip with small logical current increments; most examples use only 10  $\mu\text{A}$ . Some individual test circuits are connected to input and output pads and package leads. This configuration allows examination of all important comparator and current signals and is intended for DC and low-frequency functional characterization, not for maximum operating speed evaluation. Gains of comparators realized with simple Widlar current mirrors of 4  $\mu\text{m}$  channel lengths and greater have been found to be adequate to resolve the eight-valued signals used in this circuit. Since logical currents vary in only 10  $\mu\text{A}$  increments, the circuits have insufficient capability to drive off-chip loads. Thus, meaningful on-chip delays can not be measured with these test circuits. Propagation delay is defined as the time between the midpoint of the transition between two adjacent input logic levels to the midpoint of the transition between two adjacent output logic levels. For example, if the output switches from logical ZERO to logical THREE, then the midpoint between TWO and THREE is used in the propagation delay measurement. To obtain realistic on-chip delays, we used a chain of  $N$  cascaded QFA circuits connected between an input pad and an output pad. This configuration does not allow examination of internal signals. We also used a delay test path that is a direct on-chip connection between an input pad and an output pad. The delay through the I/O only path is subtracted from the total delay measured for the group of  $N$  QFA circuits. This difference is approximately the total delay through  $N$  latched QFA circuits. The average delay of an individual latched QFA circuit may then be calculated. Under these conditions, using test circuits with 4  $\mu\text{m}$  channel lengths, propagation delay times for single logic level transitions (ZERO-ONE, ONE-TWO, etc.) of about 35 ns have been measured. In simulations of circuits with the same device sizes and using another QFA as a load, single logic level transitions were simulated to have delay times of about 10 ns, and worst-case propagation delay times were found to be about 60 ns for full-scale (ZERO-SEVEN, SEVEN-ZERO) input current signal transitions. To reduce delay times as much as 25%, we can include at the input a DC bias current source of one-half the logical current value to keep the input transistors always in the conducting mode, and shift the threshold currents by an equal amount.

## Current-Mode CMOS Multiple-Valued Latch

Although the use of current signals allows easy and area efficient formation of the multiple-valued sum of signals, storage of the information in this quantized analog signal might require storage of a set of binary signals if it were not for multiple-valued memory circuits [15] similar to that described next. A current-mode CMOS multiple-valued memory circuit organization is shown in a block diagram in Fig. 11.9. When clock signal  $\phi$  is at a CMOS logical HIGH, the memory is in the SETUP mode. In the SETUP mode, the circuit accepts a multiple-valued input current  $I_{\text{in}}$  and, with a quantizer, regenerates it as a feedback current,  $I_f$ , and an output current,  $I_{\text{out}}$ . When the clock signal  $\phi$  goes to a CMOS logical LOW, the circuit goes into the HOLD mode. In the HOLD mode, the input current is disconnected from the quantizer and the regenerated current  $I_f$  is switched to the input of the quantizer. This positive feedback circuit now holds the value of the input current that appeared during the preceding SETUP cycle. Changes in the input current  $I_{\text{in}}$  during the HOLD mode do not alter the latch's output until a new SETUP cycle is entered. The memory circuit's quantizer is chosen to accommodate the range defined for the input current. We will summarize first the more easily described four-valued current-mode memory circuit [15]. An eight-valued, current-mode memory circuit will be presented in the discussion of the latched QFA.

A current-mode CMOS quaternary threshold logic latch circuit is shown in Fig. 11.10. Consider the situation in which the clock signal,  $\phi$ , is logically HIGH and the latch is in the SETUP mode. Transistor  $M_1$  receives the input current,  $I_{\text{in}}$ , and in response generates a voltage  $V_{\text{GS1}}$  that is coupled through pass transistor  $M_{11}$  to the input of the quantizer portion of the latch. Under these conditions the input current

FIGURE 11.9 Current-mode CMOS quaternary latch block diagram.

FIGURE 11.10 Current-mode CMOS quaternary latch schematic.

$I_{in}$  is reproduced as  $I'_{IN}$  by transistors  $M_2, M_3,$  and  $M_4$ , the three NMOS current mirror inputs to the three current comparators in the quantizer. The current comparators' thresholds are set to detect input currents of logical values ONE, TWO, and THREE by the three PMOS current sources  $M_5, M_6,$  and  $M_7$ , respectively. As the input current exceeds the threshold of each comparator, each comparator output falls to a logical LOW and the current in each mirror transistor  $M_2, M_3,$  and  $M_4$  limits at the threshold value. Each comparator drives a standard CMOS inverter, with output labels  $A, B,$  or  $C$  in the schematic, which, in turn, drives a pass transistor with input labels  $\bar{A}, \bar{B},$  or  $\bar{C}$ . Each of these pass transistors, when activated, passes the appropriate quantity of current to the feedback summing node to form regenerated current  $I_F$ . Regenerated current  $I_F$  is mirrored by transistors  $M_8, M_9,$  and  $M_{10}$  to generate the latch output current,  $I_{out}$ . The  $\bar{\phi}$  signal turns off pass transistor  $M_{99}$ , and the regenerated current is isolated from the comparator input.

Clock signal  $\phi$  is then set LOW to HOLD the multiple-valued current data. With  $\phi$  LOW and  $\bar{\phi}$  HIGH, transistor  $M_{11}$  is off, disconnecting input transistor  $M_1$  from the quantizer, and transistor  $M_{99}$  is on, connecting the regenerated current to the quantizer input. Because the quantizer and  $I_F$  are in a positive feedback loop, the regenerated current,  $I_F$ , and the output current,  $I_{out}$ , remain stable at the value of the previous input current.

A variety of forms of the current-mode latched QFA circuit has been designed, fabricated in a standard 2- $\mu\text{m}$  polysilicon-gate, double-metal CMOS process, and tested. These simple current-mode test circuits are intended to drive each other on-chip with small logical current increments of only 10  $\mu\text{A}$ . Logical currents of 10, 20, and 30  $\mu\text{A}$  are used in the quaternary latch, requiring threshold currents of 5, 15, and 25  $\mu\text{A}$ . Gains of comparators realized with simple Widlar current mirrors of 2- $\mu\text{m}$  channel lengths have been found to be adequate to resolve the four-valued signals used in the latch circuit. For purposes of oscilloscope display, the quaternary output current is driven into nominally 10 k $\Omega$  resistors connected

**FIGURE 11.11** Current-mode CMOS quaternary\_latch output waveforms: (a) Quaternary latch output and  $\bar{\phi}$  holding a ZERO, (b) Quaternary latch output and  $\bar{\phi}$  holding a ONE, (c) Quaternary latch output and  $\bar{\phi}$  holding a TWO, and (d) Quaternary latch output and  $\bar{\phi}$  holding a THREE.

on a standard prototyping board. The waveforms in Fig. 11.11 show a sequence of HOLD operations at times necessary to hold each of the four possible values of the output. In each photo, the pulse in the lower trace is  $\bar{\phi}$ , which goes HIGH to HOLD the value of the output signal at that time. SETUP and HOLD times have been inferred from measured experimental data to be about 10 ns for single level transitions and about 35 ns for ZERO-THREE and THREE-ZERO transitions.

### Current-Mode CMOS Latched Quaternary Logic Full Adder Circuit

The current-mode CMOS latched QFA circuit is described with the aid of the block diagram in Fig. 11.12. The single output quaternary quantizer shown in Fig. 11.9 is replaced by a modified QFA circuit that serves as the quantizer, creating the feedback current and the quaternary full adder outputs. Again, the latched QFA circuit is in the FOLLOW mode when  $\phi$  is HIGH and  $\bar{\phi}$  is LOW. The circuit is in the HOLD

(d)

FIGURE 11.11 (Continued)

mode when  $\phi$  is LOW and  $\bar{\phi}$  is HIGH. In the block diagram, an eight-valued weighted sum of input currents,  $I_{in}$ , enters the QFA's diode connected NMOS input transistor  $MN_A$  generating a gate-to-source voltage  $V_{GSA}$ . When in the FOLLOW mode  $\phi$  is high, turning on NMOS pass transistor  $MN_B$ , coupling  $V_{GSA}$  to the input of the QFA block as input voltage  $V_1$ . In the FOLLOW mode, the input is converted by the combinational QFA circuit to the quaternary SUM and CARRY output currents. A quantized regenerated feedback current,  $I_F$ , is also created by the QFA block to logically replicate the input current. Simultaneously, the feedback current,  $I_F$ , generates  $V_{GSC}$  in the diode-connected NMOS transistor  $MN_C$ .  $\bar{\phi}$  is LOW disconnecting  $V_{GSC}$  from the  $V_1$  QFA input node. In the HOLD mode, with  $\phi$  LOW and  $\bar{\phi}$  HIGH, transistor  $MN_B$  is off, disconnecting the effect of the input current from the input of the QFA. Transistor  $MN_C$  is on, connecting the  $V_{GSC}$  created by the regenerated feedback current,  $I_F$ , to the  $V_1$  QFA input. Thus, in the HOLD mode  $I_F$  regenerates itself with positive feedback through the nonlinear quantizer in the QFA block. The QFA block in Fig. 11.12 may be realized with a slight modification of the first QFA presented in this paper. The QFA section of the latched QFA is described next.

FIGURE 11.12 Current-mode CMOS latched QFA: block diagram.

FIGURE 11.13 Current-mode CMOS latched QFA: QFA-block schematic.

A simple combinational QFA circuit [15] is shown in Fig. 11.13 that includes a sub-circuit that creates the regenerated feedback current,  $I_F$ , allowing the capability of latching the eight-valued input current. Notice in Fig. 11.13 that only four current sources and four transmission gates are used to create the regenerated feedback current that allows latching. The transmission gates are controlled by the same control signals that control the SUM and CARRY outputs. At the  $I_F$  summing node, signals  $X$ ,  $Y$ , and  $Z$  each control one unit of current as is done at the SUM current summing node, thus reproducing the least significant digit of the two quaternary digit number represented by the pair of QFA output currents. The CARRY output is weighted four times the SUM output. In Fig. 11.13, we see that  $\bar{D}$ , the CARRY control signal, also controls the passage of four units of current to the  $I_F$  summing node. Thus, at the  $I_F$  summing node, the input current is requantized by the threshold current comparators and its logical value regenerated as  $I_F$  by the current sources and transmission gates. The clock signal controls the input to the threshold current comparators. In the FOLLOW mode, the input current is converted by the QFA circuit to the quaternary SUM and CARRY output currents, and requantized to create regenerated feedback current,  $I_F$ . In the HOLD mode,  $I_F$  regenerates itself and the QFA outputs with positive feedback through the nonlinear quantizer in the QFA circuit.

Logical currents of 10, 20, and 30  $\mu\text{A}$  are used in the latched QFA circuit presented here, requiring threshold currents of 5, 15, 25, 35, 45, 55, and 65  $\mu\text{A}$ . Gains of comparators realized with simple Widlar current mirrors of 4  $\mu\text{m}$  channel lengths and greater have been found to be adequate to resolve the eight-valued signals used in this circuit.

A variety of forms of the current-mode latched QFA circuit has been designed, fabricated in a standard 2- $\mu\text{m}$  polysilicon-gate, double-metal CMOS process, and tested. These simple current-mode test circuits

are intended to drive each other on-chip with small logical current increments of only  $10\ \mu\text{A}$ . Our individual test circuits are connected to input and output pads and package leads. This configuration allows examination of all important comparator and current signals and is intended for DC and low-frequency functional characterization, not for maximum operating speed evaluation. Since logical currents vary in only  $10\ \mu\text{A}$  increments, the circuits have insufficient capability to drive off-chip loads. Thus, meaningful on-chip delays must be inferred as described earlier. Test circuits with devices the same size as those used in the QFA yield SETUP about the same as the QFA delay times, and HOLD times of approximately zero. To reduce delay times as much as 25%, we can include at the input a DC bias current source of one-half the logical current value to keep the input transistors always in the conducting mode, and shift the threshold currents by an equal amount.

Maximum DC power required for the current-mode CMOS latched QFA circuit shown in Figs. 11.12 and 11.13 may be calculated as the product of the 5 V supply and the maximum DC current through the circuit. If we consider the input current,  $I_{\text{in}}$ , to be supplied by the output of another QFA, the maximum DC current occurs when  $I_{\text{in}}$  and thus  $I_F$  are at logical SEVEN. Using nominal logical current increments of  $10\ \mu\text{A}$ , the maximum DC current under these conditions is the sum of the following currents (in  $\mu\text{A}$ ): 70 in  $I_F$ ; 30 in SUM; 10 in CARRY; 5, 15, 25, 35, 45, 55, and 65 in the seven current comparators; and 20 in the current source bias circuit for a total current of  $375\ \mu\text{A}$ . The minimum total DC current occurs when  $I_{\text{in}}$  is logical ZERO and essentially only the  $20\ \mu\text{A}$  bias current is used. Input bias currents must be added to these numbers if they are used, as well as the offset increases added to the threshold currents. A variety of approaches to reducing current requirements are being evaluated, including the obvious introduction of dynamic clocking of all current paths between power and ground and the reduction of the logical current increment. Both of these approaches require speed performance trade-offs.

Circuits nearly identical to those described above have been used for current-mode analog-to-digital conversion [23]. In the next section, we describe the use of our current-mode MVL circuits for analog-to-quaternary conversion.

## Current-Mode CMOS Algorithmic Analog-to-Quaternary Converter

Algorithmic (or cyclic or recirculating) analog-to-digital (A/D) (binary) data converters have been shown to be less dependent upon component matching and require less silicon area than other approaches. These data converters follow an iterative procedure of breaking the input range of interest into two sections and determining within which of the two sections the input signal lies. This process is repeated on each selected range of interest until the final bit of resolution is determined. This is summarized adequately in [23].

An algorithmic analog-to-quaternary (A/Q) data converter algorithm uses a procedure like that described in [23] for the algorithmic analog-to-digital (A/D) (binary) data converter except that the algorithmic A/Q procedure breaks the range-of-interest into quarters and determines within which quarter of the range-of-interest the signal lies at each decision step. This process is repeated on each selected range-of-interest until the final quaternary digit of resolution is determined. To accomplish this we may follow the procedure described below. The block diagram in Fig. 11.14 mimics the block diagram in [23] used to describe the algorithm used for binary converters. The quaternary comparator labeled CQ with four-valued output signal Q in Fig. 11.14 is used to convey the concept of breaking the range of interest into four sections (rather than two) and indicating the result with a four-valued “comparator” output signal (rather than a binary signal). Figure 11.14 is useful in visualizing the algorithm. The circuit that realizes the function is not organized exactly as shown in Fig. 11.14. The circuit schematic will be described later. Referring to Fig. 11.14 we see that the input IN is multiplied by 4 and the signal 4IN is compared to the full-scale reference signal REF in a quaternary comparator labeled CQ. This quaternary comparator CQ generates a quaternary-valued output signal Q that indicates which quarter of the full-scale range the input signal lies within. Q values ZERO, ONE, TWO, and THREE indicate that the signal lies within the bottom, second, third, and top quarter of the full-scale signal range, respectively. If this comparison is

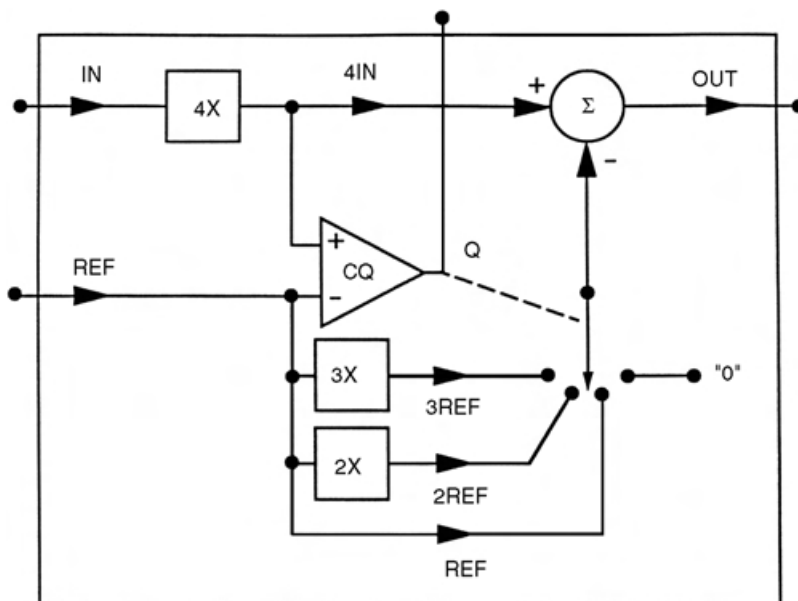

FIGURE 11.14 Current-mode CMOS analog-to-quaternary converter block diagram.

the first done on the input, then the resultant  $Q$  is the most-significant-digit (MSD) of the quaternary-valued output. Having identified the quarter-of-full-scale within which the input lies, we eliminate from further consideration the other regions by subtracting the number of full quarters above which the input lies from the input signal. Equivalently, we may subtract  $Q \cdot \text{REF}$  from  $4\text{IN}$  and obtain four times this desired difference. This factor of 4 weight of the difference signal is necessary to keep the bit significance correct as we continue to process the signal. The quaternary signal  $Q$  controls the switch, which effectively subtracts  $Q \cdot \text{REF}$  from  $4\text{IN}$ . The output signal is thus

$$\text{OUT} = 4\text{IN} - Q \cdot \text{REF}.$$

After the appropriate quarter of full-scale that is now defined as the region-of-interest is identified, this new region-of-interest is then searched for the quarter within which the input signal lies. The signal  $\text{OUT}$  may be used as the input to another identical stage or the value of  $Q$  may be stored and the signal  $\text{OUT}$  fed back to the input of this circuit for continued processing. Each pass through the procedure yields another digit of one lower level of significance until we reach the final least-significant-digit (LSD) decision. Thus, the MSD is determined first and the LSD determined last. The procedure may be implemented with some memory, control logic, and a single cell that performs the operations in Fig. 11.14, feeding the output back to the input. Or the procedure can be implemented by a cascade of  $N$  cells, each using the same  $\text{REF}$ . In the next section, we describe the current-mode CMOS circuitry that implements this algorithmic analog-to-quaternary (A/Q) data converter function.

The schematic of the current-mode CMOS algorithmic A/Q data converter circuit is shown in Fig. 11.15. The circuit operates as follows. For our initial discussion, assume that the bias current  $I_{\text{BIAS}}$  is zero and PMOS transistor  $M_1$  is not used. The analog input current  $I_{\text{IN}}$  into diode-connected input NMOS transistor  $M_2$  is reproduced and multiplied by a factor of 4, 2, 2, and 4 by NMOS current mirror transistors  $M_4$ ,  $M_6$ ,  $M_8$ , and  $M_{20}$ , respectively. The full scale reference current  $I_{\text{REF}}$  is brought into diode connected PMOS transistor  $M_{21}$  and reproduced and multiplied by a factor of 1, 1, 1.5, 1, 1, and 1 by PMOS current mirror transistors  $M_5$ ,  $M_7$ ,  $M_9$ ,  $M_{12}$ ,  $M_{13}$ , and  $M_{14}$ , respectively. Transistors  $M_4$  and  $M_5$  form a current comparator circuit that compares  $4 I_{\text{IN}}$  to the full-scale reference current  $I_{\text{REF}}$ . Transistors  $M_6$  and  $M_7$  form a current comparator circuit that compares  $2I_{\text{IN}}$  to the full-scale reference current  $I_{\text{REF}}$ . Transistors

FIGURE 11.15 Current-mode CMOS analog-to-quaternary converter schematic.

$M_8$  and  $M_9$  form a current comparator circuit that compares  $2I_{IN}$  to the one and one-half times the full scale reference current,  $1.5I_{REF}$ . In each of these three current comparators, when the current in the input NMOS transistor is greater than the reference current in the PMOS transistor, the common drain connection of the transistors falls to a (low) voltage near  $V_{SS}$ . In each of these three current comparators, when the current in the input NMOS transistor is less than the reference current in the PMOS transistor, the common drain connection of the transistors rises to a (high) voltage near  $V_{DD}$ . These current comparator output voltages are inverted by standard CMOS inverters to yield signals  $A$ ,  $B$ , and  $C$  that drive NMOS switch transistors  $M_{16}$ ,  $M_{17}$ ,  $M_{18}$ ,  $M_{76}$ ,  $M_{77}$ , and  $M_{78}$ . The sum of signals  $A$ ,  $B$ , and  $C$  yield the value of  $Q$ . PMOS transistors  $M_{12}$ ,  $M_{13}$ , and  $M_{14}$  each provide one unit of  $I_{REF}$  current to NMOS switches  $M_{16}$ ,  $M_{17}$ , and  $M_{18}$  that are controlled by signals  $A$ ,  $B$ , and  $C$ , respectively. The signal  $Q \cdot I_{REF}$  is created when signals  $A$ ,  $B$ , and  $C$  each switch one unit of  $I_{REF}$  current to the summing node as the three thresholds are exceeded. This  $Q \cdot I_{REF}$  current, the output current  $I_\theta$ , and  $4I_{IN}$  current are summed at the drain of NMOS transistor  $M_{20}$ . Thus, the output current  $I_\theta$  is  $4I_{IN} - Q \cdot I_{REF}$ .  $I_\theta$  is mirrored by PMOS transistors  $M_{42}$  and  $M_{43}$  for delivery out of the cell. The full scale reference current,  $I_{REF}$ , is set externally based upon the particular application.

The logical output of the quaternary comparator,  $I_Q$ , is created by switching zero, one, two, or three units of logical current, controlled by comparator signals  $A$ ,  $B$ , and  $C$ , to the logical output summing node through NMOS switches  $M_{76}$ ,  $M_{77}$ , and  $M_{78}$ . PMOS transistors  $M_{72}$ ,  $M_{73}$ , and  $M_{74}$  mirror the reference logical current  $I_{LOGIC}$  that is input to diode connected transistor  $M_{24}$ . The logical current reference,  $I_{LOGIC}$ , is set externally to be compatible with the rest of the current-mode logic used in the system.  $I_{LOGIC}$  used here is  $10 \mu A$ , making the logical currents 10, 20, and  $30 \mu A$ .

A key component in this design, the current comparator, is described in [16]. Its gain will be greater when implemented with higher impedance current mirror driver and load circuits, such as the cascode current mirror. This higher impedance output node slows the circuit and the cascode mirror configuration reduces the voltage swing of the current comparator circuit; however, in this application, the additional current mirror accuracy provided by the cascode mirror outweighs the disadvantages as will be discussed later.

To improve the overall transfer and delay characteristics of the current mode  $A/Q$ , a bias current may be added to the input, each of the comparator thresholds, and the  $Q \cdot I_{REF}$  signal. The small input bias current keeps the input transistor biased slightly on, allowing quicker mirror response and faster switching. The comparator thresholds and  $Q \cdot I_{REF}$  must be offset by the same amount. The circuitry required to maintain bias level compatibility among cells is important but not discussed here.

$A/Q$  decision circuit cells has been designed, fabricated, and tested in a variety of forms. We have studied circuits using simple Widlar and cascode current mirrors, with and without bias current. Experimental test

results confirm the DC transfer functions and low frequency functional operation predicted in the simulations. Because of the replication and differencing of input currents used in these decision cells, it is important to use current mirrors with accuracy sufficient to provide correct conversion for the number of quaternary digits desired. It was observed that simple Widlar current mirrors were sufficient to provide three-quaternary-digit outputs using reference currents between 10 and 50  $\mu\text{A}$ . To create a four-quaternary-digit output word, the additional accuracy of cascode current mirrors was found to be necessary. None of our test circuits would operate 100% correctly as a full five-quaternary-digit converter because of the accumulated error in the current signal transferred to the fifth decision cell.

Timing characteristics were evaluated using single decision cells and A/Q converter circuits made up of a cascade of five identical cells. We used  $V_{\text{DD}}$  of 5 V, logical currents stated above, and reference currents,  $I_{\text{REF}}$ , ranging from 10 to 50  $\mu\text{A}$ . The individual decision cell test circuits are in packaged parts and must be driven at their input with an external high resistance current source and loaded at the outputs with a 1 k $\Omega$  resistors. Thus, experimental delay measurements made on individual cells are dominated by the RC time constants of the voltage waveforms appearing at the package terminals. Using reference current of 10  $\mu\text{A}$ , the delay between when the input crosses a threshold and the output's single level transition (the very best case delay) was measured to be of about 55 ns in both the Widlar and cascode realizations. Worst-case delay, which occurs when all the decision cell's comparators change state, was observed to be about 800 ns in the cascode realization. Worst-case delay through two cascaded cascode cells was observed to be about 2.44  $\mu\text{s}$  and through four cascaded cascode cells to be about 5.2  $\mu\text{s}$ .

## 11.4 Summary and Conclusion

---

MVL circuits that are presently used in commercial products and that have the potential to be used in the future were discussed in this chapter. Application of MVL to the design of nonvolatile memory is receiving a great deal of attention because the memory density of multilevel ROM and multilevel flash memory is significantly greater than that possible using binary signals using the same fabrication technology. In multilevel flash memory, the floating-gate memory cell transistor has multiple values of charge stored on its floating gate, which results in multiple values of the effective transistor threshold voltage that produces multiple values of cell transistor drain current when the memory cell transistor is addressed. This provides the potential for almost doubling the bit density of the memory when four valued signals are stored. Advantages and disadvantages of various memory architectures, memory cell layouts, addressing schemes, column read amplifier designs, and potential fabrication technologies changes for multilevel memory cell optimization are of current research interest.

Current-mode CMOS circuits can provide interesting performance characteristics, in some cases, improved characteristics [21], and are receiving increasing attention. Current-mode CMOS MVL circuits [15] have been reported that illustrate feasible circuit realizations of important functions. In this presentation, we have reviewed several of the current-mode CMOS MVL circuits that we have developed. It is widely acknowledged in the field of electronic design that multiple-valued-threshold-logic circuits will not, in general, supplant binary-logic circuits. However, situations exist in which the characteristics of certain multiple-valued-threshold-logic circuits will make their use advantageous; most likely when imbedded in a binary design. One possible situation in which current-mode CMOS MVL circuits may be advantageous involves pipelined signal processing in a DCT/IDCT chip [20]. A 32-bit multiplier [18] realized with signed-digit arithmetic, symmetric functions, and bi-directional current-mode CMOS plus depletion mode transistors MVL circuits has been shown to provide both speed and area advantages over voltage-mode binary logic. Our studies and those of other MVL circuits researchers attempt to identify and characterize circuitry that may feasibly be used advantageously in integrated systems. Similar system improvements may be possible by combining the characteristics of MVL with the potentials of other approaches to signal processing, such as pipelining, parallel processing, or artificial neural networks. Characteristics of artificial neural networks, such as fault tolerance, and increased system speed due to parallel processing, combined with the hybrid analog-digital circuitry used in many neural network realizations make neural networks an attractive potential application for MVL.

### 12.1 Programmable Logic Technology

---

Digital systems can be implemented using several hardware technologies. As shown in [Fig. 12.1](#), field programmable gate arrays (FPGAs), complex programmable logic devices (CPLDs), and application specific integrated circuits (ASICs), are integrated circuits whose internal functional operation is defined by the user. ASICs require a final customized manufacturing step for the user-defined function. Programmable logic devices such as CPLDs or FPGAs require user configuration or programming to implement the desired function. Full custom VLSI devices are internally hardwired and optimized to perform a fixed function. Examples of full custom very large scale integrated (VLSI) devices include the microprocessor and RAM chips used in computers.

#### **PALs, PLAs, CPLDs, FPGAs, ASICs, and Full Custom VLSI Devices**

The different device technologies each have a different set of design tradeoffs as seen in [Fig. 12.2](#). The design of a full custom VLSI device at the transistor level requires several years of engineering effort for design, testing, and fabrication [1,2]. This expensive development effort is only economical for the highest volume devices. Full custom VLSI devices will produce the highest performance, but they also have the highest development cost and the longest time to market.

ASICs are typically divided into two categories, gate arrays and standard cells. Gate arrays are built from arrays of pre-manufactured logic cells. A single logic cell implements only a few gates or a flip-flop. A final custom manufacturing step is required to interconnect the sea of logic cells on a gate array. This interconnection pattern is created by the user to implement a particular design. Standard cell devices contain no fixed internal structure. For standard cell devices, the device manufacturer creates a custom photographic mask to build the chip based on the user's selection of devices. These devices typically include communications and bus controllers, ALUs, RAM, ROM, and microprocessors from the manufacturer's standard cell library.

FIGURE 12.1 Device technologies used for implementation of digital systems.

FIGURE 12.2 Comparison of device technologies used for digital systems.

ASICs will require additional time and development costs due to custom manufacturing. Several months are normally required to produce the device and substantial mask setup fees are charged. Additional effort in testing must be performed by the user, since chips can only be tested after the final custom-manufacturing step [3]. Any design error in the chip will lead to additional manufacturing delays and costs. For products with long lifetimes and large volumes, this approach has a lower cost per unit than CPLDs or FPGAs. Economic and performance trade-offs between ASICs, CPLDs, and FPGAs change constantly with each new generation of devices and design tools.

Several factors including higher densities, higher speed, and increased pressure to reduce time to market have enabled the use of programmable logic devices in a wider variety of designs. CPLDs and FPGAs are the highest density and most advanced programmable logic devices. These devices are also collectively called field programmable logic devices (FPLDs). Designs using a CPLD or FPGA typically require several weeks of engineering effort instead of months.

Because ASICs and full custom VLSI designs are hardwired and do not have programmable interconnect delays they provide faster clock times than CPLDs or FPGAs. ASICs and full custom VLSI designs do not require programmable interconnect circuitry so they also use less chip area and have a lower per unit manufacturing cost in large volumes. Initial engineering development costs for ASICs and full custom VLSI designs are higher. Initial prototypes of ASICs and full custom VLSI devices are often developed using CPLDs and FPGAs.

## Applications of FPGAs

FPGAs have become more widely used in the last decade. Higher densities, improved performance, and cost advantages have enabled the use of programmable logic devices in a wider variety of designs. A recent market survey indicated that there are over ten times as many CPLD and FPGA-based designs as ASIC-based designs. New generation FPGAs contain several million gates and can provide clock rates

approaching 1 GHz. Example application areas include single chip replacements for old multichip technology designs, digital signal processing (DSP), image processing, multimedia applications, high-speed networking and communications equipment, bus protocols such as peripheral component interconnect (PCI), microprocessor glue logic, co-processors, and microperipheral controllers. RISC microprocessors are also starting to appear inside large FPGAs that are intended for system-on-a-chip (SOC) designs. For all but the most time critical design applications, CPLDs and FPGAs have adequate speed with maximum system clock rates typically in the range of 50–400 MHz. Clock rates up to 1 GHz have been achieved on new generation FPGAs.

Several large FPGAs with an interconnection network are used to build hardware emulators. Hardware emulators are specially designed commercial systems used to prototype and test complex hardware designs that will later be implemented on ASIC or custom VLSI devices. Several recent microprocessors including Intel and AMD x86 processors used in PCs were prototyped on hardware emulators. A new application area for FPGAs is reconfigurable computing. In reconfigurable computing, FPGAs are quickly reprogrammed or reconfigured during normal operations to enable them to perform different functions at different times for a particular application.

### Product Term (EEPROM and Fuse-Based) Devices

Simple programmable logic devices (PLDs), consisting of programmable array logics (PALs) and programmable logic arrays (PLAs), have been in use for over two decades. Simple PLDs can replace several older fixed function TTL-style parts in a design. Most PLDs contain a series of AND gates with fuse programmable inputs that feed into an array of fuse programmable OR gates. In PALs, the AND array is programmable but the OR array has a fixed input connection. In a PLA or PAL, a series of AND gates feeding into an OR gate are programmed to directly implement a sum-of-products (SOP) Boolean equation. An example SOP implementation using a PLA can be seen in Fig. 12.3. Note that inverters are provided so that every input signal is also available in normal or complemented form. A shorthand notation is used for the gate inputs in PLAs. A PLA's AND and OR gates have inputs where each horizontal and vertical line cross. Initially in a PLA, all fuses are intact so each AND gate ANDs every input signal and its logical complement. By blowing unwanted fuses or programming, the unwanted AND gate inputs are disconnected by the user and the required product term is produced. In PALs, different devices are

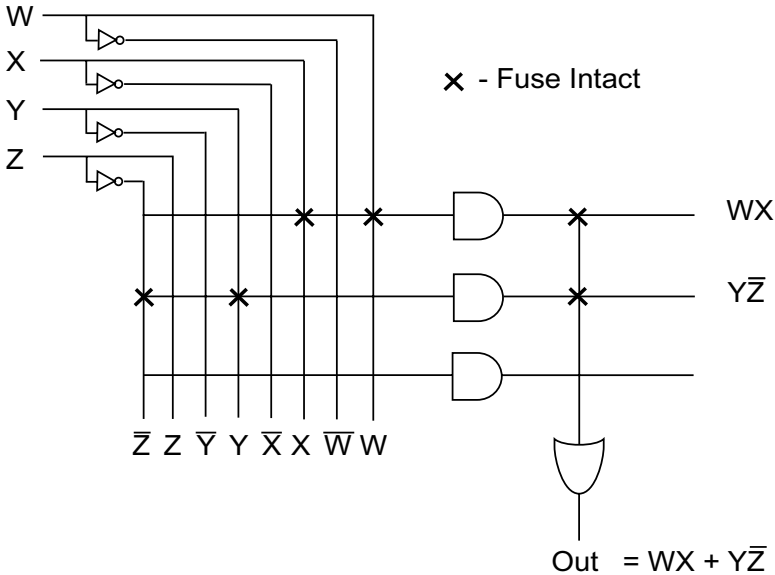

FIGURE 12.3 Using a PLA to implement a sum of products equation.

selected depending on the number of product terms (i.e., inputs to OR gate) in the SOP logic equation. Some devices have one-time programmable fuses and others have fuses that can be erased and re-programmed. On many PLDs, the output of the OR gate is connected to a flip-flop whose output can then be fed back as an input into the AND gate array. This provides PLDs with the capability to implement simple state machines. A simple PLD can contain several of these AND/OR networks. The largest product term devices contain an array of PLAs with a simple interconnection network. This type of device is called a complex programmable logic device (CPLD). Product term devices typically range in size from several hundred to a few thousand gates.

### Lookup Table (SRAM-Based) Devices

FPGAs are the highest density and most advanced programmable logic devices. The size of CPLDs and FPGAs is typically described in terms of useable or equivalent gates. This refers to the maximum number of two input NAND gates available in the device. Different device manufacturers use different standards to determine the gate count of their device. This should be viewed as a rough estimate of size only. The gate utilization achieved in a particular design will vary considerably.

Most FPGAs use SRAM look-up tables (LUTs) to implement logic circuits with gates. An example showing how a LUT can model a gate network is shown in Fig. 12.4. First, the gate network is converted into a truth table. Because four inputs and one output are used, a truth table with 16 rows and one output is needed. The truth table is then loaded into the LUT's 16 by 1 high-speed SRAM when the FPLD is programmed. Note that the four gate inputs, W, X, Y, and Z are used as address lines for the RAM and that OUT, the output of the circuit and truth table, is the data that is stored in the LUT's RAM. Using this technique, the LUT's SRAM implements the gate network by performing a RAM-based truth table look-up instead of using actual logic gates. In some devices, LUTs can also be used directly to implement RAM or shift registers.

Internally, FPGAs contain multiple copies of a basic programmable logic element (LE), also called a logic cell (LC) or configurable logic block (CLB). A typical LE is shown in Fig. 12.5. Using one or more LUTs, the logic element can implement a network of several logic gates that then feed into a programmable flip-flop. The flip-flop can be bypassed when only combinational logic is needed. Some FPGA devices contain two similar circuits in each logic element or CLB. Numerous LEs or CLBs are arranged in a two

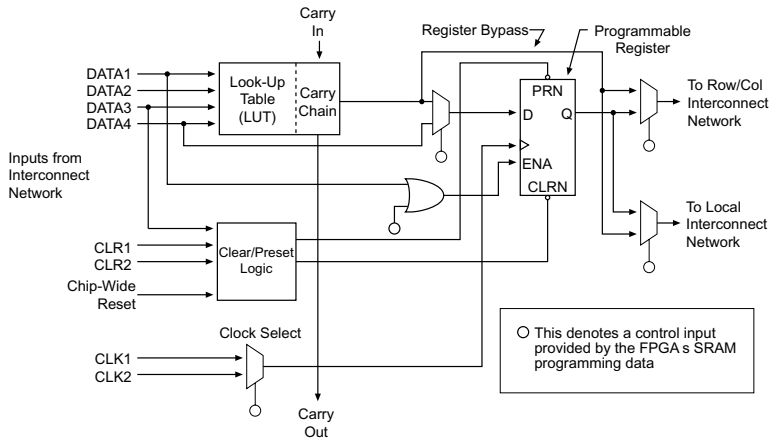

FIGURE 12.4 Using an FPGA's look-up table (LUT) to implement a logic gate network.

**FIGURE 12.5** Typical FPGA logic element.

dimensional array on the chip. Current FPGAs contain a few hundred to over a hundred thousand logic elements. To perform complex operations, logic elements can be automatically connected to other logic elements on the chip using a programmable interconnection network. The programmable interconnection network is also contained in the FPGA.

The interconnection network used to connect the logic elements contains row and column chip-wide interconnects. In addition, the interconnection network usually contains shorter and faster programmable interconnects limited only to neighboring logic elements. The internal interconnect delays are an important performance factor since they are of the same order of magnitude as the logic element delay times. Using a shorter interconnect path means less delay time. So that high-speed adders can be produced, there is often a dedicated fast carry logic connection to neighboring logic elements.

Clock signals in large FPGAs must use special low-skew global clock buffer lines. These are dedicated pins connected to special internal high-speed busses. These special busses are used to distribute the clock signal to all flip-flops in the device at the same time to minimize clock skew. If the global clock buffer lines are not used, the clock is routed through the chip just like a normal signal. The clock signals could arrive at flip-flops at widely different times since interconnect delays will vary significantly in different parts of the chip. This delay time or clock skew may violate flip-flop setup and hold times. This causes metastability or unpredictable operation in flip-flops. Most large designs with clock signals that are used throughout the FPGA will require the use of the global clock buffers. Some CAD tools will automatically detect and assign clocks to the global clock buffers and others require designers to identify clock signals and assign them to one of the global clock buffers.

General purpose external I/O pins on CPLDs and FPGAs contain programmable bidirectional tristate drivers and flip-flops. Pins can be programmed for input, output, or bidirectional operation. The I/O signal can be loaded into the I/O pin's flip-flop or directly connected to the interconnection network and routed from there to internal logic elements. Multiple power and ground pins are also required on large CPLDs and FPGAs. FPGA internal core voltages range from 1.5 to 5 V. FPGAs using advanced package types such as pin grid array (PGA) and ball grid array (BGA) are available with several hundred pins.

When a design approaches the device size limits, it is possible to run out of either logic, interconnect, or pin resources when using a CPLD or FPGA. CPLD and FPGA families include multiple devices in a wide range of gates with varying numbers of pins available on different package types. To minimize cost, part of the design problem is selecting a device with just enough logic, interconnect, and pins. Another important device selection factor is the speed or clock rate needed for a particular design.

## Architecture of Newer Generation FPGAs

New generation FPGAs have continued to increase in size and are adding additional features. Several FPGAs now include a mix of both product term and LUT-based logic gate resources. Product term logic blocks are more efficient for the more complex control logic present in larger state machines and address decoders. Phase-locked loops (PLLs) are available in many newer FPGAs to multiply and shift clock signals.

Many recent generation FPGAs also contain internal or embedded RAM memory blocks. Although the RAM can be implemented using the FPGA's logic elements, it is more efficient to build dedicated memory blocks for larger amounts of RAM and ROM. These memory blocks are normally distributed throughout the chip and can be initialized when the chip is programmed. The capacity of these internal memory blocks is limited to a few thousand bits per block. Memory intensive designs may still require additional external memory devices.

Some new generation FPGAs also contain internal hardware multipliers. These offer higher performance than multipliers built using the FPGA's logic elements and are useful for many DSP and graphics applications that require intensive multiply operations. Several of the largest FPGAs are available with internal commercial RISC microprocessor cores.

Most recent FPGAs support a number of I/O standards on external input and output pins. This feature makes it easier to interface to external high-speed devices. Several different I/O standards are used on processors, memory, and peripheral devices. The I/O standard is selected when the device is programmed. These I/O standards have varying voltage levels to increase bandwidth, reduce emissions, and lower power consumption. One recently announced FPGA family also features selectable impedance on output drivers. This eliminates the need for external terminating resistors on high-speed signal lines.

The largest FPGAs have started to use redundant logic to increase chip yields. As any VLSI device gets larger, the probability of a manufacturing defect increases. Some devices now include extra rows or columns of logic elements. After the device is tested, bad rows of logic elements are automatically mapped out and replaced with an extra row. This occurs when the device is initially tested and is transparent to the user.

Presently, the two major FPGA manufacturers are Altera and Xilinx. Altera refers to their larger FPGA-like devices as CPLDs. Other companies include Actel, Atmel, Lucent Technologies, and Quicklogic. Extensive data on devices is available at each manufacturer's website. Currently available FPGA devices range in size from a few thousand to several million gates. Trade publications such as Electronic Design News periodically have a comparison of the available devices and manufacturers [4].

## 12.2 CAD Tools for Rapid Prototyping Using FPGAs

---

### Design Entry

Most FPGA CAD tools support both schematic capture and hardware description language (HDL) based design entry. With logic capacities of an individual FPGA chip approaching 10,000,000 gates, manual design of the entire system at the gate level is not a viable option. Rapid prototyping using an HDL with an automatic logic synthesis tool is quickly replacing the more traditional gate-level design approach using schematic capture entry. These new HDL-based logic synthesis tools can be used for ASIC-, CPLD-, and FPGA-based designs. The two most widely used HDLs at the present time are VHDL and Verilog. VHDL is based on ADA or PASCAL style syntax and Verilog is based on a C-like syntax. Historically, most ASIC designs used Verilog and most FPGA-based designs used VHDL. This has changed in the last decade. DoD funded design projects in the United States must use VHDL and most FPGA CAD tools now support both VHDL and Verilog [5,6]. Currently, most FPGA synthesis projects written in VHDL or Verilog specify the model at the register transfer level (RTL). RTL models list the exact sequence of register transfers that will take place at each clock cycle. It is crucial to understand that HDLs model parallel operations unlike the traditional sequential programming languages such as C or PASCAL.

Because synthesis tools do not support every language feature, models used for synthesis must use a subset of the HDL's features. In VHDL, signals should be used for synthesis models instead of variables. HDL models intended for synthesis should not include propagation delay times. After logic synthesis, actual delay times will be automatically calculated by the FPGA CAD tools for use in simulation. Initial values for variables or signals are not supported in HDL synthesis tools. This means that most HDL models originally written only for simulation use will not synthesize.

## Using HDLs for Design Entry and Synthesis

To illustrate and compare the features of the two most widely used HDLs, VHDL and Verilog, two example synthesis models will be examined. As seen in [Table 12.1](#), VHDL and Verilog have a similar set of synthesis operators with VHDL operators based on PASCAL and Verilog operators based on C. Some shift operators are missing in Verilog, but they can be implemented in a single line of code with a few additional characters. In VHDL processes, concurrent statements and entities execute in parallel. Inside a process, statements execute in sequential order. In Verilog, modules and always blocks execute in parallel and statements inside an always block execute sequentially just like processes in VHDL. Processes and always blocks have sensitivity lists that specify when they should be reevaluated. Any signal that can change the output of a block must be listed in the sensitivity list. VHDL processes and Verilog always blocks with a clock signal sensitivity will generate flip-flops when synthesized.

FIGURE 12.6 VHDL and Verilog state machine model.

An example of a simple state machine is shown in Fig. 12.6. The state diagram shows that the state machine has three states with two inputs and one output that is active only in state B. The state machine resets to state A. Most FPGAs offer some advantages for Moore type state machines (i.e., output a function of state only) with one-hot encoding (i.e., one flip-flop per state) since they contain a register-rich architecture with limited gating logic. One-hot state machines are also less prone to timing problems and are the default encoding used in many FPGA synthesis tools. Since there are undefined states, a reset should always be provided to force the state machine into a known state. Most FPGAs automatically clear all flip-flops at power up. The first step in each model is to declare inputs and outputs. An internal signal, state, is then declared and used to hold the current state. Note that the actual encoding of the three states is not specified in VHDL, but it must be specified in the Verilog model. The first VHDL PROCESS and Verilog ALWAYS block are sensitive to the rising clock edge; so positive edge-triggered flip-flops are synthesized to hold the state signal. Inside the first PROCESS or ALWAYS block, if a synchronous reset occurs the state is set to state A. If there is no reset, a CASE statement is used to assign the next value of state based on the current value of state and the inputs. The new assignments to state will not take effect

**FIGURE 12.7** VHDL and Verilog ALU model.

until the next clock. In the second block of code in each model, a VHDL WITH SELECT concurrent statement and a Verilog ALWAYS block assigns the output signal based on the current state (i.e., a Moore state machine). This generates gates or combinational logic only with no flip-flops since there is no sensitivity to the clock edge.

In the second example seen in Fig. 12.7, the hardware to be synthesized consists of a 16-bit registered ALU. The ALU supports four operations, add, subtract, bitwise AND, and bitwise OR. The operation is selected with the high two bits of ALU\_control. After the ALU operation, an optional shift left operation is performed. The shift operation is controlled by the low-bit of ALU\_control. The output from the shift operation is then loaded in a 16-bit register on the positive edge of the clock.

At the start of each of the VHDL and Verilog ALU models, the input and output signals are declared specifying the number of bits in each signal. The top-level I/O signals would normally be assigned to I/O pins on the FPGA. An internal signal, ALU\_output, is declared and used for the output of the ALU. Next, the CASE statements in both models synthesize a 4-to-1 multiplexer that selects one of the four ALU functions. The +, -, AND (&), and OR (!) operators in each model automatically synthesize a 16-bit adder/subtractor with fast carry logic, a bitwise AND, and a bitwise OR circuit. In most synthesis

tools, the +1 operation is a special case and it generates a smaller and faster increment circuit instead of an adder. Following the CASE statement, the next section of code in each model generates the shift operation and selects the shifted or non-shifted value with a 16-bit wide 2-to-1 multiplexer generated by the IF statement. The result is then loaded into a 16-bit register. All signal assignments following the VHDL WAIT or second Verilog ALWAYS block will be registered since they are a function of the clock signal. In VHDL WAIT UNTIL RISING\_EDGE(CLOCK) and in Verilog ALWAYS@(POSEDGE CLOCK) instructs the synthesis tool to use positive edge-triggered D flip-flops to build the register. A few additional Library and Use statements at the start of each VHDL model will be required in some VHDL tools to define the IEEE standard logic type. For additional information on writing HDLs for logic synthesis models, select an HDL reference text that includes example models intended for synthesis and not just simulation [6–15].

Behavioral synthesis tools using VHDL and Verilog behavioral level models have also been developed. Unlike RTL level models, behavioral level models do not specify states and the required sequence of register transfers. Behavioral compilers automatically design the state machine, allocate and schedule the logic and ALU operations, and register transfers subject to a set of constraints. These constraints are typically the number of clock cycles required to obtain selected signals [16]. By modifying these constraints, different design architectures and alternatives are automatically generated.

Newer system-level synthesis languages based on C and Java have also been recently developed but are not currently in widespread use in industry. These languages more closely resemble a traditional program that describes an algorithm without specifying register transfers at the clock level. Many of these tools output a VHDL or Verilog RTL description as an intermediate step. Some new tools are also appearing that automatically generate FPGA designs using other popular engineering design software such as MATLAB.

CAD tools for synthesis are available from the both the device manufacturers and third party vendors. Third party logic synthesis tools often provide higher performance and offer the advantage of supporting devices from several manufacturers. This makes it easier to retarget a design to a device from a different chip manufacturer. Following logic synthesis, many of the third party tools use the device manufacturer's standard place and route tools. Interfacing, configuring, and maintaining a design flow that uses various CAD tools provided by different vendors can be a complex task. Several academically oriented texts contain additional details on the logic synthesis and optimization algorithms used internally in FPGA CAD tools [17–20].

## IP Cores for FPGAs

Intellectual property (IP) cores are widely used in large designs. IP cores are commercial hardware designs that provide frequently used operations. These previously developed designs are available as commercially licensed products from both FPGA manufacturers and third party IP vendors. FPGA manufacturers typically provide several basic hardware functions bundled with their devices and CAD tools. These functions will work on their devices only. They include RAM, ROM, CAM, FIFO buffers, shift registers, addition, multiply, and divide hardware. A few of these device specific functions may be used by an HDL synthesis tool automatically, some must be called as library functions from an HDL, or entered using special symbols in a schematic. Explicitly invoking these FPGA vendor specific functions in HDL function calls or using the special symbols in a schematic may improve performance, but it also makes it more difficult to retarget a design to a different FPGA manufacturer.

Commercial third-party IP cores include microprocessors, communications controllers, standard bus interfaces, and DSP functions. IP cores can reduce development time and help promote design reuse by providing widely used hardware functions in complex hierarchical designs. For FPGAs, commercial IP cores are typically a synthesizable HDL model or in a few cases a custom VLSI layout that is added to the FPGA. Several large FPGA families are now available with multipliers or RISC microprocessor IP cores [21]. FPGAs with RISC microprocessors have additional support tools such as C compilers and design tools to configure the processor and I/O systems. In the near future, it is likely that a small operating system kernel will also be supplied with these tools. These new devices are a hybrid that contains both ASIC and FPGA features.

**FIGURE 12.8** CAD tool flow for FPGAs and CPLDs.

## Logic Simulation and Test

A typical FPGA CAD tool design flow is shown in Fig. 12.8. First, the design is entered, using an HDL or schematic. Large designs are often simulated first using a faster running functional simulation tool that uses a zero gate delay model (i.e., it does not contain any gate level timing information). Functional simulation will detect logical errors but not synthesis related timing problems. Timing simulations are performed later after synthesis and mapping of the design onto the FPGA.

A test bench (also called a test harness or a test fixture) is a specially written module that provides input stimulus to a simulation and automatically monitors the output of the hardware unit under test (UUT) [8,22]. Using a test bench isolates the test-only code portion of a design from the hardware synthesis model. By running the same test bench code and test vectors in both a functional and timing simulation, it is possible to check for any synthesis related problems. It is common for the test bench code to require as much development time as the HDL synthesis model.

Following functional simulation of the design, the logic is automatically minimized, the design is synthesized, and saved as a netlist. A netlist is a text-based representation of a logic circuit's schematic diagram.

## FPGA Place and Route Tools

An automatic fitting or place and route tool then reads in the design's netlist and fits the design into the device. The design is mapped into the FPGA's logic elements, first by partitioning the design into small pieces that fit in an FPGA's logic element, and then by placing the design in specific logic element locations in the FPGA. After placement, the interconnection network routing paths are determined. Many logic elements must be connected to form a design, so the interconnect delays are a function of the distance between the logic elements selected in the place process. The place and route process can be quite involved and can take several minutes to compute on large designs. Combinatorial explosion prevents the tools from examining all possible place and route assignments for a design. Heuristic algorithms such as simulated annealing are used for place and route, so running the place and route tool multiple times may produce better performance. External I/O signals can be constrained to particular device pin numbers, but allowing them to be selected automatically by the place and route tools often results in improved performance. Many tools also allow the designer to specify timing constraints on critical signal paths to help meet performance goals. Most tools still include a floorplan editor that allows manual placement of the design into logic elements, but current generation tools, using automatic placement with appropriate timing constraints, are likely to produce superior performance. Place and route errors will occur when there are not enough logic elements, interconnect, or pin resources on the specified FPGA to support the design.

After partition, place, and route, accurate timing simulations can be performed using logic and interconnect time delays automatically obtained from the manufacturer's detailed timing model of the device. Although errors can occur at any step in the process, the most common step where errors are detected is during tests in an exhaustive simulation.

## Device Programming and Hardware Verification

After successful simulation, the final step is device programming and hardware verification using the actual FPGA. Smaller PLD and CPLD devices with fuses or EEPROM will only need to be programmed once since the memory is nonvolatile. Most FPGAs use volatile RAM memory for programming, so they need to be reprogrammed each time power is turned on. For initial prototyping, FPGA CAD tools can

download the programming data to the FPGA, using a special cable attached to the development computer's parallel or serial port. For initial testing without the need for a custom printed circuit board, FPGA development boards are available from the device manufacturers and other vendors. The development boards typically contain an FPGA with a download cable, a small prototyping area, and I/O expansion connectors. In a final production system, FPGAs automatically read in their internal RAM programming data from a small external PROM each time power is turned on. Since FPGAs read in this programming data whenever they power up, it is possible to build systems that automatically install design updates by downloading the new FPGA programming data into an EEPROM or FLASH memory using a network connection.

Successful design of high-frequency processors is predominantly the act of balancing two competing forces: striving to exploit the most advanced technology, circuits, logic implementations, and system organization; and the necessity to encapsulate the resulting complexity so as to make the task tractable. This chapter addresses some of the compelling issues in high-frequency processor design, both in taking advantage of the technology and circuits and avoiding the pitfalls.

Advances in silicon technology, circuit design techniques, physical design tools, processor organization and architecture, and market demand are producing frequency improvement in high-performance microprocessors. [Figure 13.1](#) shows the anticipated global and local clock frequency of high-performance microprocessors from the SIA International Technology Roadmap for Semiconductors.<sup>1,2</sup> Because silicon technology continuously advances, it is necessary to either define high frequency at each time or define it in a technology-independent manner. For the remainder of this chapter, high frequency will be defined in terms of the technology-independent unit of fanout-of-4 (FO4) inverter delay.<sup>3</sup> [Figure 13.2](#) presents the expected global clock frequency in terms of the ITRS gate delays.<sup>1,2</sup> From this figure, it is apparent that the local cycle time of high-performance microprocessors is expected to shrink by about a factor of two in number of gate delays. The ITRS gate delay is approximately a fanout-1 inverter delay, which is roughly a fixed fraction of one FO4. This cycle time improvement must be provided by improvements in the use of devices and interconnect, circuits, arithmetic, and organizational changes.

This chapter will concentrate on high-frequency designs, currently defined as less than 18 FO4 inverter delays for a 64-bit processor and 16 FO4 for a 32-bit processor. These break-points are chosen because (1) representative designs have been developed, which satisfy these criteria,<sup>4-7</sup> (2) they are sufficiently aggressive to demonstrate the difficulties in achieving high-frequency designs, and (3) they fall firmly within the expected targets of the high-performance microprocessor roadmaps.

In the remainder of this chapter, issues related to the design of processors for these high-frequency targets will be described. The ultimate dependence of the achievable cycle times on interconnect efficiency on low latency circuits will be discussed, and potential problems will be described.

## 13.1 The Processor Implementation Performance Food-Chain

Performance of high-frequency processor designs is becoming increasingly centered around interconnect. Thus, designing for high frequency is largely a matter of interconnect engineering. The importance of optimizing designs by optimizing wiring will continue to accelerate.

Device placement determines interunit and global wiring. The electrical characteristics of this wiring and expected loads, in turn, determine the size of macro output drivers and global buffers. The sizes of these drivers and buffers coupled with the cycle time constraints determine the device sizes, transistor topologies, and combinational logic gate designs. These characteristics influence the size of the macros, which affects the placement. The combinational circuits also determine the topologies, size, and placement of latches. The latches and, in some designs, the combinational logic circuits determine the clock generation and distribution. The circuits drive the design of the power distribution. The delay, power, and noise susceptibility characteristics of the available topologies for logic circuits determine the arithmetic, which can be supported in a design. The same characteristics for memory circuits determine which latches, registers, SRAM arrays, and DRAM arrays can be supported in a design. Although the design of high-frequency processors is a complex process, one in which performance can be lost at any stage, the basis of the process is placement and routing.

FIGURE 13.3 Custom or semi-custom macro cell placement and wiring.

### Placement and Routing: Distance and Wire Loads Are Performance

Custom and semi-custom design processes generally fix the dimension of one of the two wiring directions. This fixed dimension is most often in the direction of the width of the datapath. Each bit position in the datapath has a fixed number of available wiring tracks through the bit slice. The cross direction, or control direction, dimension varies with the complexity of the cells, the number of counter-datapath or control signals. In Fig. 13.3 the horizontal direction is fixed and the vertical dimension is variable. Thus, within a datapath, one dimension is determined by the maximum number of signals, which must travel within that bit position, and the cross dimension is determined by the sum of the individual cell dimensions, which are, in turn, determined by either the number of control signals which must pass through the cell or the size of the transistors and the complexity of the interconnections within the individual cells. From this simple analysis it is clear that the length of the wires, which drive control signals into the datapath, is determined by the datapath width, which is a function of the worst datapath-direction wiring needs. In the most general case, control signals must span all datapath bit positions.

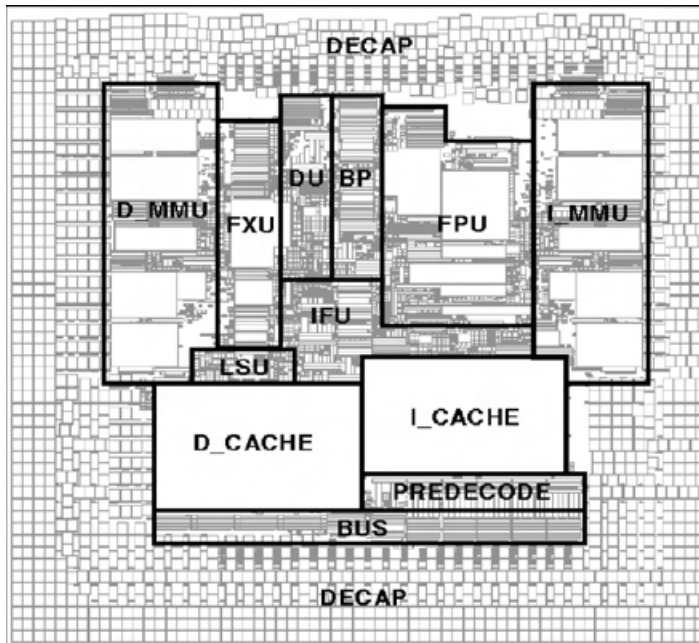

Datapath signals are much more variable in length. Global datapath signals, including data span the entire dataflow stack. Some macro output datapath signals and forwarding busses may cross a significant portion of the dataflow stack. Other macro outputs will simply be driven back to the inputs of the macro for dependent operations or locally to an adjacent latch. In each of these cases, the wire lengths are determined primarily by the sum of the heights of the cells over which these signals must traverse. Important exceptions are for wide control buses and for cross wiring dominated structures like shifters and rotators whose height is determined by the cross, or control-direction, wiring.

Sizing the datapath bit width is performed by analyzing the interconnect needs for global buses and forwarding buses and local datapath interconnects. Once the maximum number of signals, which must travel through a bit position, is known and additional datapath wiring resources are allocated for power and ground signals, this dimension can be fixed.

Wire length analysis in the datapath direction is a more complex iterative process. It involves summing cross wiring needs for shifters and rotators and wide control buses and the lengths of spanned datapath circuits. The size of the spanned circuits are often estimated based upon scaling of previous designs and/or preliminary layout of representative cells. At this point, it is the length of the global and macro crossing signals which are important. Once the length of these signals is known, estimates of the size of global buffers and macro output drivers can be made. With repeated application of rather simple sizing rules, an analysis of the size and topologies of the macro circuits can then be performed. The wire and estimated sink gates form the load for the macro and global drivers, which determine the size of the drivers. Through straightforward rules, such as those presented by Sutherland, et. al.,<sup>8</sup> alternatives for

combinational logic circuits can be evaluated. In the end, final device sizings, placements, wire level assignments, buffer sizing and placement, and indeed some circuit designs will be adjusted, as the design becomes fixed. The final process is aided by device tuning, extraction, simulation, and static timing tools.

In high-frequency designs, the accurate analysis of the wiring becomes critical. Because the designer is only able to reduce to a limited extent the amount of the cycle time, which must be allocated to clock uncertainty, latching overhead, and the minimum required function (e.g., a 32-bit addition/subtraction and muxing of a logical result) pressure to minimize time in signal distribution, is intense. To date, the shortest technology-independent cycle time for a 64-bit processor, 14.5 FO4 inverter delays, has been an IBM research prototype.<sup>5</sup> The cycle time for this design was allocated according to the budget presented in [Table 13.1](#).

The time available for distribution of results limits the placement of communicating macros. For results, which must be driven out of a macro through a wire into a remote receiving latch, an inverter was placed at the macro output to provide gain to drive the wire and another inverter was placed at the input of the latch to isolate the dynamic multiplexor from any noise on the wire.<sup>9</sup> Thus, the distribution wires could only be at most about 3.5 mm and thus the core of such a short cycle design with full forwarding must be quite small. For full-cycle latch-to-latch transfers, the wires were limited to about 10 mm. [Figure 13.4](#) presents the floorplan of the processor with a representative full-cycle latch-to-latch transfer path of 6.5 mm from the fixed point instruction register to the floating-point decoder latches. [Figure 13.5](#) presents a portion of the fixed point data-flow, FXU, with a representative maximum length forwarding wire of

**FIGURE 13.5** Expanded view of fixed-point unit with macro distribution path.

3 mm from the output of the ALU to the operand latch of the load-store unit. In this technology, with a cycle time partitioning as presented, the scope of intracycle communication is small. As cycle times decrease, in terms of the FO4 technology-independent metric, either a greater portion of the cycle must be devoted to covering communication amongst units within the core, or this communication must be completed in subsequent cycles.

Distribution of results in subsequent cycles and forwarding path elimination would eliminate the signal distribution time from the cycle time, at the cost of increased cycles on adjacent dependent operations. Superpipelining of the datapath macro over multiple cycles can increase the throughput of the design, but affects the execution latency due to additional intra-macro latches. Again, the additional cycles to complete the operation are observed on adjacent dependent operations.

Although the interconnect performance is important, it must be tempered by the demands of reliable operation. Many of the noise mechanisms in a design are due directly or indirectly to the design of the interconnects. These effects will be revisited in section 13.2.

The thesis of this work is that there must be a balance between the pursuit of the ultimate exploitation of the technology and the management of the resulting explosion in design complexity. Wire engineering is fraught with such complexity traps. While it is recognized that, for example, inductance can be a concern for on-chip wires, not every wire needs to be modelled as a distributed RLC network. Complexity can be reasonable managed by (1) generating metrics for the classification of wires into modeling classes and (2) determining when individual wires (e.g., global clock nets, bias voltages, critical busses) need to be more carefully analyzed. For the 0.22  $\mu\text{m}$  technology used in the IBM design,<sup>5</sup> Table 13.2 indicates the classification of general modeling classes for use in the preparation of detailed schematic simulation netlisting and schematic cross-section netlisting. For several wiring levels, the maximum wire length, where the application of each of the models resulted in approximately a 1% delay error, is presented. The T model placed the lumped capacitor to ground between two lumped resistors of value  $R/2$ . The multiple-T model divided the wires into four sections of T models. Use of these classes provides reasonably

accurate wire modelling while limiting the complexity of the simulation and analysis. In the final design, more detailed analysis of global wiring is warranted. Extraction, including 3D extraction, and analysis of delays and noise are commonly included in a high-frequency design methodology.

From Fig. 13.5, several potential traps are exposed. It should be clear that signals should be produced as locally as possible. Round trip signalling into a datapath and back out in a single cycle consumes almost the entire cycle. In addition, multi-source (multi-sink) buses should have the sources (sinks) located such that the wire lengths are short.

One method of limiting the complexity of the signal distribution was used in an IBM research gigahertz microprocessor.<sup>4,10</sup> In this design, each circuit macro was connected locally to a source operand latch with an integrated data multiplexor and all control signals were required to meet the datapath data at either the input of the macro or at the multiplexor select inputs of the receiving latch. In this way, it was guaranteed that round-trip signals were avoided.

## Fast Wires and Fast Devices: Gain Is Performance

From the previous section, it is clear that the circuit topologies and the device sizes used in the design of macros are dependent upon the wires and device load, which the macro must drive. Macro output drivers can be sized to minimize the delay of driving the networks. The problem sizing CMOS inverters to drive a load is well established.<sup>11</sup> In general, fanout-3 (FO3) to fanout-6 (FO6) rules-of-thumb can be used to size arbitrary CMOS circuits.

As part of the high-frequency design process, logic is sized by stage from output to input. The macro load is the sum of the wire and estimated gate loads attached to the output. The size of the transistors, channel-connected to the output, is such that the current delivered is equivalent to an inverter, which has an input capacitance of 1/3 to 1/6 of an inverter, with an input capacitance equal to the gate's load. This process is repeatedly applied until the primary inputs are reached. These inputs then constitute the load on gates or latches, which drive these inputs. This sizing process can be conducted either manually with simple guidelines<sup>8</sup> or using sizing design automation tools.

The delay of each stage is approximately proportional to the capacitive load, which must be driven. Physical design techniques and technology improvements, which lower capacitance such as routing on higher and more widely spaced wires, low-k dielectrics, and the reduced junction capacitance of SOI technologies,<sup>12-15</sup> can improve the performance of these circuits. Technology improvements to raise the current of the driving transistors such as low-threshold devices, strained silicon, and high-k gate oxides will also improve the performance of these circuits. To the circuit designer, these improvements change not just the performance of the devices and interconnect, but the wiring density, noise margins, noise generation, and reliability characteristics of the wires and devices.

Although the capacitance of the wires and the capacitance of the gates associated with the signal sinks were summed to represent the loads on a macro output, these loads may actually be quite separable and may be sized independently. If the delay of a circuit is modelled by the charging or discharging of a capacitive load:

$$T_d = (C_{\text{int}}V_{\text{dd}} + C_{\text{gate}}V_{\text{dd}})/I_{\text{ds\_avg}}$$

where  $C_{\text{int}}$  is the interconnect capacitance,  $V_{\text{dd}}$  is the supply voltage,  $C_{\text{gate}}$  is the gate capacitance of the load, and  $I_{\text{ds\_avg}}$  is the average driver current, and  $C_{\text{gate}} = \text{const} \times W$ , and  $I_{\text{ds\_avg}} = \text{const} \times W$ , then the delay is minimized as  $W$  approaches infinity. Or equivalently, as the  $C_{\text{gate}}$  is made to fully dominate  $C_{\text{int}}$ . In practice, this relation does not hold; however, even if this were true, the energy consumed would also go to infinity. The ratio of gate capacitance to interconnect capacitance should be maintained at between 1:1 and 2:1 for power efficiency.<sup>16</sup> Driving interconnect significantly harder than this results in larger energy consumption and more severe coupled noise and power supply noise.

## Gate Design: Boolean Efficiency Is Performance

In the previous section, transistor topologies were abstracted as currents, which charged and discharged load capacitances. In this section, the constraints imposed by the short cycle time and the minimum allowable function to be completed in a cycle will be shown to determine the circuit topologies, which can be employed for high frequency designs.

When the clock and latch overhead presented in Table 13.1 is applied to a 64-bit processor with a cycle time target of 18 FO4, it is evident that addition and subtraction must be completed in less than 12.4 FO4. Achieving this target requires: (1) a selection of the true or complement value of all bits of one input, (2) the formation of the sums, of which the most significant bit is the most difficult:

$$S_0 = p_0 \text{ xor } G_{1\dots 63}$$

where

$$p_i = A_i \text{ xor } b_i \quad \beta_i = B_i \text{ xor subtract}$$

$$G_{1\dots 63} = g_1 \text{ or } p_1g_2 \text{ or } p_1p_2g_3 \text{ or } p_1p_2p_3g_4 \text{ or } \dots p_1p_2p_3p_4 \dots p_{62}g_{63}$$

where  $g_i = A_iB_i$ , (3) the selection of the result of the add/subtract or a logical operation, and (4) the distribution of the result.

Very fast dynamic adders have been demonstrated, which perform the addition/subtraction in less than 10 FO4s.<sup>17–19</sup> These adders have achieved their high frequency through<sup>9</sup> (1) high degree of boolean complexity per logic stage, (2) aggressive sizing of device sizes, (3) ground interrupt NMOS elimination, and (4) high output inverter beta ratios.

Dynamic logic is well suited to complex boolean functions. The elimination of the PMOS pull-up network associated with static CMOS limits the amount of gate input capacitance, thereby increasing the capacitive gain of the gate. Thus, for a given input capacitance, domino logic can perform functions of greater boolean complexity. In addition, the dotting of the pull-down net-works allows for efficient implementation of wide OR functions. Finally, use of multiple-output domino allows for even greater boolean complexity for a given input capacitance.<sup>20</sup> Figure 13.6 is an example of a multiple-output, unfooted domino gate from a floating-point multiplier. This is a dual-rail output gate, which is generally required for domino logic as logical inversion cannot be performed within a traditional domino gate.

To illustrate the efficiency, in which complex boolean functions can be in domino logic, a series of carry merge structures were simulated. Carry merge gates perform a form of a priority encoding. The function implemented is:

$$G_{0\dots n} = g_0 + p_0g_1 + p_0p_1g_2 + \dots + p_0p_1p_2p_3 \dots p_{n-1}g_n \quad (13.1)$$

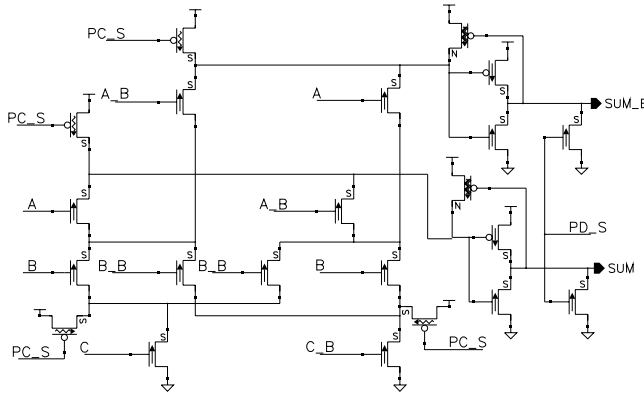

FIGURE 13.6 Dual-rail, multiple-output domino sum circuit.

FIGURE 13.7 Carry merge delay vs. group size.

An implementation of this function contains an NMOS pull-down network, which is  $n + 1$  transistors high and has  $n + 1$  paths to ground. Delays for feasible, single level domino implementations for a  $0.18 \mu\text{m}$  SOI technology are shown in Fig. 13.7. From Eq. (13.1), it can be shown that the higher order merging can be accomplished through the cascading of lower group size merge blocks and AND gates. From Fig. 13.7, however, it is clear that for merges up to group-6, a single level merge is more efficient than two group-3 or three group-2 merges.

Table 13.3 presents FO4 inverter normalized delays for a variety of custom, unfooted dynamic circuit units from the IBM  $0.225 \mu\text{m}$  bulk-CMOS 1 GHz PowerPC.<sup>5</sup> To achieve these delays, particularly for the complex functions, dynamic gates with pull-down networks up to five NMOS transistors high were used.

As indicated earlier, increasing the width of the transistors in a design generally improves the propagation delay through the logic. Increasing the transistor widths, however, directly increases the energy consumed in the design. The power versus delay curve of a datapath macro is presented in Fig. 13.8. In this figure, the widths of all nonminimum width transistors were reduced linearly. The resulting macro power and delay including a fixed output load is presented. The nominal design was optimized for delay where about 4% marginal power was devoted to reduce the delay by 1%.

In addition to the use of relatively large transistor widths, performance of dynamic gates can be improved through the elimination of the ground interrupt NMOS. Figure 13.9 shows the ratio of footed domino gate delay to unfooted domino gate delay for a range of NMOS transistor pull-down network heights implemented in a  $0.18\text{-}\mu\text{m}$  SOI process. In this graph the foot NMOS transistor is either two or four times the width of the logic NMOS transistors in the pull-down network.

**FIGURE 13.9** Performance potential of unfooted domino.

FIGURE 13.10 Effect of output inverter P:N size on delay.

In a very short-pipeline, high-frequency processor design, the 5–15% performance lost to the ground interrupt device was unacceptable. Unfooted domino also lowers the load on the clock, which, in turn, may lower the area and power required for generating and distributing the clock.

The delay of a domino gate can also be influenced by the sizing of the output inverter. The larger the ratio of PMOS to NMOS width, or beta ratio, the lower the delay for the output rising transition. The costs are an increase in the delay of the output reset operation and a decrease in noise-margin at the dynamic node.

Figure 13.10 shows the effect of the beta ratio on the output evaluate (rising) delay and output resetting (falling) delay. Adjusting the beta ratio of the output inverter can improve the delay of domino gates by 5–15% depending on the complexity of the gate. For the carry-merge gate used to derive Fig. 13.10, beta ratios of 3–6 provide most of the performance benefit without serious degradation of the delay of the reset operation or noise margins.

In the design of microprocessors with millions of logic transistors, it is of dubious value to do full analysis and optimization of the device topologies and sizings. To control the complexity of the design generation of simple guidelines for acceptable topologies and sizing, rules based upon simple device size ratios suffice for much of the design.

## 13.2 Noise, Robustness, and Reliability

The techniques described previously to improve performance cannot be applied indiscriminately. Performance can only be realized if sufficient noise margins are maintained. Dynamic circuits are subject to several potential noise events: Precharge-evaluation collisions, coupled noise on the input of the gates or onto the dynamic node, AC-noise or DC-offset in the  $V_{dd}$  or ground power supplies, subthreshold leakage in the pull-down network or through the PMOS pre-charge device, charge sharing between the dynamic node and the parasitic capacitances in the NMOS pull-down network, substrate charge collection at the dynamic node, tunnelling current through the gates of the output inverter, and SER events at the dynamic node. Dynamic circuits in partially-depleted SOI technologies have the additional challenge of bipolar leakage currents through the pull-down network but have improved charge-sharing characteristics.

Dynamic circuits are more prone to these noise events primarily because of the undriven dynamic node. These noise events all tend to either remove charge from a precharged and undriven dynamic node or add charge to a discharged and undriven dynamic node. Increasing the capacitance of the dynamic node improves this problem, but generally slows the circuit. Alternative for most of these problems is to

(1) control the adjacency of noise sources, (2) limit the allowed topologies to those which have tolerable leakage, and (3) the introduction of additional devices onto the dynamic node, which either source or sink current in response to these noise events.

Precharge/evaluation collisions occur when the precharge transistor has not fully turned off prior to evaluation or when the pull-down paths have not been disconnected from the ground prior to initiation of precharge. As the pull-down paths are usually designed to overpower the pre-charge device, the result of these collisions is an increase in short-circuit power, a degradation of the noise margin on the dynamic node, and an increase in the delay of the gate. Careful timing of the precharge and the input signals can minimize the chance for these collisions.

Charge redistribution or charge sharing occurs when the charge is transferred from the dynamic node to parasitic capacitances within the pull-down network during the evaluation phase of operation. When the gate is not supposed to switch, the resulting transfer of charge and reduction of voltage on the dynamic node reduces noise margin and can potentially cause false evaluation of the gate. This is particularly problematic in dynamic gates with complex pull-down networks, with significant wiring in the pull-down network, and/or relatively small capacitance on the dynamic node when compared to the capacitance within the pull-down network. Because the voltage on the dynamic node is affected, both the noise margin and potentially the delay of the dynamic gate are affected. These events can be minimized through the increasing of the capacitance on the dynamic node through the increasing of the size of the output inverter, the introduction of a keeper device which helps maintain the precharged level, the introduction of pre-charge transistors within the pull-down network where capacitances are significant, and the maintenance of small beta ratio in the output inverter.

Coupled noise on the input of gates results in the increase in leakage current through the pull-down network and possibly a false evaluation. This effect can be minimized by avoiding routing hostile nets near the inputs, protecting the inputs to dynamic nodes by introducing high-noise margin gates between any long wires and the inputs to the dynamic gates, and/or introducing sufficiently large keeper devices on the dynamic node.

Coupled noise to the dynamic node, like coupled noise to the inputs, may result in a false evaluation. The coupled noise can degrade the voltage on the dynamic node, and thus, degrade the noise margin of the gate. As this changes the voltage on the dynamic node, it also can affect the delay of the gate. This effect can be minimized by avoiding routing hostile nets near the dynamic node, minimizing the wire associated with the dynamic node, and/or introducing sufficiently large keeper devices on the dynamic node. Critical signals may be required to be isolated or shielded by supply lines or power planes.

Subthreshold leakage through the pull-down network for precharged dynamic nodes and through the precharge and keeper PMOS transistors remove or introduce charge on the dynamic node of a dynamic gate. Use of higher threshold devices as precharge devices or integration of higher threshold devices in the pull-down network can minimize this problem. Other techniques include using nonminimum length devices and introducing appropriately sized keeper devices.

Power-supply and ground noise degrade the noise margins as they shift the transfer function of the gate. Ground offset in the gate driving an input to a dynamic node can lead to increased subthreshold leakage through the NMOS pull-down network. Supply variation also modifies the propagation delay through the dynamic gates. Careful design of the distribution network and correctly sized and placed decoupling to meet the DC and AC switching characteristics of the design avoids this problem. As in other failure modes keeper devices can protect the dynamic node from power supply induced failures.

Substrate charge collection and SER events can affect the voltage on the dynamic node of the dynamic gate. Increased dynamic node capacitance, keepers, and minimizing the occurrence of substrate current injection, and avoiding proximity to lead solder ball locations for critical dynamic circuits should be considered to avoid these problems.

Tunneling currents are increasingly becoming a concern for the circuit designer as gate oxide thicknesses are reduced. For dynamic circuits, tunneling currents can cause a degradation of the voltage on the dynamic node.

FIGURE 13.11 Unfooted dynamic 4:1 multiplexer.

FIGURE 13.12 SOI noise simulation.

Because of the reduced junction capacitance of SOI devices, the charge redistribution problem presented earlier is significantly better in SOI than bulk technologies. Partially-depleted SOI has several other challenges for the circuit designer: bipolar leakage, the “kink effect” in the I-V characteristic, and the “history effect.” Each of these effects is related to the body of the SOI device. Although the body can be terminated through a body contact,<sup>21</sup> the capacitive and delay overhead of the contact generally prevents them from being used for logic transistors. The voltage on the floating body of the device influences the on-current through the dynamic raising or lowering of the device threshold and the off-current through the flow of bipolar current and MOS leakage current due to the variation of the device threshold.

For the SOI 4-to-1 unfooted dynamic multiplexer circuit shown in Fig. 13.11 a noise event waveform is presented in Fig. 13.12. The waveform shows the voltages and the resulting currents through a leg of the mux which should be off. At location A in the waveform, the body of device  $N_1$  has drifted to a relatively high steady-state voltage. At B, the device  $N_2$  is made to conduct. This has the effect of coupling the body of device  $N_1$  down as the source of  $N_1$  is driven low; however, the body of  $N_1$  is still sufficiently high to allow current to flow through the parasitic bipolar device. In addition, the voltage on the body of the device lowers the threshold of the MOS device  $N_1$ , making it particularly susceptible to noise at the gate of  $N_1$ . At C, a 300 mV noise pulse on the gate of  $N_1$  results in the dynamic node discharging sufficiently low to produce an approximately 300 mV output noise pulse.

The failure mechanism is a leakage mechanism, therefore, this failure mode can be minimized through the introduction and proper sizing of keeper devices. In the previous example, the size of the keeper device helps determine the amplitude and duration of the noise output pulse. In addition, the precharge of the internal nodes in the pull-down network can limit the excursion of the body voltages, thereby limiting the bipolar leakage current and the reduction in MOS threshold voltage due to the floating body. Limiting the number of potential leakage paths through pull-down network topology changes can also limit the floating body induced leakage effects.

Because both the current flow and thus the delay of the gate can be modified by the floating body, the delay of a circuit becomes time and state dependent. This “history effect” has been shown to lead to variations in delay of approximately 3–8% depending upon the technology, circuit, and time between activity.<sup>22,23</sup>

As is the case with sizing and topologies for performance, complexity in the analysis and optimization for robustness and reliability can be controlled through the generation of rather simple guidelines in sizing, wire length versus spacings, keeper size ratios, etc. In the case of reliability and robustness, however, verification that noise criteria are met is critical.

### 13.3 Logic Design Implications

---

As the technology-independent (FO4-based) cycle time shrinks, and signal distribution and clock and latch overhead shrink less quickly, the arithmetic and logic design must be more efficient. Linear depth arithmetic and logic structures quickly become impractical. Linear carry ripple addition, even on small group size, must be replaced with logarithmic carry-lookahead structures. Multiple arithmetic computations with a late selection, for example compound addition, may become necessary. In critical macros, additional logic may need to be introduced to avoid waiting for external select signals. For example, the carry-generation logic from a floating-point adder needed to be reproduced within the leading-zero-anticipator of a high-frequency, floating-point unit to avoid waiting for the sign of the add to be formed and delivered from the floating-point adder.<sup>24</sup>

Traditionally sequential events may need to be performed in parallel. For instance, to compute condition codes, rather than waiting for the result of the ALU operation and using additional levels of logic to form the condition codes, a parallel condition code generation unit, which formed the condition codes directly from the ALU input operands faster than the ALU result was required.<sup>25</sup> Sum-addressed caches have also been used to replace the sequential effective-address addition followed by cache access with a carry-free addition as part of the cache decoder.<sup>26,27</sup> Of more ubiquitous application, merging of logic with the latch is important as cycle times shrink. With increased pressure on cycle time, the latches and clocked circuits need a low skew and low jitter clock. Low jitter clock generation and low skew distribution require significant design, wiring, and power resource.<sup>28,29</sup>

### 13.4 Variability and Uncertainty

---

The wires and devices, which are actually fabricated in a design, may differ significantly from the nominal devices. In addition, the operating environment of the devices may vary widely in temperature, supply voltage, and noise. Usually delay analysis and simulation are performed at multiple corner conditions in which combinations of best and worst device and environmental conditions are used. For circuits in which the matching of individual transistors is required for correct operation such as current and voltage reference circuits and amplifiers, despite care being taken in the design and layout, mismatch does occur.<sup>30</sup> For timing chains, strobes, latches, and memories as well as the analog functions previously described, Monte Carlo analysis as well as worst-case analysis is often used to ensure correct operation and ascertain delays.

In the design of a high-frequency processor, performance gain can be made by minimizing the variation where possible and then taking advantage of systematic variation and only guard banding for random variations, variations which are time variant, and those for which the cost of taking advantage of the systematic variation exceeds the benefit. Methods of efficient models of the systematic and random components for device and interconnect can be used by the designer to optimize the design and determine what guard band is necessary to account for the random variations.<sup>31,32</sup>

### 13.5 Summary

---

Designing for the increasingly difficult task of high-frequency processors is largely a process of optimizing a design to within a reasonable distance of the constraints of (1) the ability of the interconnect to communicate signals, distribute clocks, and supply power, (2) the current delivering capabilities and noise margins of the devices, (3) the random or difficult to predict systematic variations in the processing, and

(4) the limit of designers to manage the resulting complexity. In technology-independent metrics, several high-frequency designs have been produced in this way.<sup>5,6</sup> Making better use of the technology should allow designers to meet or exceed cycle time expectations of the SIA International Technology Roadmap for Semiconductors.

### 14.1 Introduction

---

Power consumption has emerged as one of the most important design constraints in today's systems. This is largely due to the rapid growth of mobile systems, which run on the limited energy available in batteries. In addition, increased power consumption implies increased heat dissipation, which leads to higher cooling and packaging costs. Increased power consumption is also detrimental to the reliability of integrated circuits (ICs). In addition, concerns about the environmental cost of electronic systems motivate the need to reduce their power requirements.

The increasing speed and complexity of today's designs implies that the power consumption is also increasing in the future. To meet this challenge, we need to develop design techniques for low power. The complexity of today's ICs with over 100 million transistors, clocked at over 1 GHz, demands computer-aided design (CAD) tools and methodologies for a successful design in time to market. Therefore, we also need low power techniques to be part of CAD tools. In addition, the overall system design, including software components needs to be power aware.

[Figure 14.1](#) shows the historic power consumption for Intel CPUs. The X-axis shows the technology generation and the Y-axis the maximum power consumption. As indicated by the dashed line in the main part of the curve, power consumption has been increasing for each new CPU generation. The points to the side of the main curve indicate newer versions of each processor family. These are implemented in

newer semiconductor processes with smaller geometries than the lead processor in that family. Smaller feature sizes in conjunction with lower supply voltages lead to lower power consumption in the newer versions; however, moving to a new CPU generation in the same process is associated with an increase in the power consumption (Fig. 14.2).

Table 14.1 also depicts Compaq’s Alpha\* series in power, clock rate, die size, and supply voltage [1a]. Note the trend in increasing power though V<sub>dd</sub> the supply voltage, is decreased.

Why is this cause for concern? The reason is that increased power consumption directly impacts IC and system cost. This cost has two components. The first is *thermal* or *cooling cost*, which is associated with keeping the devices below the specified operating temperature limits. Maintaining the integrity of packaging at higher temperatures also requires expensive solutions. The second component of the cost of power consumption is the cost of power delivery, i.e., the on-chip, on-package, and on-board decoupling capacitances and interconnect associated with the power distribution network. Increased power consumption at lower voltages increases the magnitude of the current drawn by the IC. In addition,

today’s design trends are such that the variability in the amount of current drawn from cycle to cycle is also increasing. These factors combine to make resistive and inductive noise a big problem. Dealing with this is becoming increasingly costly.

Figure 14.3 gives an idea of the range of dollar amounts associated with the above costs for different system components in a personal computer. As can be seen, when the CPU power is in the 35–40 W range, the cost of each additional watt goes above \$1 per watt per chip. An interesting observation is that the power cost of the other system components (DRAM, chipsets, graphics) is on a steeper curve than the CPU. This is because the spatial layout of today’s system chassis designs is such that these components are harder to cool. This is likely to change with new designs, further increasing the relative importance of the CPU power cost. Given the above trends, there is a clear need to analyze and optimize power consumption for all components of a given system.

This chapter is organized as follows. The need for reducing power consumption in systems is motivated in greater detail in the section on “The Need for Low Power.” The sources of power consumption are reviewed in “Sources of Power Consumption,” where a basic power model for complementary metal oxide semiconductor (CMOS) circuits is presented. “Reducing Power Consumption” provides an overview of basic power reduction methods. Section 14.2 deals with power estimation, which is a prerequisite for power aware design. Section 14.3 describes power reduction techniques at various levels of the design process in greater detail.

## The Need for Low Power

The different factors that have led to the increasing importance of the power metric are described in the following subsections.

### Heat Dissipation

The power consumed in an IC is dissipated as heat. Unless this heat is removed, the IC gets hot. The electrical properties of the devices on the chip are rated for specific temperature ranges, and exceeding the ranges shifts the parameters and the behavior of circuits. In addition, as an IC gets hot, catastrophic failure mechanisms become more likely. These include silicon interconnect and junction fatigue, package failure, thermal runaway, and gate dielectric breakdown. It has been estimated that each 10°C rise in operating temperature roughly doubles the component failure rate.

The power consumption in today’s ICs has reached the point that expensive packaging and cooling mechanisms are needed to keep the operating temperature in check. The peak sustained power consumption in recent high-performance microprocessors is in excess of 70 W, as shown in Fig 14.1 and Table 14.1. Packaging and cooling costs are of direct concern even in the domain of lower performance and low power microprocessors and microcontrollers. The high volume nature of the market for these devices means that even slight reductions in cost can translate into large revenue increases for the manufacturer.

The cost impact of power consumption on packaging and cooling costs can be seen from the following data points. (The cost values are from the 1997 timeframe, but the relative trends still hold.)

If the power consumption of a chip is under 1 W, a plastic package can be used for it, at the cost of about 1 cent per pin. If the power consumption is between 1 and 2 W, a plastic package can still be used, but special heat conductors are required. The cost for a package of this kind is approximately 2–3 cents per pin. Exceeding 2 W, however, requires the use of ceramic packages. These packages cost between 5 and 10 cents per pin. Exceeding 10 W requires external cooling (air or liquid cooling) and a further increase in cost. The package cost for a 200-pin device would therefore be either \$2, \$4–6, or \$10–20, depending on whether its power consumption is below 1 W, between 1 and 2 W, or above 2 W. Moving up from one power consumption range to another is therefore accompanied by significant cost increases, which are significant if the devices are manufactured in large volumes. A specific consideration in this regard is to keep the power consumption below 2 W. This allows the use of plastic packages, which are much cheaper than the ceramic packages that are otherwise needed.

### Portable Systems

The rising popularity of portable systems is primarily responsible for the upsurge in interest in power consumption in recent years. Portable systems include palmtop, laptop, notebook computers, telecommunication devices such as pagers, cellular phones, wireless modems, and consumer products such as audio players, video cameras, and electronic games. The defining characteristic of a portable system is that it is not connected to a fixed power source. It runs on the limited energy stored in a rechargeable battery. In any portable system, the length of battery driven operation (the *battery life*) is of prime importance. Longer battery life can provide a competitive advantage in the marketplace. In each of these applications, size, weight, and battery life are primary considerations. Low-power DSPs allow designers to extend battery life without the size and weight increases associated with more powerful batteries.

The trend in portable devices is towards increased computational requirements. Portable computer users desire performance levels that are comparable to those of desktop systems. In addition, personal communication applications, with multimedia access supporting full-motion digital video and speech recognition capabilities are being proposed. What this implies is that portability can no longer be associated with limited computational rates.

Meeting the increased energy requirements through use of larger and more batteries is not really an option. This increases the size and the weight—parameters that are also extremely important in portable systems. Increasing the amount of energy stored in the batteries (the *battery capacity*) is one way to solve the problem; however, growth in rechargeable battery capacity has been slow. Incremental improvements in nickel-cadmium (NiCd) technology, the mainstay of portable power, have led to about the doubling of capacity over the last 30 years. Newer battery chemistries, such as nickel-metal hydride (NiMH) are expected to have 20–30% higher capacity. Thus, battery capacity has increased by a factor of less than 4 over the last three decades. Recently, the ever-growing market for portable systems has motivated a faster rate of innovation in the battery industry. Lithium-ion, a newer technology, is rapidly gaining popularity since it allows lighter batteries with higher capacities. This may change with even newer battery technologies such as lithium-polymer, and zinc-air, which are claimed to have 2 and 10 times higher capacity than NiMH, respectively.

In any case, growth in battery capacity lags far behind the rapid growth in microprocessor power consumption, which has gone from under 1 W to over 50 W over the last 20 years. Thus, improvements in battery technology alone cannot be relied upon to meet the constraints of portable systems. The *energy demand* on the batteries has to be reduced.

A noteworthy research project was recently completed at UC Berkeley, California. A butane-powered Wankel internal combustion engine with a generator about as small as a chip-cooling fan was developed to power a laptop for longer durations while enabling a very small weight increase. Although it is amusing to note that an IC (internal combustion) engine is powering the IC (integrated circuit), it will be worth watching to see the evolution of practicality and application of this technology, in view of its safe and hazard-free use. The engine reportedly pollutes only as much as a human body.

## Data Center Issues

The growth of the Internet is driving increased awareness of power in the server, communication, and networking domains. The trend is to pack more and more computational resources in smaller spaces. A typical data center consists of racks of computation equipment, each rack with a maximum of 42 slots, each slot  $1\frac{3}{4}$  inches high. Because data center space is at a premium, the desire is to pack more computational resources per rack and more racks per square yard. This drives the need for power efficiency mainly due to the following: First, when there are constraints on how much power a data center can draw from the public power grid, increasing computation density of a data center can only be done if the power efficiency of the equipment increases; second, it has been estimated that as much as 25% of the total cost of running a data center is directly related to power consumption (the cost of cooling, power delivery equipment, and the net consumption of electricity). Power has thus become a major design constraint for servers and high-performance communication and networking equipment.

## Reliability Issues

Certain issues related to reliable operation of ICs are directly related to the power drain of the on-chip circuits. Electromigration is one such issue. Under high electrical currents, the atoms in the metal power supply line may migrate, leading to electrical shorts and breakages. Reliable design of the power grid therefore requires a careful analysis of the current flow in different parts of the power grid. Reliable operation of ICs also requires verifiable electrical behavior. Some electrical verification problems are directly related to power consumption.

The first of these is voltage drops due to the resistance of power supply lines (also known as the *iR* problem). These drops lead to power supply DC voltage differences between the driver and receiver circuits. Thus, portions of the chip would receive a lower supply voltage than what they are designed for. In addition, transient currents drawn by one set of circuits causes transient *noise* in the supply rail of another and this noise can be only reduced by bulky capacitors. (But one cannot eliminate the perturbations.) The inductance of the power supply lines is the other problem. Rapid variation in the current flow on these lines can also lead to voltage variations (also known as the *supply bounce* or *L .di/dt* problem) that can affect the operation of the receiver circuits. The above problems necessitate specialized power analysis and design tools.

They also require tools to help avoid these problems, e.g., power line sizing tools. Increasing frequencies and device counts, coupled with shrinking feature sizes, will only exacerbate these problems [2]. Reduction in the total power consumption, on the other hand, helps to alleviate the impact of these problems.

## Environmental Considerations

Concerns about the environmental impact of the electricity consumed by computers are providing additional motivation for low power design. The U.S. Environmental Protection Agency (EPA) estimates that computers are a leading cause of the increased electricity demands in the U.S., accounting for about 5% of commercial demand (the figure is expected to reach 10% by the end of the decade). At present, PCs and their peripherals consume about \$2 billion worth of electricity annually, and indirectly produce as much carbon-dioxide as 5 million cars. Also, of the total office equipment electricity consumption, 80% comes from PCs, monitors, and printers [2].

A large part of this is wasteful power consumption, coming from systems that are left turned on even when not in use. In order to encourage the development of power-saving systems, the EPA created the "Energy Star Program." The requirements of this program state that each of a PC's main elements (CPU unit, monitor, and printer) should consume less than 30 W when they are idle, i.e., not being used. In return, PC vendors can use the "Energy Star" logo and market their systems as being "Energy Star Compliant." It is expected that being identified as an energy-wise or "Green" PC will provide a competitive edge over otherwise comparable, but "non-Green," systems. There is even a political angle here. The President of the United States has declared a goal for the U.S. government to buy only PCs that qualify for the Energy Star Program.

In any case, the move toward “Green” desktop PCs implies that the technologies that would be otherwise meant for just portable computers have applications in the entire PC domain. The mindset for power efficient design is therefore starting to take hold within the industry. This provides additional justification for the consolidation of tested techniques, and continuous development of newer techniques.

### Sources of Power Consumption

The four sources of power consumption in digital CMOS circuits are [4]:

1. Capacitive switching power ( $P_{\text{switching}}$ )
2. Short circuit current ( $I_{\text{short-circuit}}$ )
3. Leakage current ( $I_{\text{leakage}}$ )
4. Static currents from specialized circuits ( $I_{\text{static}}$ )

The effects of these sources on the average power consumption ( $P_{\text{avg}}$ ) can be summarized as:

$$P_{\text{avg}} = P_{\text{switching}} + (I_{\text{short-circuit}} + I_{\text{leakage}} + I_{\text{static}}) \times V_{\text{dd}} \tag{14.1}$$

where  $V_{\text{dd}}$  is the supply voltage. These sources of power consumption are explained in the next section.

### Switching Power

The dominant source of power consumption in a CMOS gate is the current due to the charging and discharging of the capacitance at the gate output. This capacitance,  $C_{\text{out}}$ , is the parasitic capacitance that can be lumped at the output of the gate. To understand this source of power consumption, consider the operation of a basic CMOS gate (an inverter), as its input goes through a high(1) to low(0) and a low to high transition (see Fig. 14.4). (In general, the bottom transistor (nMOS) can be replaced by a network of nMOS transistors, and the top transistor (pMOS) by a complementary network of pMOS transistors.) When the input goes low, the nMOS transistor is cut-off and the pMOS transistor conducts. This creates a direct path between the voltage supply and  $C_{\text{out}}$ . Current flows from the supply to charge up to the voltage level  $V_{\text{dd}}$ . The amount of charge drawn from the supply is  $C_{\text{out}} \times V_{\text{dd}}$  and the energy drawn from the supply equals  $C_{\text{out}} \times V_{\text{dd}}^2$ . The energy actually stored in the capacitor  $E_c$  is only half of this  $E_c = 1/2 \times C_{\text{out}} \times V_{\text{dd}}^2$ . The other half is dissipated in the resistance represented by the pMOS transistor. During the subsequent low to high input transition, the pMOS transistor is cut-off and the nMOS transistor conducts. This connects  $C_{\text{out}}$  to the ground, leading to the flow of current  $I_n$ .  $C_{\text{out}}$  discharges and its stored energy  $E_c$  is dissipated in the resistance represented by the nMOS transistor. Therefore an amount of energy equal to  $E_c$  is dissipated (consumed) every time the output transitions.

If  $N$  is the average number of transitions per clock cycle, the average energy consumed per clock cycle is  $E_c \times N$ . Power is the rate at which energy is consumed. Therefore, if  $f$  is the clock frequency, the average

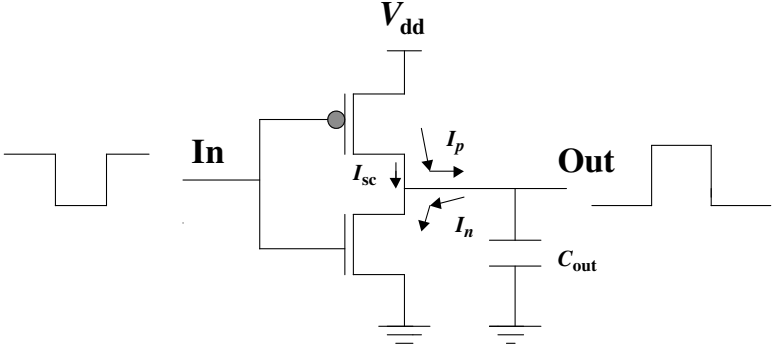

FIGURE 14.4 Dynamic power dissipation in a CMOS gate.

power consumption  $P_{\text{switching}}$  is given by

$$P_{\text{switching}} = \frac{1}{2} \times C_{\text{out}} \times V_{\text{dd}}^2 \times N \times f \quad (14.2)$$

$C_{\text{out}}$  is the sum of three components [3]  $C_{\text{int}}$ ,  $C_{\text{wire}}$ ,  $C_{\text{load}}$ . Of these,  $C_{\text{int}}$  represents the internal capacitance of the gate. This basically consists of the diffusion capacitance of the drain regions connected to the output.  $C_{\text{load}}$  represents the sum of gate capacitances of the transistors fed by the output.  $C_{\text{wire}}$  is the parasitic capacitance of the wiring used to interconnect the gates. It is a function of the placement of gates and the routing between them.  $N$  is a measure of the switching activity of the circuit. It is a function of the logical behavior of the circuit and of the sequence of inputs applied to it. The three components of this interconnect capacitance are: The parallel plate capacitance between the wire and the substrate, the capacitance due to the (fringe effect) of electric fields, and the capacitance between neighboring wires.

### Short-Circuit Current

The capacitive switching power is independent of the rise and fall times (ramp times) of the input and output waveforms. There is, however, a transient source of power consumption that is dependent on these ramp times. As shown by the broken lines in Fig. 14.4, during the time that the input waveform is transitioning between its extreme values, a current flows from  $V_{\text{dd}}$  to ground through both the nMOS and the pMOS transistors. This current, known as the *short-circuit* current, only occurs during the period of time when both the pMOS and the nMOS transistors conduct, i.e., when the input voltage  $V_{\text{in}}$  is such that  $V_{\text{tn}} < V_{\text{in}} < V_{\text{dd}} - V_{\text{tp}}$ , where  $V_{\text{tn}}$  and  $V_{\text{tp}}$  are the threshold voltages of the nMOS and the pMOS transistors, respectively. The nMOS transistor conducts when  $V_{\text{in}}$  exceeds  $V_{\text{tn}}$ , and the pMOS transistor conducts when  $V_{\text{in}}$  is below  $V_{\text{dd}} - V_{\text{tp}}$ .

It has been shown that the impact of short-circuit current is reduced if the input ramp times are faster, relative to the output ramp times. This minimizes the time when significant short-circuit current can flow, but it also increases the gate delay. A good trade-off is to keep the input and output ramp times about equal. Careful design, including appropriate sizing of the transistors can keep the power contribution of short circuit current  $I_{\text{short-circuit}} \times V_{\text{dd}}$  below 10% of the total power. So, while short-circuit current should not be completely ignored, it is reasonable to consider it as only a second order effect. It is even possible to eliminate short-circuit current altogether [5]. This happens if the chosen supply voltage  $V_{\text{dd}}$  is such that  $V_{\text{dd}} < V_{\text{tn}} + V_{\text{tp}}$ . Under this condition, the nMOS and the pMOS transistors can never conduct simultaneously.

### Leakage Current

The previous two sources are dynamic sources of power consumption, i.e., they contribute to power only during transitions. It would seem that CMOS circuits should not consume any power at other times, since there are no available current paths when inputs are at stable logic levels.

There are, however, two types of leakage currents that also contribute to power consumption. These are:

- *Diode leakage current:* The source and drain regions of a metal oxide semiconductor field effect transistor (MOSFET) can form reverse biased parasitic diodes with the substrate. There is leakage current associated with these diodes. This current is very small and is usually negligible compared to dynamic power consumption.
- *Subthreshold leakage current:* This current occurs due to the diffusion of carriers between the source and drain even when the MOSFET is in the cut-off region, i.e., when the magnitude of the gate-source voltage  $V_{\text{gs}}$  is below the threshold voltage  $V_t$ . In this region the MOSFET behaves like a bipolar transistor and the subthreshold current is exponentially dependent on  $V_{\text{gs}} - V_t$ . The significance of this current increases with technology scaling, as shown in Figure 14.9.

### Static Current

In certain designs, the pMOS network of a CMOS gate may be replaced by a single pMOS transistor that always conducts. This logic style, known as pseudo-nMOS, will lead to a constant current flow static at all times so that the output is at logic 0, i.e., when there is a direct path to ground through the nMOS network.

This static current is obviously undesirable, but it does not exist for true CMOS logic. This is one of the main reasons for the popularity of CMOS in low power applications.

Another situation that can lead to static power dissipation in CMOS is when a degraded voltage level (e.g., the “high” output level of a nMOS pass transistor) is applied to the inputs of a CMOS gate. A degraded voltage level may leave both the nMOS and pMOS transistors in a conducting state, leading to continuous flow of short-circuit current. This again is undesirable and care should be taken to avoid it in practice.

## Reducing Power Consumption

The capacitive switching power ( $P_{\text{switching}}$ ), as given by the formula in Eq. (14.1), is the dominant source of power consumption in CMOS circuits today. Research and design efforts aimed at low power are therefore largely focussed on reducing  $P_{\text{switching}}$ . The parameters in its formula  $V_{\text{dd}}$ ,  $f$ ,  $C$ ,  $N$  provide avenues for power reduction. The idea is to either reduce each of the parameters individually without adversely impacting the others, or to trade them off against each other.

It should be noted that  $f$  is also a measure of the performance (speed) of a system. Therefore, reduction in power through simply a reduction in  $f$  is an option only if it is acceptable to trade off speed for power. Power is proportional to the square of  $V_{\text{dd}}$ . This makes reduction in  $V_{\text{dd}}$  as the most effective way for power reduction. This has motivated the acceptance of 3.3 V as the standard supply voltage, down from 5 V. The downward trend in  $V_{\text{dd}}$  continues, with processors with 1.5 V internal supply voltage and lower, already being shipped.

The problem with reducing  $V_{\text{dd}}$  is that it leads to an increase in circuit delay. Circuit delay is inversely proportional to  $V_{\text{dd}}$  as a first order of approximation. The increased delay can be overcome if device dimensions are also scaled down along with  $V_{\text{dd}}$ . In particular, in constant-field scaling,  $V_{\text{dd}}$  and the horizontal and vertical dimensions of devices are scaled down by the same factor  $k$ . This is done in order to maintain constant electric fields in the devices. To the first order of approximation, the power consumption scales down by  $k^2$ , and the delays go up by  $k$ . Reducing device dimensions (or feature size reduction) is a very costly proposition, requiring changes in fabrication technology and semiconductor processes.

The other problem is that circuit delay actually rises rapidly as  $V_{\text{dd}}$  approaches the threshold voltage  $V_t$ . As a general rule,  $V_{\text{dd}}$  should be larger than  $4V_t$ , if speed is not to suffer excessively  $V_t$  does not scale easily and, therefore, reducing  $V_{\text{dd}}$  below  $V_t$  will be difficult.

The speed degradation (increase in delay) may be reduced by circuit technologies that allow lower  $V_t$ ; however, decrease in  $V_t$  leads to a significant increase in subthreshold leakage current—every 0.1 V reduction in  $V_t$  raises subthreshold leakage current by a factor of 10.

A tradeoff is involved in choosing a very low  $V_{\text{dd}}$ . Some design options in this regard are to either dynamically vary  $V_t$  (lower  $V_t$  when the circuit is active, higher when it is not) or using different  $V_t$  for sub-circuits with different speed requirements. The speed degradation may also be compensated for by increasing the amount of parallelism in the system. This works well for applications such as digital signal processing, where throughput is used as the performance metric.

It is also worth noting that  $V_{\text{dd}}$  reduction only provides temporary relief in the course of technological change. Please refer back to Fig. 14.1 and Table 14.1. These processors shown represent recent data points for a trend that has persisted for over 25 years—increased performance through higher clock frequencies or increased number of transistors, or both. This, however, directly increases the power consumption. Reductions in supply voltage and feature size do help to offset the effect of increased clock frequency and to reduce power.

For example, the original Intel Pentium processor had 0.8  $\mu\text{m}$  feature size, 5 V supply voltage, 66 MHz clock frequency, and 16 W power consumption. Reduction in the feature size to 0.5  $\mu\text{m}$  and voltage to 3.3 V, led to 10 W power consumption, even at 100 MHz. But such reductions are only temporary, since the march toward increased clock frequencies shows no signs of slowing. Thus, the power consumption of the 200 MHz Pentium climbed back to 17 W.

Also, the area made available from feature size reductions is immediately filled up with more transistors—for larger caches and increased instruction-level parallelism, in case of processors. For example, the Pentium Pro, the successor of the Pentium, has 70% more transistors and about 50% more power consumption at 200 MHz.

The trend in special purpose ICs is also to push the limits of integration by integrating as much functionality on a chip as possible. The goal of a host of multimedia capabilities on a single chip was being sought in earnest. These capabilities are now real but power consumption has gone up. Integration helps to reduce the overall power for the system. A rule of thumb stated is that four devices incorporated into an IC consume only half as much power as would be the case if they were configured as discrete components; however, it also implies that the power dissipation burden on the resulting single IC will increase. Thus, the current trends indicate that the voltage and feature size reduction notwithstanding, the power consumption problem in ICs will only get worse in the future. Therefore, it is important to explore other avenues of power reduction as described below.

### Reduction of Switched Capacitance

The parameters  $N$  and  $C_{out}$  in Eq. (14.2) provide the other set of avenues for power reduction. Their product  $N \times C$  can be called the average switched capacitance per cycle (referred to as switched capacitance) of the circuit. Reduction in switched capacitance is in general orthogonal to the power reduction techniques described previously. It can therefore lead to power reductions beyond what is possible by voltage scaling alone. It may also be the only option if the large investments in time and money associated with the migration to newer processes and lower voltages are not feasible. Reduction in switched capacitance has thus been the subject of intense study in recent years since the last 10 years or so. Ideas and techniques at all levels of the design process are being developed. Figure 14.5 presents an overview of the salient directions that are being pursued in today's designs. Some of these are aimed specifically at reducing  $N$  or  $N \times C_{out}$ . Others represent well-established design/synthesis problem domains, in which  $N \times C_{out}$  can be considered as an additional target metric. The aim of all of these is to reduce  $N \times C_{out}$ . It should be kept in mind that these efforts are not isolated from one another. Thus, the impact of design decisions at any level cuts across other levels of the hierarchy too. Overviews of the published work in this area are available in several references [1,5,6].

# 14.2 Power Estimation

As we saw in the last section, power dissipation in VLSI circuits is a major concern in the electronics industry. The rapid increase in the complexity and the decrease in design time have resulted in the need for efficient power estimation tools that can help in making important design decisions early in the design process. To accomplish this objective, the estimation tools must operate with a design description at the higher levels of abstraction; however, trade-offs exists between accuracy and speed in power estimation at various levels of a design hierarchy. In this section, an overview of the different power estimation tools and techniques are covered.

## Need for Power Estimation Tools

Low-power design requires good power analysis tools to evaluate the alternate choices in design. Consider modern high-performance CPUs, large portions of which are typically custom designed. These designs involve manual tweaking of transistors to upsize drivers in critical paths. If too many transistors are upsized, certain designs can lie on the steep part of a circuit's power-delay curve. The choice of logic family used, e.g., static versus domino logic, can also greatly influence the circuit's power consumption. Figure 14.6 illustrates these scenarios for a 32-bit adder. Suppose a designer has the data shown in the figure at his disposal. Knowledge of where on the power-delay curve the circuit operates can tell the designer whether he/she can trade a little performance for larger power savings. In this example, a total of 69% savings can be gained by transistor sizing and using domino instead of static logic. There is a 23% delay penalty. This extra delay penalty may be overcome by upsizing adjacent blocks at a much less power penalty and ending up with an overall power benefit. Experiments with this methodology have yielded 10% power savings with no delay increase in real designs. CAD tools that enable this kind of logic and circuit design exploration for custom circuits can thus have a significant impact at the full-chip level. Specifically, power analysis tools enable designers to:

1. Verify whether the power budgets are met by different parts of the design and identify the parts that do not satisfy the power requirements
2. Evaluate the effect of various optimizations and design modifications on power

A typical design flow has four steps. It starts with very high-level description of a design, called HLM (high-level modeling) or architectural description. Then the HLM is converted into RTL (register transfer level), and then RTL is synthesized into a gate level design. Finally, gates are replaced by transistors/layout

FIGURE 14.6 Power-delay curves for two different 32-bit adders.

and validated for design specs. As design flows into lower level of abstraction it becomes more complex and design changes become more difficult. So, it is advisable to start design trade-offs at the early stage of the design—HLM or RTL. Also, the higher level of abstraction allows greater impact on the design with less effort. So, power estimation tools are needed at all design levels. At the early stage they are needed to make smart decisions about power-performance trade-offs, and at lower levels to validate design changes and to quantify impact of design changes.

## Issues in Power Estimation

How do you know how much power your design will consume before plugging the chip into your board and measuring it? To perform these calculations, knowing the circuit's clock frequencies and the multiplicative constants (activity factors) provided by the vendor can help to some extent. But the more difficult parameter to be determined is the average number of flip-flops and routing nodes that transition during each clock edge. Determining this value is especially tough for hardware description language-based designs, as one may have little or no insight into the logic implementation of the chosen device. Some vendors suggest the use of a 12.5% usage estimate (refer to the section on "Switching Power," where this amounts to  $N = 0.125$ ) corresponding to the average toggle percentage of a 16-bit counter. Others believe that a 25% estimate for an 8-bit counter is more typical. Some circuits, such as arithmetic units, have even higher toggle percentages. The choice can radically impact the accuracy of the estimate.

In general, the most effective design decisions can be derived from choosing and optimizing algorithms at the highest level of the design hierarchy. This dictates the need for an effective high-level power estimation tool. In the absence of a high-level power analysis tool, the designer has to first synthesize and validate the functionality of a lower-level netlist, and then run a logic or transistor-level power analysis tool to estimate power consumption. The large iteration times of lower-level power analysis tools, and the long time required to obtain and validate a gate-level or transistor-level netlist, makes this methodology inefficient to estimate power. At the same time, there is a penalty associated with high-level power estimation tools. The absolute accuracy of high-level power estimation tool tends to be lower than the accuracy provided by using low-level estimation tools. These are some of the issues in power estimation that need to be considered for a good design. In the following section, several power estimation tools operating at different levels of design abstraction are discussed.

## Power Estimation Techniques

Power estimation techniques can be broadly classified into statistical, probabilistic, and macromodeling techniques. In *statistical* techniques, the circuit is simulated using a timing or logic simulator, while monitoring the power being consumed. This procedure is repeated for various sets of input vectors until a desired level of accuracy is achieved. Eventually power converges to the average value. One example of accurate statistical analysis method is the activity-based control model. This model expresses the complexity of control units and input activities making it easy to analyze the power consumption of regular implementations, such as ROM and PLA-based structures.

In *probabilistic* techniques, the signals are represented with probabilities that substitute for the time consuming simulations; however, there is a loss in accuracy. The signal probability is defined as the probability of having a logic value of "1" on a signal and the transition probability represents the probability of the proportion of transitions on the signal. These probabilities lead to a simple computation of switching activity, the parameter that needs to be determined for power computation. The simplest way to propagate probabilities is to work at the gate-level description of the circuit. When the circuit is built from Boolean components that are not part of a predefined gate library, the signal probability can be computed by using a binary decision diagram (BDD) to represent the Boolean functions.

Another popular approach, mostly used for high level power estimation is the *macromodeling* technique. In this method, a macromodel is constructed by obtaining and characterizing a lower-level implementation. Based on the power consumption characteristics of the macroblock for various training sequences, a macromodel or function is then constructed that describes the power consumption of the

block as a function of various parameters like the signal statistics of the block inputs, outputs, and states. A simplified example of macromodeling is the power factor approximation (PFA) technique. In this technique, the power consumption of a given type of functional block, implemented using a given design style that operates at frequency  $f$  is estimated using the following equation,

$$P = KGf$$

where  $K$  is the PFA constant and  $G$  is a measure of the hardware complexity of the functional block. The PFA constant may be generated by characterizing one or a few implementations of the functional block.

## Examples of Power Estimation Tools

This subsection discusses practical implementations of different power estimation techniques.

### RT-Level/Gate-Level Techniques

At RT-level, power is estimated primarily in two ways: the top-down way and the bottom-up way. In the top-down approach, at first, power density (power/unit area) is calculated from the full-chip power and area estimates, where estimates are usually obtained from historical data. Then power values for the lower level blocks are calculated by scaling the estimated block area with the power density. This approach is good for a very quick power analysis. It suffers from very serious accuracy issues, it does not take into account the block's functionality, logic and circuit topologies, performance requirements or switching activities.

For better accuracy the bottom-up approach is used. It uses macromodeling technique, where analytical or table lookup models are built, using historical data or real simulation data, for each bottom level blocks. These models are usually parameterized for output load capacitances and input/output (I/O) switching activities for better accuracy. For power estimation, lower level blocks are first mapped to these precharacterized models. Then, a power value for each block is calculated by evaluating corresponding power models. The bottom-up roll-up is now done to generate power estimates for higher level blocks. Here, power estimate accuracy depends on the accuracy of models, which is typically good if simulation data is used for model building. This approach is advisable where design exploration is needed at the early stage.

### Transistor Level Power Estimation Techniques

At the transistor level, power per net is first estimated and then it is rolled up to generate block or system power. Two approaches to estimate power per net are used primarily: static and dynamic (simulation-based). In the static approach, capacitance ( $C$ ) per net is first estimated (extracted if layout is available) then a blanket switching activity ( $AF$ ) is used to calculate the switching component of power. The constant power component is then added to take leakage and short-circuit power into account. This approach is very quick and can be quickly automated and applied to very large designs. But its absolute accuracy is not high. Sometimes switching activity is varied based on net types—clock, CMOS, domino, gated clock, etc., to improve accuracy. This method is advisable for a large design and also where daily/weekly tracking of power is required.

For more accurate power estimate the dynamic approach is used. In this approach switching activity for each net is generated by simulating real test vectors on switch level or circuit simulation engines. Then the capacitive power component for each net is calculated using extracted/estimated capacitance data along with real switching activity data. For the short circuit and leakage power estimation, analytical models are used. These models are typically parameterized for transistor widths, rise/fall times, switching activity, etc., for better accuracy. This approach generates very accurate, test vector dependent, power estimates, but it takes very long run-time. Usage of this approach is limited by design size, length of test vectors, computing resources, and project timelines. This approach is typically used for transient power analysis and where absolute power estimates are a must, such as power-specing or power savings validation.

### Examples of Commercial Power Estimation Tools

A few examples of power estimation tools are provided here for reference. This is not a complete list, but only provides an example of what is available commercially. Power CAD is an active area of research.

WattWatcher is an RTL/gate-level, power-estimation tool from Sequence Design, Inc. It adopts a sophisticated bottom-up approach that focuses on the specific analysis methodology applicable to the major consumers of power such as memories on large ASIC, I/O pads, clock circuits, data path circuits, control logic, etc.

PowerMill is a circuit level power estimation tool from Synopsys, Inc. Its algorithm is based on fast circuit simulation employing table lookup of currents for a given transistor sizes (see Fig. 14.7).

## 14.3 Power Reduction Methodologies

The following subsections provide a brief overview of the concepts behind power reduction through various aspects of the design (process technology, circuit, tools, and system/software).

### Power Reduction through Process Technology

Power dissipation consists of a static component and a dynamic component. As described in section 14.1, dynamic power is due to charging and discharging of the load capacitance and is, by far, the dominant component in CMOS circuits. Static power is controlled by leakage currents of transistors and pn-junctions. Static power also arises from circuits that have a steady DC current source between the power supply rails (such as bias circuitry, analog circuits, pseudo-NMOS logic families).

Since dynamic power is proportional to the square of the supply voltage ( $V_{dd}$ ), reduction of  $V_{dd}$  is the most effective way for reducing power. The industry has thus steadily moved to lower  $V_{dd}$ . Indeed, reducing the supply voltage is the key to low-power operation, even after taking into account the modifications to the system architecture, which is required to maintain the computational throughput; however, the drive toward higher performance can sometimes outstrip the benefits of voltage scaling, as described in the section on “Reducing Power Consumption.”

Another issue with voltage scaling is that to maintain performance, threshold voltage ( $V_t$ ) also needs to be scaled down since circuit speed is roughly inversely proportional to  $(V_{dd} - V_t)$ . Typically,  $V_{dd}$  should be larger than  $4V_t$  if speed is not to suffer excessively. As threshold voltage decreases, subthreshold leakage current increases exponentially. At present,  $V_t$  is high enough such that subthreshold current is only a small portion of the total active current although it dominates the total standby current. However, with every 0.1 V reduction in  $V_t$ , subthreshold current increases by 10 times. In the future, with further  $V_t$  reduction, subthreshold current will become a significant portion or even a dominant portion of the overall chip current. A first order analysis, using constant electric field scaling of the process parameters, illustrates this as shown in Fig. 14.9 [8]. At sub-0.1  $\mu\text{m}$  feature sizes, the leakage power starts eating into the benefits for lower  $V_{dd}$ . In addition, design of dynamic circuits, caches, sense-amps, PLAs, etc., becomes difficult at higher subthreshold leakage currents. Lower  $V_{dd}$  also exacerbates noise and reliability concerns. To combat subthreshold current increase, various techniques have been developed. Most techniques focus

FIGURE 14.8 Sleep transistors to control circuit activity.

FIGURE 14.9 First-order analysis for leakage power trends.

on replacing low  $V_t$  devices with high  $V_t$  devices whenever and wherever it is possible in the design. High  $V_t$  devices can be obtained either by an additional ion-implant with additional masks to the low  $V_t$  devices or by back biasing the substrate of low  $V_t$  devices. In addition, subthreshold leakage current can also be reduced by introducing special transistors called *sleep control transistors*. These are a pair of pass transistors, which act like circuit breakers through which current passes from  $V_{dd}$  to ground. The gates of these transistors are controlled by signals, which can turn *both* devices of this  $p$  and  $n$  pair *off* (for inactive mode) or *on* for active mode. The concerned circuit operates between a *virtual*  $V_{dd}$  rail and *virtual ground* rail between the pair of transistors (see Fig. 14.8).

As technology continues to scale down, oxide is becoming so thin that oxide tunneling current can also become a significant portion of the total chip power for feature size of  $0.1 \mu\text{m}$  or below. Oxide tunneling current consists of gate leakage and decoupling capacitance leakage. Large gate leakage current not only increases the total chip power, it also imposes additional challenges for circuit design. Without effective solutions for subthreshold and gate leakage, CMOS LSI technology would eventually lose its low power advantage and face the same fate as bipolar LSI circuits.

In addition to the low power techniques that are discussed in this subsection and in the next few subsections many other novel high-speed and low-power techniques have been proposed [1]. Silicon-on-insulator (SOI) technology has been shown to improve delay and power through a  $\sim 25\%$  reduction in total capacitance. SOI substrates are produced by either wafer bonding or separation by implantation of oxygen (SIMOX). Optimized SOI MOSFETs can have lower capacitance and slightly higher drive current because of the reduced body charge and slightly lower minimum acceptable  $V_t$ . Together with some improvement in layout density, this potentially can result in up to 40% improvement in speed [1]. This may be traded for lower  $V_{dd}$  and hence a significant reduction in power.

Another way to reduce capacitance is to use the minimum possible width for metal interconnects that carry AC signals such as clock and data buses. A study in electromigration research indicates that AC interconnects can operate at much higher current density than design rules based on DC tests would allow. It has been shown that electromigration lifetime is orders-of-magnitude longer under AC stress than under DC stress. Similar behavior has also been reported for vias and other metal systems.

Yet another possible way to reduce metal capacitance would be to use insulators with lower permittivity for inter-metal dielectrics. Relative to SiO<sub>2</sub> which has  $\epsilon$  of  $\sim 4.2$ , SiOF has an  $\epsilon$  of  $\sim 3.3$  and organic polymers may achieve an  $\epsilon$  of  $\sim 2.5$ .

There appears to be no revolutionary low power device/technology, such as quantum devices, that is manufacturable or compatible with mainstream circuit architectures today. The intrinsic speed-power benefit of gallium arsenide technology (GaAs) is probably not sufficient to overcome the difference in cost and technology momentum with respect to silicon except for very high-speed circuits. Devices based on quantum tunneling or single electron effect have excellent intrinsic switching speed and energy, but they are not capable of driving the capacitance of long interconnects. In addition to the difficulty in manufacturing, there are no suitable circuit architectures that are compatible with the characteristic of these devices today. Fortunately, evolutionary innovations and optimization for low power plus continued device scaling in silicon CMOS technology have been sufficient to support the need for low power ULSI up to today, and hopefully for a long time into the future.

### Power Reduction through Circuit Design

In general, power spent in the clock network is the largest contributor to the total power on high-performance ICs such as a modern CPU, as indicated by the Fig. 14.2. The most effective impact for reducing the total power is accomplished by reduction of switching capacitance on the clock network. This is achieved through clock and data enabling (or gating). *Clock gating* is achieved by qualifying different clock partitions by enable signals. Figure 14.10 illustrates the mechanics of clock gating and clock networks. This in effect allows only the partitions that are active to toggle in each given cycle (Fig. 14.11).

FIGURE 14.10 Clock gating and clock networks.

FIGURE 14.11 Clock enabling.

FIGURE 14.12 Data enabling.

In addition, this also helps the  $di/dt$  issues on the chip as sub-regions/blocks will be turned off selectively. Although this technique offers great power saving advantages, it also carries a few design challenges. Some of the concerns in clock gating are that the disabled block may not power up in time and also that modified clocks may generate glitches. As a result the enable signals will have a very strict timing requirement. In addition, at high frequencies, clock skew becomes a significant portion of cycle time and the gated clocks will add to the clock network skews, thus becoming undesirable. Therefore, the granularity at which clock gating can be applied becomes a tradeoff against overall clock network design time and complexity. Some other side effects of clock gating that a designer needs to consider are the area penalty due to generation of the enable signal, clock gating elements, and also the routing overhead to distribute enable signals.

An alternate method for power saving is through *data enabling*. Data enabling implementation is shown in Fig. 14.12. The enable signal generates a data enable signal that indicates whether the current data is valid or not. This prevents input data updates for invalid data or an idle condition. Thus it avoids unnecessary transitions within the design. One disadvantage of this implementation is that clock nodes are toggling during idle conditions. Due to low level of activity in static blocks, data enabling does not offer a large power saving advantage since clock nodes consume majority of the power. In high-frequency design, where aggressive circuit techniques such as domino logic are employed, this technique offers a great deal of power saving. In domino logic, data/non-clocked node activity factors are relatively high. In these cases, the “data enable” signal can be used to avoid evaluation of the first stage of a domino block or to set data inputs to a default state such that the domino gate does not discharge. It is also important to note that clock enabling (gating) for a block will save both clock and data power since the block will be turned off and there is no activity within the block unlike the data enabling.

Datapath circuits are the second highest power consuming category of circuits, after clock in modern high-performance designs. In such designs, datapath including register files fall in critical paths and hence they are custom designed (that is, carefully designed manually by expert designers). These designs involve manual tweaking of transistors and can lead to over-sizing of the devices, which become excessive power wasters. In addition, the choice of circuit family used, e.g., static versus domino can also influence the circuit’s power consumption. To design a power-efficient circuit, the power-delay curve approach can be of great help, as described in the “Need for Power Estimation Tools” section (Fig. 14.6). CAD tools that enable a circuit family of this kind and design exploration for custom circuits can thus have a significant impact at full-chip level.

In the CPU arena, a lot of circuits, which are performance critical, get implemented as domino circuits. Wide datapaths such as adders, incrementors, and shifters are implemented in domino. In that case, specific optimizations on individual circuits can be done to reduce power. Consider an example of a domino multiplexer, which usually appear in shifters, as shown in Fig. 14.13.

In this circuit, at least one of  $selA$ ,  $selB$ , and  $selC$  is high every cycle. The data inputs  $A\#$ ,  $B\#$ ,  $C\#$  are mostly high ( $A$ ,  $B$ ,  $C$  have very low signal probability). In this situation, all the capacitances associated with the data nodes toggle almost every cycle. This total capacitance is almost three times that associated with the clocked nodes. Consequently, when the polarity of the data inputs is changed, as shown on the right, large power savings are seen.

FIGURE 14.13 Domino AF reduction in a Mux.

FIGURE 14.14 Power/area/delay trade-offs for PLA vs. synthesized logic.

FIGURE 14.15 Latch redesign example.

Another example of power/performance trade-off is in the case of control logic, which can either be implemented in PLAs or synthesized gates. Figure 14.14 shows the results for a logic block whose seven sub-blocks can be implemented in PLAs or as synthesized random logic. Increasing the number of synthesized blocks leads to some increase in delay but with much larger power savings.

In library-based design, power savings from the design of the cell libraries can come from device sizing and from restructuring of the logical and physical schematics of the cell. Again, device sizing for optimizing switching energy versus delay ensures better power efficiency; however, resizing of the sequential cells requires extensive recharacterization for setup and hold times in addition to delays of clock to data output.

The second way to optimize a cell library is to change the schematics of the most commonly used and most power hungry cells in the design. These typically consist of latches and master slave flip-flops since these have clock nodes which switch on at every clock edge. Figure 14.15 shows an example of latch redesign that gets rid of clock nodes while still maintaining functionality and performance. Thus, it is advisable to replace more dissipative sequential cells by more efficient types. A small amount of redesign effort on some selected cells often can have a significant power impact for the full chip.

## Power Reduction through CAD Tools

Power estimation tools allow quantification of the power consumption of a whole system and the power contribution of its sub blocks. These help in identifying high power consuming blocks and power wasting blocks. The next step, after identifying the troubled areas is, to reduce power consumption of those blocks. Many techniques are discussed in this chapter, including clock gating, data gating, transistor sizing, and many other design techniques. To reduce time-to-market, designers want to make all the necessary modifications quickly without compromising the quality of the designs. This can be achieved by CAD tools. These tools can identify automatically those design areas where low power techniques can be applied and also perform feasibility of making design changes. CAD tools have limitations, especially dealing with complex clocked designs. So, not all techniques can be automated as quite a few need to go through very complex validation processes, which typically can only be done manually. These techniques were discussed in the circuits section. The following subsection discusses design techniques and CAD tools that help implement and validate many RTL, gate level, and transistor level techniques.

### Low-Power Design Rule Checker

Design rule checkers are usually implemented to look for violations of electrical design rules and layout guidelines. The design rule checking concept can also be applied to identify high impact areas for power savings as well as power wasting components. At different design levels, design rules are different. For example, at RTL, design rules can help us identify block level power optimization opportunities—such as clock gating, data gating, etc.—while at gate and transistor level they can identify over-sized drivers, wasted activity as that of glitches etc.

Two main design rules are: *static* and *dynamic*. Static design rules work on the raw design description and collect information about high power consuming design structures. A few examples of static design rules are: identify wide state buses controlled by a free running clock; identify wide buses driven by unmuxed multiple drivers, etc. Dynamic design rules need design simulation data, like toggle counts per cycle. Dynamic rules identify wasted activity. A few example of dynamic rules are: identify multiplexor blocks whose inputs are toggling even though they are not selected; identify nets toggling multiple times in a single clock cycle, etc. Design rule checking can also help by generating statistical data of the design—such as a list of clock controlled blocks, a list of gated clocks, a list of nets toggling above a specified range, etc. The idea here is that the tool identifies problem areas that the designer can fix to reduce power.

### Low-Power Synthesis

A lot of the CAD research in low power has been in the area of low power logic synthesis. Technology dependent phases of synthesis are particularly suited for practical applications, since they have access to low-level circuit information. It is possible to save power with these methods, even when they are constrained not to increase the delay of the circuit. Table 14.2 shows the results of applying these techniques on a couple of sample circuits from a high-performance CPU. Column 2 shows the power savings when only the combinational part of the circuit is allowed to be changed. Column 3 shows the results when the sequential elements are also allowed to be changed. The area impact is low (Column 5) and there is no increase in delay. The results show ~10% power savings for synthesized blocks, but this

**TABLE 14.2** Low-Power Logic Synthesis Results (in percent)

Circuit	After LPSynth. (%)	After Seq. dnsizing (%)	Total (%)	Area (%)
1	1.4	7.39	8.52	-1.85
2	0.76	4.89	5.65	-0.69
3	8.40	1.53	9.92	1.99
4	6.13	3.31	9.44	7.12
5	11.03	1.07	12.09	1.09
Total	5.16	3.81	8.97	0.53

translates into only 1% full-chip power savings. This is because only 10% of total power is from synthesized logic for CPUs such as the one whose power breakdown was shown in Fig. 14.13.

It is pertinent to note that the system power consumption problem also encompasses chipsets, i.e., devices such as the memory, I/O, and graphics controllers. These operate at a fraction of the CPU clock frequency, and large portions of these are well-suited to be implemented as ASICs. Low power synthesis thus has a much larger impact in this domain.

**Transistor Sizing**

A large part of high-performance CPUs is typically custom designed. These designs typically involve manual tweaking of transistors to upsize drivers in critical paths. If too many transistors are upsized unnecessarily, certain designs can operate on the steep part of a circuit’s power-delay curve. In addition, the choice of logic family used, e.g., static vs. dynamic logic, can also greatly influence the circuit’s power consumption. Please see the “Need for Power Estimation Tools” subsection and Fig. 14.6.

Figure 14.14 shows an example of another kind of intelligent tradeoff for power/performance. It shows the results for a logic block whose seven sub-blocks can either be implemented as PLAs or as synthesized random logic. Increasing the number of synthesized blocks leads to some increase in delay but for much larger power savings.

The traditional emphasis on performance often leads to over-design, that is, wasteful for power. An emphasis on lower power, however, motivates identification of such sources of power wastage. An example of this is the case where paths that are designed faster than they ultimately need to be. For synthesized blocks, the synthesis tool can automatically reduce power by downsizing devices in such paths. For manually designed blocks, on the other hand, downsizing may not always get done. Automated downsizing tools can thus have a big impact. Transistor width savings (with no delay increase) from the use of one such tool are shown in Table 14.3. The benefit of such tools is power savings, as well as productivity enhancement over manual designs.

Many custom designers are now exploring dual- $V_t$  technique to take greater advantage of the transistor sizing. The main idea here is to use low- $V_t$  transistors in critical paths rather than upsizing high- $V_t$  transistors. The main issue with this technique is the increase in subthreshold leakage due to low- $V_t$ . So it is very important to use low- $V_t$  transistor selectively and to optimize their usage to achieve a good balance between capacitive current and leakage current in order to minimize total current.

**Examples of Power Reduction Tools**

A few examples of power reduction tools and their features are provided here for reference. This is not a complete list, but only provides an example of what is available commercially. Low-power CAD is thus an active area of research.

**PowerCompiler**

It is a gate-level power optimization tool offered by Synopsys, Inc. It helps in achieving low power by identifying low power opportunities for clock gating, data-gating, logic restructuring, and downsizing. It also automatically checks feasibility of many low-power design techniques, such as low-power synthesis, clock gating, etc. and implements it. It also quantifies power savings.

**WattSmith**

Wattsmith is an RTL power optimization tool offered by Sequence Design, Inc. It helps in identifying block level power reduction opportunities. It also does automatic implementation of many design techniques for low power, to name a few: memory banking, clock gating, etc.

## AMPS

AMPS is a circuit power optimization tool from Synopsys, Inc. It optimizes existing transistor level netlist by downsizing individual transistors in noncritical parts of a given design. It has the capability to optimize designs for delay and area as well. It has configuration file commands to allow users more control on the optimization. AMPS has two major features: Downsize oversized transistor devices for area and power and upsize transistors selectively to fix critical paths. AMPs also performs power analysis, if toggle-count information is provided.

## Power Reduction Methodologies: System/Software

### System Level Power Reduction

The general design principles described in the previous subsections can also be extended at the higher-levels of design to obtain power reductions at the system level. Power should be used as a design constraint in the overall system interaction. System Power Management is a specific class of techniques that has been used effectively for power reduction. This is easiest to explain in the case of processor-based systems, but the ideas are applicable in other types of designs too.

The interaction of the processor (CPU) with the rest of the system provides avenues for reducing average power. Often the CPU is waiting for inputs from peripherals and its power is being wasted. To reduce this waste, CPUs are now provided with a hierarchy of power states. Each state defines a certain level of activity on the CPUs and a certain time penalty for it to get back into a fully active state. Memory and I/O devices often also have similar power states. It is the *system power management* mechanism that monitors the system activity and enforces the movement of the system components between different power states. System power management has its roots in mobile systems; however, EPA requirements under the Energy Star program motivated the migration of these techniques to desktop systems. A recent development in this area is a cross-company initiative called ACPI (advanced configuration and power interface) [1]. The recognition of the need to eliminate wasted power ensures that system power management will continue to be an area of high interest and active development.

### Software-Based Power Reduction

Traditionally, the focus on low-power design has been purely hardware based. This tends to ignore the fact that it is the software that executes on a CPU that determines its power consumption. The software perspective on power consumption has been the subject of recent work [9]. Here a detailed instruction-level power model of the Intel486DX2 was built. The impact of software on the CPU's power and energy consumption, and software optimizations to reduce these were studied. An important conclusion from this work was that in complex CPUs such as the 486DX2, software energy and performance track each other, i.e., for a given task, a faster program implementation will also have lower energy. This is because the CPU power consumption is dominated by a large cost factor (clocks, caches, etc.) that for the most part, does not vary much from one cycle to the other.

Some issues arise when this work is extended to recent CPUs. First, multiple-issue and out-of-order execution mechanisms make it hard to model power on a "per instruction" basis, and more complex power models are required. Also, increased use of clock gating implies that there is greater variation in power consumption from cycle to cycle; however, it is expected that the relationship between software energy and power that was observed before will continue to hold. In any case, it is important to realize that software directly impacts energy/power consumption, and thus, it should be designed to be efficient with respect to these metrics.

A classic example of inefficient software is "busy wait loops." Consider an application such as a spreadsheet that requires frequent user input. During the times when the spreadsheet is recalculating values, high CPU activity is desired in order to complete the recalculation in a short time. In contrast, when the application is waiting for the user to type in values, the CPU should be inactive and in a low-power state. However, a busy wait loop will prevent this from happening, and will keep the CPU in a high-power state. The power wastage is significant since the CPU is essentially fully active, even though it really is *not doing anything*. The Intel Power Monitor (IPM) is a publicly available [3] software analysis

tool that monitors system activity to provide information about software that may be wasting power in this and other cases.

## 14.4 Conclusion

---

Power consumption has emerged as a key constraint in computing applications of almost all kinds. Today's design trends point to the fact that the importance of power consumption will grow in the future. The intent of this chapter was to explain the reasons why this is so and to introduce the reader to the basic concepts and ideas behind power reduction techniques. The interested reader can refer to the listed references for more in-depth information.

### 15.1 Introduction

---

Low-power complementary metal oxide semiconductor (CMOS) circuit design is required to extend the battery lifetime of portable electronics such as cellular phones or personal digital assistants. [Table 15.1](#) shows a classification of various low-voltage and low-power approaches previously proposed. A system can be in one of two states. It can be active (or dynamic) performing useful computation, or idle (or standby) waiting for an external trigger. A processor, for instance, can transit to the idle state once a required computation is complete. The supply voltage ( $V_{dd}$ ), the threshold voltage ( $V_{th}$ ) and the clock frequency ( $f_{clk}$ ) are parameters that can be dynamically controlled to reduce power dissipation.

In low-voltage systems, the use of reduced threshold devices has caused leakage to become an important idle state problem. There are several ways to control leakage. One approach is to use a transistor as a supply switch to cut off leakage during the idle state. Another approach to control leakage involves threshold voltage adaptation using substrate bias ( $V_{bb}$ ) control. The use of multiple thresholds can be easily incorporated during the synthesis phase. The use of conditional (or gated) clocks is the most common approach to reduce energy. Unused modules are turned off by suppressing the clock to the module.

Low  $V_{dd}$  operation is very effective for active-power reduction because the power is proportional to  $V_{dd}^2$ . Adapting the power supply dynamically is widely employed. A less aggressive approach is the use of multiple static supplies where noncritical path circuits are powered by lower voltages. Dynamic  $V_{th}$  scaling by  $V_{bb}$  control compensates for transistors'  $V_{th}$  fluctuations caused by fabrication process variations. As a result, the technique suppresses the excess leakage power. When the  $V_{th}$  of transistors is very low, the suppression of leakage current is useful in the total operating power savings. Conditional clocking also reduces the dynamic-power consumption since the clock signals are only distributed to operating modules. The multiple frequency method delivers several frequencies of clock signals in accordance with required performance in each module. The clock frequency is scheduled depending on data load, and

dynamic  $V_{dd}$  scaling is usually applied with the frequency scheduling. These active-power controls can also be used as leakage reduction techniques during the idle state.

This chapter explores various circuit technologies for low-power systems grouped by the controllable parameters mentioned above.

## 15.2 Basic Theories of CMOS Circuits

In this section, a general analysis of a CMOS circuit is presented. The propagation delay and the power consumption are correlated in the circuit. The power dissipation of a CMOS circuit is described [1] as

$$P_{total} = P_{charge} + P_{leak} = af_{clk}C_LV_{dd}^2 + I_{l0} \times 10^{-(V_{th}/S)} \times V_{dd} \quad (15.1)$$

where  $a$  is the switching probability (transition activity),  $C_L$  is the load capacitance,  $I_{l0}$  is a constant, and  $S$  is the subthreshold slope. Circuit operation causes dynamic charging and discharging power of load capacitance, represented as  $P_{charge}$ . Static leakage current resulting from subthreshold leakage of MOS transistors is represented as  $P_{leak}$ . Until recently, power consumption in CMOS circuits was dominated by  $P_{charge}$  because of their high  $V_{th}$  devices. In the idle state, the switching probability equals 0, and power is determined solely by  $P_{leak}$ .

The propagation delay of a CMOS circuit is approximately given in [2] by

$$T_{pd} = \beta C_L \frac{V_{dd}}{(V_{dd} - V_{th})^\alpha} \quad (15.2)$$

where  $\beta$  is a constant. The mobility degradation factor  $\alpha$  is typically 1.3. With regard to performance, low  $V_{dd}$  increases the delay, whereas low  $V_{th}$  decreases it. Low  $V_{dd}$  operation reduces  $P_{charge}$ , but increases  $T_{pd}$ . To maintain a low  $T_{pd}$ ,  $V_{th}$  must be reduced. As a result,  $P_{leak}$  increases because of the low  $V_{th}$  devices. In recent circuits developed for low  $V_{dd}$  applications,  $V_{th}$  is reduced to improve performance.  $P_{leak}$  is becoming larger than  $P_{charge}$  in devices with low  $V_{th}$ .  $V_{th}$  is controllable by  $V_{bb}$ , and the relationship between them is described as

$$V_{th} = V_{th0} + \gamma(\sqrt{2\Phi_b - V_{bb}} - \sqrt{2\Phi_b}) \quad (15.3)$$

where  $V_{th0}$  is a constant,  $\gamma$  is the substrate-bias coefficient and  $\Phi_b$  is the Fermi potential. A substrate-bias current ( $I_{bb}$ ) must be added to Eq. (15.1) when  $V_{bb}$  is used to control  $V_{th}$ . This is necessary in the case of forward  $V_{bb}$ , which causes large substrate leakage because of p/n junctions and parasitic-bipolar transistors in the substrate.

# 15.3 Supply Voltage Management

## Supply Switch

A supply switch is one of the most effective means to cut off power in the idle state. Actually, the subthreshold leakage current caused by reduced  $V_{th}$  devices is a major problem in that state. The supply switch realizes high-speed operation in the active state and low-leakage current in the standby state. The switch was originally applied to a dynamic random access memory (DRAM) to reduce its data-retention current [3]. As shown in Fig. 15.1, a switching transistor  $W_s$  is inserted as the word drivers' supply switch. The transistor width of the switch  $W_s$  is equal to the width of the driver  $W_d$  because two or more word drivers will not be on at the same time.  $W_s$  determines total leakage current in the data-retention mode. Without the switch, the total driver width is  $n \times W_d$  and consumes large leakage. The supply switch is adopted to a microprocessor in [4].

A supply switch designed with high- $V_{th}$  MOS devices reduces leakage current, as represented by the multiple threshold-voltage CMOS (MT-CMOS) scheme [5]. The MT-CMOS circuit scheme is shown in Fig. 15.2. This technique combines two types of transistors: low- $V_{th}$  transistors for high-speed switching and high- $V_{th}$  transistors for low leakage. In the active state, SL is negated (low) and the high- $V_{th}$  supply switch transistors Q1 and Q2 supply  $V_{dd}$  and GND voltage to the virtual  $V_{dd}$  line ( $V_{dd}V$ ) and to the virtual GND line (GNDV) respectively. The operating circuit itself is made of low- $V_{th}$  transistors to accelerate the switching speed of the gate. In the idle state, SL is asserted (high) and Q1 and Q2 disconnect the  $V_{dd}V$  and GNDV to reduce leakage current when the circuits are in the idle state, with the asserted (high) SL signals. In a  $0.5\text{-}\mu\text{m}$  gate-length technology,  $0.6\text{ V}$   $V_{th}$  devices are used for high- $V_{th}$  switches and  $0.3\text{ V}$   $V_{th}$  devices are used for low- $V_{th}$  circuits. When the  $V_{th}$  difference between the two devices is  $0.3\text{ V}$ , the switches reduce the circuit's idle current by three orders of magnitude.

FIGURE 15.1 Word driver with subthreshold-current reduction [3].

FIGURE 15.2 MT-CMOS circuit scheme [5].

FIGURE 15.3 Latch circuit for the MT-CMOS flip-flop [5].

The size of the power switch is an important factor in MT-CMOS design [6]. To supply enough driving current to the circuit, the impedance of the switch must be low. To realize a reliable power supply, the capacitance of  $V_{dd}V$  line must be large. Hence, the total gate width of the switch must be large. Here, it is assumed that the total width of all transistors in the logic circuit is  $W_l$ , the width of the supply switch is  $W_h$ . When  $W_h = W_l$ , the supply voltage drop across the switch becomes 15%, causing a 25% increase in gate propagation delay. In the case of  $W_h = 10W_l$ , the drop is 2.5% and the delay increase is 3.6%. Therefore, MT-CMOS with a large  $W_h$  switch enables, at the same time, the high-speed operation of low- $V_{th}$  devices and the low-power consumption of high- $V_{th}$  devices.

When the MT-CMOS switches disconnect power, data stored in registers and memories disappears. Therefore, additional circuits are required to hold data in the idle state. There are several approaches to solve the problem: (a) the MT-CMOS latch [5], (b) the balloon circuit [7], (c) the intermittent power supply (IPS) scheme [8], and (d) the virtual rail clamp (VRC) circuit [9]. The MT-CMOS latch is a simple solution. As shown in Fig. 15.3, inverters G2 and G3 construct a latch circuit and are directly connected to  $V_{dd}$ . The local power switches  $Q_{L1}$  and  $Q_{L2}$  are applied to G1. This latch maintains the data in the idle state when G1 is powered down. To reduce the size of the local power switches and improve the latch delay, the balloon circuit is proposed in Fig. 15.4. In the active state, only TG3 is on and the balloon memory is disconnected from the logic circuit. Therefore, the balloon circuit does not degrade the low- $V_{th}$  circuit's performance. When the system goes to sleep, TG2 and TG3 briefly turn on so that data is

FIGURE 15.4 MT-CMOS balloon circuit [7].

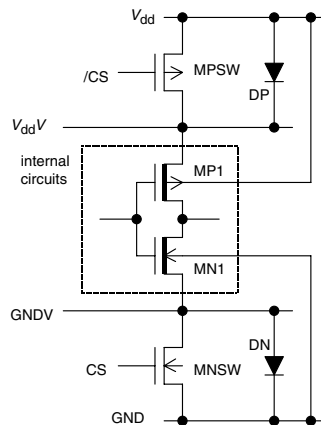

FIGURE 15.5 The VRC scheme [9].

written into the balloon latch. During the standby state, TG1 is on to keep the information. When the system wakes up, TG1 and TG2 briefly turn on so that the held data can be written back into the low- $V_{th}$  circuit. The balloon can be made of minimum size transistors, so it can be designed to occupy a small area. The third method is IPS. The IPS supplies power in about 20 ms intervals in the idle state to maintain voltage on the  $V_{ddV}$  line. The IPS acts similarly to the refresh operation of DRAM. The VRC circuit, as shown in Fig. 15.5, does not need extra circuits to maintain the data in the standby state. While the power switches MPSW and MNSW are disconnected,  $V_{ddV}$  and GNDV voltage variations are clamped by the built-in potential of diodes DP and DN. The voltage between  $V_{dd}$  and GNDV keeps data in memories.

MT-CMOS has been applied to reduce the power consumed by a digital signal processor (DSP) [10]. The DSP includes a small processor named power management processor (PMP) that handles signal-processing computations for small amounts of data. Idle power is reduced to 1/37 of its original value by the MT-CMOS leakage reduction. Operating power is decreased by 1/2 because loads with small amount of data are processed by the PMP instead of the DSP. Therefore, total power is reduced to 1/9 of its original value.

## Dynamic Voltage Scaling

The active power is in proportion to  $V_{dd}^2$ , as shown in Eq. (15.1). The  $V_{dd}$  reduction substantially reduces power. On the other hand, a low  $V_{dd}$  increases the CMOS circuit propagation delay, as shown in Eq. (15.2). Fixed supply voltage reduction is applied to a DRAM [11]. The supply for the memory array is reduced

FIGURE 15.6 Principle of a supply voltage reducer [12].

FIGURE 15.7 Power consumption with dynamic voltage scaling [13].

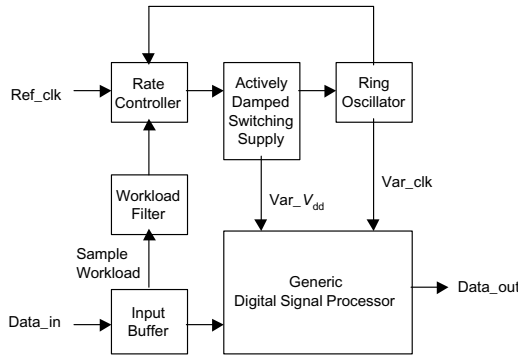

FIGURE 15.8 System diagram of variable supply-voltage processing [13].

to 3.7 V from a 5 V  $V_{dd}$ . It enables low-power operation and a high signal-to-noise ratio. Dynamic voltage scaling (DVS) in accordance with demanded performance is applied to a digital circuit [12]. This scheme can be realized with a phase-locked loop (PLL) system, as shown in Fig. 15.6. The voltage-controlled oscillator (VCO) is made of the critical path in the controlled digital system. This scheme provides a minimum  $V_{dd}$  so that the digital system operates at clock frequency  $f_{in}$ .

$f_{clk}$  and  $V_{dd}$  are controlled depending on the workload in [13]. This system is a combination of frequency scheduling and DVS. Depending on the workload, a frequency  $f_{clk}$  is selected, and the DVS circuitry selects the minimum  $V_{dd}$  in which a processor can operate at that frequency. The effect of DVS is shown in Fig. 15.7. Compared with a constant  $V_{dd}$  case (i), DVS reduces power dissipation of a processor. The DVS method has two variations: discrete  $V_{dd}$  scaling (ii) and arbitrary  $V_{dd}$  scaling (iii). The arbitrary  $V_{dd}$  scaling technique saves the most power among the three systems. Figure 15.8 shows an example of a complete DVS system [13]. The workload filter receives data and generates a signal to modulate the duty

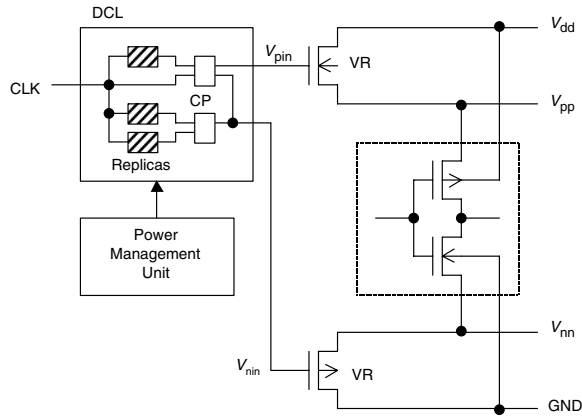

FIGURE 15.9 EVT-CMOS circuit design [19].

ratio of the reference clock. The actively damped switching supply provides the optimum  $V_{dd}$  according to the duty ratio of input signal. The ring oscillator provides the clock, whose frequency depends on the  $V_{dd}$  as given by a lookup table. DVS has been implemented on a DSP [14], an encryption processor [15], microprocessors [16,17], and I/Os [18]. DVS reduces the operating power to 1/5 in the DSP, 1/2 to 1/5 in the microprocessors, and 2/3 in the I/Os.

$V_{dd}$  control can also suppress process-induced performance fluctuations in CMOS circuits. The device characteristics have a distribution because of fabrication-process variations.  $V_{dd}$  control reduces the range of the fluctuations. Such a technique is described in elastic  $V_t$  CMOS (EVT-CMOS) [19], as shown in Fig. 15.9. EVT-CMOS changes  $V_{dd}$ ,  $V_{th}$  and the signal amplitude to reduce power and to raise operating speed. In the deviation compensated loop (DCL), signals  $V_{pin}$  and  $V_{nin}$  are generated by the charge pump (CP), so that the replica circuits operate at the given clock frequency. The voltage regulator (VR) is a  $V_{dd}$  switch that cleans the power supplies for the inner circuits and ensures performance by source-biasing the inner circuits according to  $V_{pin}$  and  $V_{nin}$ . The VR is a source-follower type to reduce the output impedance of the switch.

## Multiple Supply Voltage

If multiple supply voltages are used in a core of an LSI chip, this chip can realize both high performance and low power. The multiple supply system provides a high-voltage supply for high-performance circuits and a low-voltage supply for low-performance circuits. The clustered voltage scaling (CVS) [20] is another low-power method in which several  $V_{dd}$ s are distributed in the design phase. The CVS example shown in Fig. 15.10 uses two  $V_{dd}$ s. Between the data inputs and latches, there are circuits operated at high  $V_{dd}$  and low  $V_{dd}$ . Compared to circuits that operate at only high  $V_{dd}$ , the power is reduced. The latch circuit includes a level-transition (DC-DC converter) if there is a path where a signal propagates from low  $V_{dd}$  logic to high  $V_{dd}$  logic.

For two supply voltages  $V_{ddH}$  and  $V_{ddL}$ , there is an optimum voltage difference between the two  $V_{dd}$ s. If the difference is small, the effect of power reduction is small. If the difference is large, there are few logic circuits using the  $V_{ddL}$ . Two design approaches are used. One approach designs the entire device using high- $V_{dd}$  circuits at first. If the propagation delay of a circuit path is faster than the required clock period, the circuit is given a low- $V_{dd}$ . The other approach allows the circuits to be designed as low- $V_{dd}$  circuits at first. If a circuit path cannot operate at a required clock speed, the circuit is given a high- $V_{dd}$ . The dual  $V_{dd}$  system is applied for a media processor chip providing MPEG2 decoding and real-time MPEG1 encoding.  $V_{ddH}$  is 3.3 V and  $V_{ddL}$  is 1.9 V. This system reduces power by 47% in the random module and 69% in the clock distribution [21].

## 15.4 Threshold Voltage Management

### Substrate Bias Control for Leakage Reduction

When a CMOS circuit is running in low  $V_{dd}$  or is made of small technology devices, the  $V_{th}$  fluctuation caused by the fabrication process deviations becomes large [22], and then, circuit performance is degraded. A  $V_{bb}$  control scheme keeping the  $V_{th}$  constant is presented in [23]. As shown in Fig. 15.11, the substrate bias is automatically produced and  $V_{th}$  fluctuation caused by the short-channel effect is suppressed. If  $V_{th}$  is lowered to improve performance, subthreshold leakage current grows too large in the standby state. Another  $V_{bb}$  control method is proposed to solve the  $V_{th}$  fluctuation and large-subthreshold leakage at the

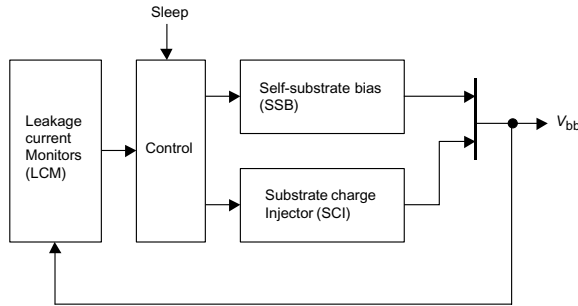

FIGURE 15.12 VT-CMOS block diagram [24].

FIGURE 15.13 Switched substrate-impedance scheme [26].

same time. This method is the variable threshold-voltage CMOS (VT-CMOS) scheme [24]. The substrate bias to the  $n$ -type well of a pMOS transistor is called  $V_{bp}$  and the bias to the  $p$ -type well of an nMOS transistor is called  $V_{bn}$ . The voltage between  $V_{dd}$  and  $V_{bp}$ , or between GND and  $V_{bn}$  is defined by  $\Delta V_{bb}$ .  $\Delta V_{bb}$  controls  $V_{th}$  as described by Eq. (15.3). This  $V_{bb}$  control system raises CMOS circuit performance by compressing  $V_{th}$  fluctuation in the active state, and reduces subthreshold leakage current by raising the MOS device  $V_{th}$  in the idle state.

The system diagram of VT-CMOS is shown in Fig. 15.12. The control circuit enables the leakage current monitor (LCM) and the self-substrate bias (SSB) circuit in the active state. The LCM measures the leakage current of MOS devices. The SSB forces the leakage current to be constant at a given value. For example, suppose  $V_{th}$  is designed at  $0.1 \pm 0.1$  V initially. Applying a  $0.4$  V  $\Delta V_{bb}$  increases the  $V_{th}$  to  $0.2$  V  $\pm 0.05$  V. Therefore, the  $V_{th}$  fluctuation is compensated from  $0.1$  to  $0.05$  V. In this way the  $V_{bb}$  control system reduces  $V_{th}$  fluctuation [25].

The SSB and the substrate charge injector (SCI) operate in the idle state. The SSB applies large  $\Delta V_{bb}$  to reduce leakage current. The SCI enables  $V_{bb}$  to drive the substrate quickly and accurately.  $\Delta V_{bb}$  becomes about  $2$  V and then the  $V_{th}$  is  $0.5$  V. The usage of the SSB and SCI results in low subthreshold leakage in the idle state. When applied to a discrete cosine transform processor, it occupies only 5% of the area. The substrate-bias current of  $V_{bb}$  control is less than 0.1% of the total current, a small power penalty.

The Switched substrate-impedance (SSI) scheme [26], as shown in Fig. 15.13, is one solution for preventing the  $V_{bb}$  noise. SSI distributes switch cells throughout a die that function as  $V_{bb}$  supplies.

FIGURE 15.14 GIDL effect and DIBL effect.

The signals  $cbp$  and  $cbn$  turn the switch cells on during the active state. The switch cells connect  $V_{dd}$  and GND lines with  $V_{bp}$  and  $V_{bn}$  lines, respectively, in the logic circuit. During the idle state, the switch cells turn off and the VBC macro scheme provides  $V_{bb}$ . The switch cells in a chip occupy less than 5% of the area. When the impedance of the switch is high, the substrate-bias lines are floating from the power-source lines, causing circuit-performance degradation. Hence, the size and layout of the switch are important issues. The switch cells are distributed uniformly, for instance, one per 100 gates.

When a MOS device shows a large gate-induced drain leakage (GIDL) effect, a large  $V_{bb}$  increases the subthreshold leakage current, as shown in Fig. 15.14 [27]. In such a case, only a small substrate bias works as a leakage-reduction approach. Subthreshold leakage current in a MOS device is reduced for low  $V_{dd}$  because of the drain-induced barrier lowering (DIBL) effect. So, the combination of small  $V_{bb}$  and low  $V_{dd}$  is useful for power reduction. In an experiment on a 360-MIPS RISC microprocessor, a 1.5-V  $V_{bb}$  reduces the leakage current from 1.3 mA to 50  $\mu\text{A}$ , and furthermore, lowering  $V_{dd}$  from 1.8 to 1 V suppresses the leakage to 18  $\mu\text{A}$ .

## Substrate Bias Control for Suppressing Device Fluctuations

As mentioned earlier, a small-size device and low  $V_{dd}$  operation present device characteristic fluctuations and thus circuit performance variations [22].  $V_{bb}$  control reduces chip-to-chip leakage current variations; however, the situation is different for performance fluctuations. When the operating temperature is changed, the subthreshold leakage variation is not the same as the saturation current variation in a MOS transistor. The reason is that diffusion current is dominant in the subthreshold region while drift current is dominant in the saturation region. Therefore, when temperature rises, the subthreshold leakage current increases and the saturation current decreases. The propagation delay of a CMOS circuit depends on the saturation current. The operating speed and leakage current respond differently to temperature variation. However, there is another way to use  $V_{bb}$  control to reduce speed fluctuations in CMOS circuits. Such a technique is applied to an encoder/decoder circuit in [28].

$V_{bb}$  is supplied to a whole LSI chip.  $V_{bb}$  control is useful to suppress chip-to-chip variations. However, the reverse  $V_{bb}$  raises the fluctuation *within* a chip [29]. In low  $V_{dd}$  operation, performance degradation becomes significant. Substrate forward biasing is one technique to avoid such problems. A forward-bias  $V_{bb}$  can be applied to CMOS circuits without latch-up problem [30]. A threshold scaling circuit named

FIGURE 15.15 SA- $V_t$  CMOS scheme with forward bias [31].

the speed-adaptive threshold-voltage CMOS (SA-VT CMOS) with forward bias for sub-1V systems is proposed in [31].

Figure 15.15 shows the SA-VT CMOS scheme, which realizes an automatic  $V_{th}$  scaling depending on a circuit speed. It is constructed from a  $V_{th}$ -controlled delay line, a comparator, a decoder, a digital-to-analog (D/A) converter, and an amplifier. The comparator measures the timing difference between the  $f_{clk}$  signal and a delayed signal from the delay line, and then, translates the difference into a digital word. After passing the delay information through the decoder, the D/A converter produces  $V_{bb}$ . The delay line is provided  $V_{bb}$  to modify its delay. Therefore, this circuit realizes a feedback loop system. The loop locks when the delay of the delay line becomes the same as the  $f_{clk}$  cycle. Once  $V_{bb}$  is decided, the circuit delivers  $V_{bb}$  to an LSI through the amplifier to set  $V_{th}$  for the LSI. The delay line is made of circuits that imitate a critical path in the LSI. Hence, matching the delay line's delay to the  $f_{clk}$  cycle ensures that the LSI's critical path completes within the clock period. The substrate biases  $V_{bp}$  and  $V_{bn}$  change discretely because the D/A converter in the SA-VT CMOS generates discrete voltages as substrate biases.  $V_{bp}$  and  $V_{bn}$  change symmetrically. Each transition time depends on the clock frequency. Therefore, the charging time of the delay line's substrate determines an upper bound on clock frequency. For high-speed circuits, the critical path replica must be divided to be used as the delay line to extend the maximum frequency.

The SA-VT CMOS keeps circuit delay constant by controlling  $V_{bb}$ . Because of this effect, it adjusts the optimum performance of an LSI along with the  $f_{clk}$  and compensates the performance fluctuations caused by fabrication process deviations,  $V_{dd}$  variations, and temperature variations. The performance degradations caused by fabrication process deviations are more critical in chip-to-chip distributions than within-chip distributions. This is because the degradations of circuit performance by within-chip distributions are statistically reduced when the circuit becomes larger. Therefore, it is sufficient to use one SA-VT CMOS control toward a whole VLSI substrate. The forward substrate biasing in SA-VT CMOS improves circuit delay degradation, especially at low  $V_{dd}$ . Although the performance variation caused by fabrication deviations becomes large with reverse substrate bias, it becomes small with forward bias.

## Multiple Threshold Voltage

Multiple  $V_{th}$  MOS devices are used to reduce power while maintaining speed. Low- $V_{th}$  devices are delivered to high-speed circuit paths. High- $V_{th}$  devices are applied to the other circuit to reduce subthreshold-leakage current. In case of multiple  $V_{th}$ , the level converter is not required, as used in the multiple  $V_{dd}$  technology.

**FIGURE 15.16** Triple- $V_{th}$  CMOS/SMOX circuit [33].

To make different  $V_{th}$  devices, some steps of fabrication process are added. A fabrication process and the effects of dual  $V_{th}$  circuits are discussed in [32].

Figure 15.16 shows an example of a dual  $V_{th}$  circuit with a high- $V_{th}$  power switch [33]. The high- $V_{th}$  transistor is used to cut off subthreshold leakage current. In the logic circuit, low- $V_{th}$  devices and medium- $V_{th}$  devices are used to make a dual- $V_{th}$  circuit system. In a 16-bit ripple-carry adder, the active-leakage current is reduced to one-third that of the all low- $V_{th}$  adder. Two design approaches are used for dual- $V_{th}$  circuit. One approach designs the entire device using low- $V_{th}$  transistors at first. If the delay of a circuit path is faster than the required clock period, the circuit is replaced to a high- $V_{th}$  transistor. The other approach allows all of circuits to be designed as high- $V_{th}$  transistors at first. If a circuit path cannot operate at a required clock speed, the circuit is replaced to a low- $V_{th}$  transistor. The synthesis algorithms are examined in [34,35].

## 15.5 Clock Distribution Management

### Conditional Clocking

A global clock network consumes 32% of the power in an Alpha 21264 processor [36]. This power is eliminated when clock distribution is suspended by gating during the idle state.

The operating power is also reduced with the conditional clocks, which deliver clock signals only to active modules. The Alpha 21264 uses conditional clocking in the data path as shown in Fig. 15.17. For instance, the control logic asserts the ADD CLK ENABLE signal when a floating-point addition is executed. The enable pulse propagates through latches to drive the AND gates. Other units are disabled while the adder is executed. When a datapath is not needed, the enable signal is negated, and the clock to that path is halted. The clock network reduces the power to 25% of the unconditional case when no floating-point instruction is executed.

### Multiple Frequency Clock

Multiple frequency clocks are used in the Super-H microprocessor [37]. This microprocessor has three kinds of clocks: I-clock for the internal main modules, B-clock for the bus lines, and P-clock for the peripheral circuits. Maximum frequencies of each clock are 200, 100, and 50 MHz, respectively. Compared to a 200 MHz single-clock design, it reduces the distribution power by 23%.

### 16.1 Introduction

---

Supply voltage ( $V_{cc}$ ) must continue to scale down at the historical rate of 30% per technology generation in order to keep power dissipation and power delivery costs under control in future high-performance microprocessor designs. To improve transistor and circuit performance by at least 30% per technology generation, transistor threshold voltage ( $V_t$ ) must also reduce at the same rate so that a sufficiently large gate overdrive ( $V_{cc}/V_t$ ) is maintained. However, reduction in  $V_t$  causes transistor subthreshold leakage current ( $I_{off}$ ) to increase exponentially. Large leakage can (1) severely degrade noise immunity of dynamic logic circuits, (2) compromise stability of 6T SRAM cells, and (3) increase leakage power consumption of the chip to an unacceptably large value. In addition, degradation of short-channel effects, such as  $V_t$  roll-off and drain induced barrier lowering (DIBL), in conventional bulk MOSFET's with low  $V_t$  can pose serious obstacles to producing high-performance, manufacturable transistors at low cost in sub-100 nm  $L_{eff}$  technology generations and beyond. To further compound the technology scaling problems, within-die and across-wafer device parameter variations are becoming increasingly untenable. This nonscalability of process tolerances is also a barrier to  $V_{cc}$  and technology scaling.

To illustrate the barrier associated with excessive leakage power, one can estimate the subthreshold leakage power of future chips, starting with the 0.25  $\mu\text{m}$  technology described in [1], and projecting subthreshold

FIGURE 16.1 Projected off currents.

FIGURE 16.2 Projected leakage power in 0.1  $\mu\text{m}$  technology.

leakage currents for 0.18  $\mu\text{m}$ , 0.13  $\mu\text{m}$ , and 0.1  $\mu\text{m}$  technologies. Because subthreshold leakage is increasingly the dominant component of transistor leakage, it can be used to illustrate the excessive leakage power barrier. Assume that 0.25  $\mu\text{m}$  technology has  $V_t$  of 450 mV, and  $I_{\text{off}}$  is around 1 nA/ $\mu\text{m}$  at 30°C. Also assume that subthreshold slopes are 80 and 100 mV/decade at 30°C and 100°C, respectively,  $V_t$  scales by 15% per generation, and  $I_{\text{off}}$  increases by 5 times each technology generation. Because  $I_{\text{off}}$  increases exponentially with temperature, it is important to consider leakage currents and leakage power as a function of temperature. Figure 16.1 shows projected  $I_{\text{off}}$  (as a function of temperature) for the four different technologies.

Next, we use these projected  $I_{\text{off}}$  values to estimate the active leakage power of a 15 mm die (small die), and compare the leakage power with the active power. The total transistor width on the die increases by  $\sim 50\%$  each technology generation; hence the total leakage current increases by  $\sim 7.5$  times. This results in leakage power of the chip increasing by  $\sim 5$  times each technology generation. Since the active power remains constant (per scaling theory) for constant die size, the leakage power will become a significant portion of the total power as shown in Fig. 16.2.

This chapter explores the various components of leakage currents at the transistor level, and also describes the effect of leakage currents at the circuit level. Finally, it concludes with a few techniques that can be used to help control subthreshold leakage currents in both sleep and active circuit modes.

## 16.2 Transistor Leakage Current Components

Transistor off-state leakage current ( $I_{\text{OFF}}$ ) is the drain current when the gate-to-source voltage is zero.  $I_{\text{OFF}}$  is influenced by threshold voltage, channel physical and effective dimensions, channel/surface doping profile, drain/source junction depth, gate oxide thickness,  $V_{\text{DD}}$ , and temperature; however,  $I_{\text{OFF}}$  as defined above is not the only leakage mechanism of importance for a deep submicron transistor.  $\log(I_D)$  versus  $V_G$  is an important transistor curve in the saturated and linear bias states (Fig. 16.3). It allows measurement

FIGURE 16.3  $n$ -channel  $I_D$  vs.  $V_G$  showing DIBL, GIDL, weak inversion, and p-n junction reverse bias leakage components in a  $0.35\ \mu\text{m}$  technology.

FIGURE 16.4 Summary of leakage current mechanisms of deep submicron transistors [10].

of many device parameters such as  $I_{\text{OFF}}$ ,  $V_T$ ,  $I_D(\text{SAT})$ ,  $I_D(\text{LIN})$ ,  $g_m(\text{SAT})$ ,  $g_m(\text{LIN})$ , and slope ( $S_d$ ) of  $V_G$  versus  $I_D$  in the weak inversion state.  $I_{\text{OFF}}$  is measured at the  $V_G = 0\ \text{V}$  intercept. Measurements will illustrate all leakage current mechanisms and their properties in deep submicron transistors. The transistors in this study were from a  $0.35\ \mu\text{m}$  CMOS process technology with  $L_{\text{eff}} \ll 0.25\ \mu\text{m}$  and nominal  $V_{\text{DD}} \approx 2.5\ \text{V}$  [2].

We describe eight short-channel leakage mechanisms illustrating certain properties with measurements (Fig. 16.4).  $I_1$  is reverse bias p-n junction leakage caused by barrier emission combined with minority carrier diffusion and band-to-band tunneling away from the oxide-silicon interface,  $I_2$  is weak inversion,  $I_3$  is DIBL,  $I_4$  is gate induced drain leakage (GIDL),  $I_5$  is channel punchthrough,  $I_6$  is channel surface current due to narrow width effect,  $I_7$  is oxide leakage, and  $I_8$  is gate current due to hot carrier injection. Currents  $I_1$ – $I_6$  are off-state leakage mechanisms, while  $I_7$  (oxide tunneling) occurs when the transistor bias states are in transition.  $I_8$  can occur in the off-state, but more typically occurs when the transistor bias states are in transition.

### p-n Junction Reverse Bias Current ( $I_1$ )

The reverse bias p-n junction leakage ( $I_1$ ) has two main components: One is minority carrier diffusion/drift near the edge of the depletion region, and the other is due to electron-hole pair generation in the depletion region of the reverse bias junction [3]. If both n- and p-regions are heavily doped (this will be the case

for advanced MOSFETs using heavily doped shallow junctions and halo doping for better short-channel effects), Zener and band-to-band tunneling may also be present. For a MOS transistor, additional leakage can occur between the drain and well junction from gated diode device action (overlap and vicinity of gate to the drain to well p-n junctions) or carrier generation in drain to well depletion regions with influences of the gate on these current components [4]. p-n reverse bias leakage ( $I_{REV}$ ) is a function of junction area and doping concentration [3,5].  $I_{REV}$  for pure diode structures in our technology [2] was a minimal contributor to total transistor  $I_{OFF}$ . p-n junction breakdown voltage was  $>8$  V.

## Weak Inversion ( $I_2$ )

Weak inversion or subthreshold conduction current between source and drain in a MOS transistor occurs when gate voltage is below  $V_T$  [3,6]. The weak inversion region is seen in Fig. 16.3 as the linear portion of the curve. The carriers move by diffusion along the surface similar to charge transport across the base of bipolar transistors. The exponential relation between driving voltage on the gate and the drain current is a straight line in a semi-log plot. Weak inversion typically dominates modern device off-state leakage due to the low  $V_T$  that is used.

## Drain-Induced Barrier Lowering ( $I_3$ )

DIBL occurs when a high voltage is applied to the drain where the depletion region of the drain interacts with the source near the channel surface to lower the source potential barrier. The source then injects carriers into the channel surface without the gate playing a role. DIBL is enhanced at higher drain voltage and shorter  $L_{eff}$ . Surface DIBL typically happens before deep bulk punchthrough. Ideally, DIBL does not change the slope,  $S_p$ , but does lower  $V_T$ . Higher surface and channel doping and shallow source/drain junction depths reduce the DIBL leakage current mechanism [6,7]. Figure 16.3 illustrates the DIBL effect as it moves the curve up and to the left as  $V_D$  increases. DIBL can be measured at constant  $V_G$  as the change in  $I_D$  for a change in  $V_D$ . For  $V_D$  between 0.1 and 2.7 V,  $I_D$  changed 1.68 decades giving a DIBL of 1.55 V/decade change of  $I_D$ . DIBL may also be quantified in units of mV/V for at a constant drain current value.

The subthreshold leakage of a MOS device including weak inversion and DIBL can be modeled according to the following equation:

$$I_{subth} = A \times e^{\frac{1}{nV_T}(V_G - V_S - V_{TH0} - \gamma' \times V_S + \eta \times V_{DS})} \times \left( 1 - e^{\frac{-V_{DS}}{V_T}} \right) \quad (16.1)$$

where

$$A = \mu_0 C'_{OX} \frac{W}{L_{eff}} (v_T)^2 e^{1.8} e^{\frac{-\Delta V_{TH}}{\eta v_T}}$$

$V_{TH0}$  is the zero bias threshold voltage,  $v_T = kT/q$  is the thermal voltage. The body effect for small values of source to bulk voltages is very nearly linear and is represented by the term  $\gamma' V_S$ , where  $\gamma'$  is the linearized body effect coefficient.  $\eta$  is the DIBL coefficient,  $C_{OX}$  is the gate oxide capacitance,  $\mu_0$  is the zero bias mobility, and  $n$  is the subthreshold swing coefficient for the transistor.  $\Delta V_{TH}$  is a term introduced to account for transistor-to-transistor leakage variations.

## Gate-Induced Drain Leakage ( $I_4$ )

GIDL current arises in the high electric field under the gate/drain overlap region causing deep depletion [7] and effectively thins out the depletion width of drain to well p-n junction. The high electric field between gate and drain (a negative  $V_G$  and high positive  $V_D$  bias for NMOS transistor) generates carriers into the substrate and drain from direct band-to-band tunneling, trap-assisted tunneling, or a combination of thermal emission and tunneling. It is localized along the channel width between the gate and drain. GIDL is at times referred to as surface band-to-band tunneling leakage. GIDL current is seen as the “hook” in the waveform of Fig. 16.3 that shows increasing current for negative values of  $V_G$  (gate bias dependent specially observed at high  $V_D$  curves). Thinner  $T_{ox}$  and higher  $V_{DD}$  (higher potential between gate and drain) enhance the electric field dependent GIDL. The impact of drain (and well) doping on GIDL is rather complicated. At low drain doping values, we do not have high electric field for tunneling to occur. For very high drain doping, the depletion volume for tunneling will be limited. Hence, GIDL is worse for drain doping values in between the above extremes. Very high and abrupt drain doping is preferred for minimizing GIDL as it provides lower series resistance required for high transistor drive current. GIDL is a major obstacle in  $I_{OFF}$  reduction. As it was discussed, a junction related bulk band-to-band tunneling component in  $I_1$  may also contribute to GIDL current, but this current will not be gate bias dependent. It will only increase baseline value of  $I_4$  current component.

We isolated  $I_{GIDL}$  by measuring source current  $\log(I_s)$  versus  $V_G$ . It is seen as the dotted line extension of the  $V_D = 4.0$  V curve in Fig. 16.3.  $I_{GIDL}$  is removed since it uses the drain and substrate (well) terminals, not the source terminal. The GIDL contribution to  $I_{OFF}$  is small at 2.7 V, but as the drain voltage rises to 4.0 V (close to burn-in voltage), the off-state current on the  $V_D = 4.0$  V curve increases from 6 nA (at the dotted line intersection with  $V_G = 0$  V) to 42 nA, for a GIDL of 36 nA. The pure weak inversion and reverse bias p-n junction current of 99 pA is approximated from the  $V_D = 0.1$  V curve.

## Punchthrough ( $I_5$ )

Punchthrough occurs when the drain and source depletion regions approach each other and electrically “touch” deep in the channel. Punchthrough is a space-charge condition that allows channel current to exist deep in the subgate region causing the gate to lose control of the subgate channel region. Punchthrough current varies quadratically with drain voltage and  $S_t$  increases reflecting the increase in drain leakage [8, p. 134]. Punchthrough is regarded as a subsurface version of DIBL.

## Narrow Width Effect ( $I_6$ )

Transistor  $V_T$  in nontrench isolated technologies increases for geometric gate widths in the order of  $\leq 0.5 \mu\text{m}$ . An opposite and more complex effect is seen for trench isolated technologies that show decrease in  $V_T$  for effective channel widths on the order of  $W \leq 0.5 \mu\text{m}$  [9]. No narrow width effect was observed in our transistor sizes with  $W \gg 0.5 \mu\text{m}$ .

## Gate Oxide Tunneling ( $I_7$ )

Gate oxide tunneling current  $I_{ox}$ , which is a function of electric field ( $E_{ox}$ ), can cause direct tunneling through the gate or Fowler–Nordheim (FN) tunneling through the oxide bands [Eq. (16.1)] [8]. FN tunneling typically lies at a higher field strength than found at product use conditions and will probably remain so. FN tunneling has a constant slope for  $E_{ox} > 6.5$  MV/cm (Fig. 16.5). Figure 16.5 shows significant direct oxide tunneling at lower  $E_{ox}$  for thin oxides.

$$I_{OX} = A \cdot E_{OX}^2 \cdot e^{-\frac{B}{E_{OX}}} \quad (16.2)$$

**FIGURE 16.5** Fowler–Nordheim and direct tunneling in  $n$ -channel transistor oxide. The 60–80 Å curve shows dominance of FN tunneling while the <50 Å curve shows FN at high  $E_{ox}$ , but significant direct tunneling at low electric fields.

**FIGURE 16.6** Components of  $I_{OFF}$  for a 0.35  $\mu\text{m}$  technology for a transistor of 20  $\mu\text{m}$  wide. Currents from various leakage mechanisms accumulate resulting in a total measured transistor  $I_{OFF}$  for a given drain bias.

Oxide tunneling current is presently not an issue for devices in production, but could surpass weak inversion and DIBL as a dominant leakage mechanism in the future as oxides get thinner.

### Hot Carrier Injection ( $I_8$ )

Short channel transistors are more susceptible to injection of hot carriers (holes and electrons) into the oxide. These charges are a reliability risk and are measurable as gate and substrate currents. While past and present transistor technologies have controlled this component, it increases in amplitude as  $L_{eff}$  is reduced unless  $V_{DD}$  is scaled accordingly.

Figure 16.6 summarizes relative contributions of main components of intrinsic leakage for a typical 0.35 micron CMOS technology. We can see that for a nominal drain voltage of 2.7 V (consistent with typical power supply voltage of the technology), DIBL is the dominant component of leakage (it elevates the amount of weak inversion subthreshold leakage current). At elevated burn-in voltage of 3.9 V, GIDL dominates; however, at low  $V_D$ , weak inversion is the primary leakage mechanism.

## 16.3 Circuit Subthreshold Leakage Current

Subthreshold leakage currents for a single device can be modeled as illustrated in Eq. (16.1), but in a CMOS circuit that contains multiple devices connected together, the net leakage effect will be highly dependent on the applied input vectors [11,12]. The underlying mechanisms are related to (1) transistor stack effect and (2) total effective width of NMOS and PMOS devices that are turned off. [13,14].

FIGURE 16.7 Two-nMOS stack in a two-input NAND gate.

FIGURE 16.8 DC solution of two-nMOS stack.

## Transistor Stack Effect

The “stack effect” refers to the leakage reduction effect in a transistor stack when more than one transistor is turned off. The dynamics of the stack effect can be best understood by considering a two-input NAND gate in Fig. 16.7. When both M1 and M2 are turned off, the voltage  $V_m$  at the intermediate node is positive due to the small drain current. Thus, the gate-to-source voltage of the upper transistor M1 is negative, i.e.,  $V_{gs1} < 0$ . The exponential characteristic of the subthreshold conductance on  $V_{gs}$  greatly reduces the leakage. In addition, the body effect of M1 due to  $V_M > 0$  further reduces the leakage current as  $V_t$  increases.

The internal node voltage  $V_M$  is determined by the cross point of the drain currents in M1 and M2. Since leakage current strongly depends on the temperature and the transistor threshold voltage, we consider two cases: (1) high  $V_t$  and room temperature at 30°C and (2) low  $V_t$  and high temperature at 110°C. Figure 16.8 shows the DC solution of nMOS subthreshold current characteristics from SPICE simulations. The leakage current of a single nMOS transistor at  $V_g = 0$  is determined by the drain current of M1 at  $V_M = 0$ . It is clear that the leakage current through a two-transistor stack is approximately an order of magnitude smaller than the leakage of a single transistor. The voltage  $V_M$  of the internal node converges to  $\sim 100$  mV, as shown in Fig. 16.8. The small  $V_M$  (= drain-to-source voltage of M2) reduces the DIBL, and hence increases  $V_t$  of M2, which also contributes to the leakage reduction.

The subthreshold swing is proportional to  $kT$ . The slope decreases when the temperature  $T$  increases, which moves the cross point (Fig. 16.8) upwards. Thus, the amount of reduction will be smaller at higher temperature. The amount of reduction is also dependent on the threshold voltage  $V_t$ , which is larger for higher  $V_t$ . For three- or four-transistor stacks, the leakage reduction is found to be 2–3 times larger in both nMOS and pMOS. Results are summarized in Fig. 16.9. Note that reductions are obtained at the room temperature, as we are only interested in standby mode.

The reduced standby stack leakage current is obtained under steady-state condition. After a logic gate has a transition, the leakage current does not immediately converge to its steady-state value. Let us again

consider the NAND gate in Fig. 16.7. Assume that the inputs switches from  $A = 0, B = 1$  to  $A = 0, B = 0$  to turn off both transistors, the voltage  $V_M$  of the internal node is approximately  $V_{DD} - V_t$  after the transition. Due to the junction capacitance  $C_j$ ,  $V_M$  will “slowly” go down as it is discharged by the subthreshold drain current of M2. In the other case, when the inputs switches from  $A = 1, B = 0$  to  $A = 0, B = 0$ ,  $V_M$  is negative after the transition due to the coupling capacitance between the gate and drain of M2 (as shown in Fig. 16.7). It also takes certain amount of time for  $V_M$  to converge to its final value as determined by the DC stack solution.

The time required for the leakage current in transistor stacks to converge to its final value is dictated by the rate of charging or discharging of the capacitance at the intermediate node by the subthreshold drain current of M1 or M2. The convergence of leakage current is shown in Fig. 16.10. We define the *time constant* as the amount of time required to converge to twice of its final stack leakage value. This time constant is, therefore, determined by (1) drain-body junction and gate-overlap capacitances per unit width, (2) the input conditions immediately before the stack transistors are turned “off,” and (3) transistor subthreshold leakage current, which depends strongly on temperature and  $V_t$ . Therefore, the convergence rate of leakage current in transistor stacks increases rapidly with  $V_t$  reduction and temperature increase. For  $V_t = 200$  mV devices in a sub-1 V,  $0.1 \mu\text{m}$  technology, this time constant in 2-nMOS stacks at  $110^\circ\text{C}$  ranges from 5 to 50 ns.

## Steady-State Leakage Model of Transistor Stacks

To investigate the leakage behavior of a stack of transistors, consider a stack of four NMOS devices. Such a structure would occur in the NMOS pull-down tree of a four input NAND tree as shown in Fig. 16.11. Let us assume that all four devices are OFF with the applied gate voltage VG1 through VG4 being zero. Additionally, the full supply voltage, 1.5 V in the figure, is impressed across the stack. After a sufficiently long time, the voltage at each of the internal nodes will reach a steady-state value. With the assumption that subthreshold leakage from the drain to the source of the MOS device is the dominant leakage component and source drain junction leakage is negligible, application of Kirchoff’s current law (KCL)

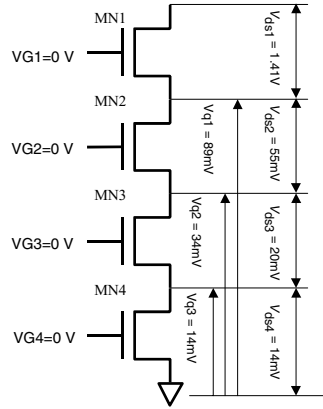

FIGURE 16.11 Four-input NAND NMOS stack.

yields the current through each transistor being the same and being identically equal to the overall stack current.

To calculate the overall leakage of the stack we use Eq. (16.1) to determine the leakage through a transistor as a function of the drain to source voltage. This yields the voltage across second transistor from the top as

$$V_{DS2} = \frac{nv_T}{(1 + 2\eta + \gamma')} \ln \left( \left( \frac{A_1}{A_2} \right) e^{\frac{nV_{DD}}{nv_T}} + 1 \right)$$

Additionally the voltage of the rest of the transistors can be expressed in a recursive fashion. The drain to source voltage of the  $i$ th transistor can be expressed in terms of the  $(i - 1)$ th transistor.

$$V_{DSi} = \frac{nv_T}{(1 + \gamma')} \ln \left( 1 + \frac{A_{i-1}}{A_i} \left( 1 - e^{-\frac{1}{v_T} V_{DS(i-1)}} \right) \right)$$

With the drain to source transistor voltages known, the leakage current through the stack can be computed by finding the leakage of the bottom transistor of the stack from the subthreshold equation. An identical method applies to the solution of leakage current for PMOS stacks. An estimate of leakage in transistor stacks was first presented by Gu and Elmasry [13]. The above analysis for transistor stack leakage was first presented by Johnson [14]. An early implementation of this idea for actively reducing leakage in word decoder-driver circuits for RAMs is presented by Kawhara [15]. The term “self-reverse biasing” used in this paper, gives a clear indication of the mechanism by which leakage of a stack of transistors is reduced.

## Transient Model of Transistor Stack Leakage

When stacked devices are turned off, the time required for the leakage currents to settle to the previously computed steady-state leakage levels can be large and can vary widely, ranging from microseconds to milliseconds. The settling time is important for determining if the quiescent leakage current model is applicable. The worst-case settling time for a stack occurs when all the internal nodes are charged to the maximum possible value  $V_{DD} - V_T$  just before every transistor of the stack is turned off. We notice that a strong reverse gate bias will now be present for all devices except for the bottom-most device. In the figure, MN1 to MN3 will have a reverse gate bias and the leakage through them is small. Hence, we approximate the discharge current of the drain node of MN4 as being the leakage current of MN4 alone. Once the drain voltage of MN4 is sufficiently small, MN3 discharges its drain node with a discharge current, which is the leakage current of the two stacked devices MN3 and MN4. The discharge time of each internal node of the stack,  $t_{disi}$ , is sequential and the overall settling time is the sum of the discharge times.

To derive a closed form solution for the discharge time, it is assumed that the capacitance of the internal nodes is not dependent on voltage. Additionally it is assumed that we know the internal node voltages after the instant the devices are cut-off—this requires a determination of the voltage to which internal nodes are bootstrapped. By using the capacitor discharge equation for the internal nodes, the discharge time can be written as

$$t_{\text{disi}} = \frac{nC_i L_{\text{eff}}}{\mu_0 C_{\text{OX}} W v_T e^{1.8} \eta} \times e^{\frac{1}{\eta v_T} [(1 + \gamma' + \eta) V_{q_{i+1}} + V_{\text{TH0}}]} \times \left( e^{\frac{-\eta V_{qi}}{\eta v_T}} - e^{\frac{-\eta V_{booti}}{\eta v_T}} \right)$$

## 16.4 Leakage Control Techniques

Many techniques have been reported in the literature to reduce leakage power during standby condition. Examples of such techniques are: (1) reverse body biasing, as discussed in another chapter of this book; (2) MTCMOS sleep transistor and variations of sleep transistor-based techniques; and (3) embedded multiple- $V_t$  CMOS design where low- $V_t$  devices are used only in the critical paths for maximizing performance, while high- $V_t$  devices are used in noncritical paths to minimize leakage power. In this section, we discuss two standby leakage reduction techniques: one through stack effect vector manipulation, and the other through embedded dual- $V_t$  design applied to domino circuits. We also discuss the applicability of reverse body biasing for improving performance and leakage power distribution of multiple die samples during active modes, as well as the impact of technology scaling on the effectiveness of this technique.

### Standby Leakage Control by Input Vector Activation

For any static CMOS gate other than the inverter, there are stacked transistors in nMOS or pMOS tree (e.g., pMOS stack in NOR, nMOS stack in NAND). Typically, a large circuit block contains high percentage of logic gates where transistor “stacks” are already present. Note that leakage reduction in a transistor stack can be achieved only when more than one device is turned off. Thus, the leakage current of a logic gate depends on its inputs. For a circuit block consisting of a large number of logic gates, the leakage current in standby mode is therefore determined by the vector at its inputs, which is fed from latches. For different vectors, the leakage is different. An input vector, which gives as small a leakage current as possible, needs to be determined. One of the following three methods can be used to select the input vector: (1) Examining the circuit topology makes it possible to find a “very good” input vector, which maximizes the stack effect, and hence minimizes the leakage current. (2) An algorithm can be developed for efficiently searching for the “best” vector. (3) Testing or simulating a large number of randomly generated input vectors, the one with the smallest leakage can also be selected and used in the standby mode. Method 1 is suitable for datapath circuits (e.g., adders, multipliers, comparators, etc.) due to their regular structure. For random logic, an algorithm in method 2 is required to find a vector with good quality. In [11], the input dependence of the leakage has been empirically observed and random search is used to determine an input vector; however, the fact that the dependence is due to the transistor stack effect has not been addressed.

Figure 16.12 shows the distribution of the standby leakage current of a 32-bit static CMOS Kogg-Stone adder generated by 1000 random input vectors, with two threshold voltages. The standby leakage power varies by 30–40%, depending on the input vector, which determines the magnitude of the transistor stack effect in the design. The best input vector for minimum leakage can be easily determined by examining the circuit structure. This predetermined vector needs to be loaded into the circuit during the standby mode. Figure 16.13 shows an implementation of the new leakage reduction technique where a “standby” control signal, derived from the “clock gating” signal, is used to generate and store the predetermined vector in the static input latches of the adder during “standby” mode so as to maximize the stack effect (the number of nMOS and pMOS stacks with “more than one ‘off’ device”). The desired input vector

for leakage minimization is encoded by using a NAND or NOR gate in the feedback loop of the static latch, so minimal penalty is incurred in adder performance. As shown in Fig. 16.14, up to  $2\times$  reduction in standby leakage can be achieved by this technique. Note that the vector found by examining the design results in significantly smaller leakage than that obtained by any of the 1000 random vectors. In order that the additional switching energy dissipated by the adder and latches, during entry into and exit from “standby mode,” be less than 10% of the total leakage energy saved by this technique during standby, the adder must remain in standby mode for at least  $5\ \mu\text{s}$ .

### Embedded Dual- $V_t$ Design for Domino Circuits

A promising technique to control subthreshold leakage currents during standby modes, while still maintaining performance, is to utilize dual  $V_t$  devices. As previously described, two main dual  $V_t$  circuit styles are common in the literature. MTCMOS, or multithreshold CMOS, involves using high  $V_t$  sleep transistors to gate the power supplies for a low  $V_t$  block [22]. Leakage currents will thus be reduced during sleep modes, but the circuit will require large areas for the sleep transistors, and active performance will be affected. Furthermore, optimal sizing of the sleep transistors is complex for larger circuits, and will be affected by the discharge and data patterns encountered [17,18].

The second family of dual  $V_t$  circuits is one in which individual devices are partitioned to be either high  $V_t$  or low  $V_t$  depending on their timing requirements. For example, gates in the critical path would be

FIGURE 16.15 Dual threshold voltage domino logic gate.

chosen to have low  $V_t$ , while noncritical gates would have high  $V_t$ 's, with correspondingly lower leakage currents [19]. This technique in general is only effective up to a certain point (diminishes with more critical paths in the circuit), and determining which paths can be made high  $V_t$  is a complex CAD problem [20].

An alternative application of dual  $V_t$  technology that can be very useful in microprocessor design is dual  $V_t$  domino logic [21]. In this style, individual gates utilize both high  $V_t$  and low  $V_t$  transistors, and the overall circuit will exhibit extremely low leakage in the standby mode, yet suffer no reduction in performance. This is achieved by exploiting the fixed transition directions in domino logic, and assigning a priori low-threshold voltages to only those devices in the critical charging/discharging paths. In effect, devices that can switch during the evaluate mode should be low  $V_t$  devices, while those devices that switch during precharge modes should be high  $V_t$  devices. Figure 16.15 shows a typical dual  $V_t$  domino stage used in a clock-delayed domino methodology, consisting of a pull-down network, inverter ( $I_1$ ), leaker device ( $P_1$ ), and clock drivers ( $I_2, I_3$ ), with the low  $V_t$  devices shaded.

During normal circuit operation, critical gate transitions occur only through low  $V_t$  devices, so high-performance operation is maintained. On the other hand, precharge transitions occur only through high  $V_t$  devices, but since precharge times in domino circuits are not in the critical path, slower transition times are acceptable. By having high  $V_t$  precharge transistors, it is possible to place the dual  $V_t$  domino gate into a very low leakage standby state merely by placing the clock in the evaluate mode and asserting the inputs. In a cascaded design with several levels of domino logic, the standby condition remains the same, requiring only an assertion of the first-level inputs. The correct polarity signal will then propagate throughout the logic to strongly turn off all high  $V_t$  devices and ensure low subthreshold leakage currents. In summary, dual  $V_t$  domino logic allows one to trade-off slower precharge time for improved standby leakage currents. As a result, using dual  $V_t$  domino logic can achieve the performance of an all low  $V_t$  design, while maintaining the low standby leakage current of an all high  $V_t$  design.

## Adaptive Body Biasing (ABB)

Another technique to control subthreshold leakage is to modulate transistor  $V_t$ 's directly through body biasing. With application of maximum reverse body bias to transistors, threshold voltage increases, resulting in lower subthreshold leakage currents during standby mode, but because the threshold voltage can be set dynamically, this technique can also be used to adaptively bias a circuit block during the active mode. Adaptive body biasing can be used to help compensate for large inter-die and within-die parameter variations by tuning the threshold voltage so that a common target frequency is reached. By applying reverse body bias to unnecessarily fast circuits, subthreshold leakage in the active mode can then be reduced as well. In order to use this technique, the initial process  $V_t$  should be targeted to a lower value than desired, and then reverse body bias can be applied to achieve a higher threshold voltage mean with lower variation.

Adaptive body biasing can easily be applied to a die as a whole (single PMOS body and NMOS body bias values for the whole chip), which will tighten the distribution of chip delays and leakage currents for a collection of dies, but because die sizes and parameter variations are becoming larger with future scaling, within-die variation becomes a problem as well. ABB can be applied aggressively at the block level, where individual functional blocks within a chip, such as a multiplier or ALU, can be independently modulated to meet a common performance target. The following subsection, however, focuses on the

**FIGURE 16.16** (a) Adaptive body bias reduces die-to-die variation in mean  $V_t$ . (b) Within-die  $V_t$  variation increases for die samples that require body bias to match their mean  $V_t$  to the target  $V_t$ .  $V_{t\text{-target}}$  is the target saturation threshold voltage for a given technology.  $V_{t\text{-low}}$  and  $V_{t\text{-nom}}$  are the minimum and mean threshold voltages of the die-to-die distribution.

effectiveness of adaptive body biasing applied at the die level and further explores the limitations of technology scaling on this technique.

### Impact of ABB on Die-to-Die and Within-Die Variations

As illustrated in Fig. 16.16(a) adaptive body biasing technique matches the mean  $V_t$  of all the die samples close to the target threshold voltage, when they were all smaller than the target to begin with. Hence, to use adaptive body bias we first need to retarget the threshold voltage of the technology to be lower than what it would have been if adaptive body bias weren't used. Also, short-channel effects of a MOS transistor degrades with body bias [6]. So as technology is scaled, this adverse effect of body biasing poses an increasingly serious challenge to controlling short-channel effects and results in (1) reduction in effectiveness of adaptive body bias to control die-to-die mean  $V_t$  variation and (2) increase in within-die  $V_t$  variation. As illustrated in Fig. 16.16(b), the die sample that requires larger body bias to match its mean  $V_t$  to the target threshold voltage will end up with higher within-die  $V_t$  variation. This increase in within-die  $V_t$  variation due to adaptive body bias can impact clock skew, worst case gate delay, worst-case device leakage, and analog circuits.

### Short-Channel Effects

In this subsection, we describe short-channel effects, namely,  $V_t$ -roll-off and DIBL that are affected by body bias. In a long-channel MOS the channel charge is controlled primarily by the gate. As MOS channel length is scaled down, the source-body and drain-body reverse-biased diode junction depletion regions contribute a larger portion of the channel charge. This diminishes the control that gate and body terminals have on the channel, resulting in  $V_t$ -roll-off and body effect reduction [22]. Another short-channel effect of interest is reduction of the barrier for inversion charge to enter the channel from the source terminal with increase in drain voltage. This dependence of MOS threshold voltage on drain voltage is DIBL. Both  $V_t$ -roll-off and DIBL degrade further with body bias because of widening diode depletions. The threshold voltage equation for short-channel MOS that captures the two short-channel effects is given as

$$V_t = V_{fb} + |2\phi_p| + \frac{\lambda_b}{C_{ox}} \sqrt{2qN\epsilon_s(|2\phi_p| + V_{sb}) - \lambda_d V_{ds}}$$

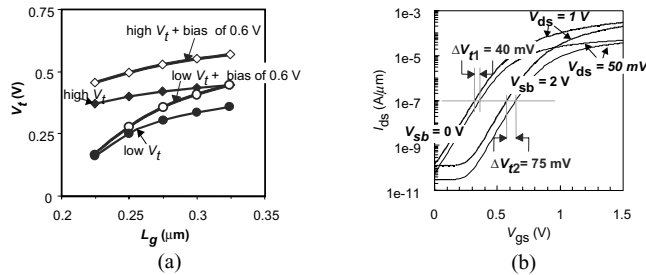

$$\lambda_b = 1 - \left( \sqrt{1 + \frac{2W}{X_j}} - 1 \right) \frac{X_j}{L}$$

$$\lambda_d = \left[ \frac{L}{2.2\mu\text{m}^2 (T_{ox} + 0.012\mu\text{m})(W_{sd} + 0.15\mu\text{m})(X_j + 2.9\mu\text{m})} \right]^{-2.7}$$

**FIGURE 16.17** Body effect reduction for low- $V_t$   $0.25\ \mu\text{m}$  device compared to a high- $V_t$   $0.25\ \mu\text{m}$  device.

**FIGURE 16.18** (a) Increase in  $V_t$ -roll-off due to  $V_t$  lowering and body bias. (b) Increase in DIBL ( $\Delta V_t/\Delta V_{ds}$ ) due to body bias, for a  $0.25\ \mu\text{m}$  NMOS.

$\lambda_b$  models the  $V_t$ -roll-off and body effect degradation with channel length reduction, and  $\lambda_d$  models DIBL. This parameter is based on empirical fitting of device parameters and has been verified to be accurate down to  $0.1\ \mu\text{m}$  channel length [23].

### Effectiveness of ABB

We know that adaptive body bias requires (1) lower  $V_t$  devices and (2) body bias to reduce die-to-die mean  $V_t$  variation. We also know that as technology is scaled, body terminal's control on the channel charge diminishes. This is further aggravated if  $V_t$  has to be reduced and/or if body bias has to be applied since both result in increased diode depletions. Figure 16.17 illustrates the shift in threshold voltage of two  $0.25\ \mu\text{m}$  MOS transistors. The two MOS transistors are identical in all aspects except in their threshold voltage values. The linear threshold voltages of the high- $V_t$  and the low- $V_t$  devices are 400 and 250 mV, respectively. It is clear from Fig. 16.17 that for 600 mV of body bias, the increase in threshold voltage for the high- $V_t$  device is significantly more than that of the low- $V_t$  device. The reasons for the reduced effectiveness of body bias for the low- $V_t$  device are (1) reduced channel doping required for  $V_t$  reduction means these devices will have lower body effect to begin with, (2) low- $V_t$  devices have more diode depletion charge degrading body effect, and (3) body bias increases diode depletion even more resulting in added body effect degradation. It has been shown in [24] that with aggressive 30%  $V_t$  scaling it will not be possible to match the mean  $V_t$  of all the die samples for  $0.13\ \mu\text{m}$  technology.

### Impact of ABB on Within-Die $V_t$ Variation

Low- $V_t$  devices that are required for adaptive body bias schemes have worse short channel effects, and these effects degrade with body bias. As Fig. 16.18(a) illustrates,  $V_t$ -roll-off behavior is larger for low- $V_t$  device compared to high- $V_t$  device, and  $V_t$ -roll-off increases further with body bias, as expected. Also, body bias increases DIBL ( $\Delta V_t/\Delta V_{ds}$ ) as expected, and this is depicted in Fig. 16.18(b).

Within-die  $V_t$  variation due to within-die variation in the critical dimension ( $\Delta L$ ) will depend on  $V_t$ -roll-off ( $\lambda_b$ ) and DIBL ( $\lambda_d$ ). So, increase in  $V_t$ -roll-off and DIBL due to adaptive body bias will result in a larger within-die  $V_t$  variation. It has been shown in [24] that this increase in within-die  $V_t$  variation

due to adaptive body bias worsens with scaling and is more pronounced under aggressive  $V_t$  scaling. So, for effective use of adaptive body bias one has to consider the maximum within-die  $V_t$  variation increase that can be tolerated. It should also be noted that adaptive body bias will become less effective with technology scaling due to increasing transistor threshold voltage variation and degrading body effect.

### 17.1 Introduction

---

The explosive proliferation of portable electronic devices, such as notebook computers, personal digital assistants (PDAs), and cellular phones, has compelled energy-efficient microprocessor design to provide longer battery run-times. At the same time, this proliferation has yielded products that require ever-increasing computational complexity. In addition, the demand for low-cost and small form-factor devices has kept the available energy supply roughly constant by driving down battery size, despite advances in battery technology that have increased battery energy density. Thus, microprocessors must continuously provide more throughput per watt.

To lower energy consumption, existing low-power design techniques generally sacrifice processor throughput [1–4]. For example, PDAs have a much longer battery life than notebook computers, but deliver proportionally less throughput to achieve this goal. A technique often referred to as voltage scaling [3], which reduces the supply voltage, is an effective technique to decrease energy consumption, which is a quadratic function of voltage; however, the delay of CMOS gates scales inversely with voltage, so this technique reduces throughput as well.

This chapter will present a design technique that dynamically varies the supply voltage to only provide high throughput when required, as most portable devices require peak throughput only some fraction of the time. This technique can decrease the system's average energy consumption by up to a factor of 10, without sacrificing perceived throughput, by exploiting the time-varying computational load that is commonly found in portable electronic devices.

# 17.2 Processor Operation

Understanding a processor’s usage pattern is essential to its optimization. Processor utilization can be evaluated in terms of the amount of processing required and the allowable latency for the processing to complete. These two parameters can be merged into a single measure, which is throughput or  $T$ . It is defined as the number of operations that can be performed in a given time:

$$\text{Throughput} \equiv T = \frac{\text{Operations}}{\text{Second}} \tag{17.1}$$

Operations are defined as the basic unit of computation and can be as fine-grained as instructions or more coarse-grained as programs. This leads to measures of throughput of MIPS (instructions/sec) and SPECint95 (programs/sec) [5] that compare the throughput on implementations of the same instruction set architecture (ISA), or different ISAs, respectively.

## Processor Usage Model

Portable devices are single-user systems whose processor’s computational requirements vary over time and typically occur in bursts. An example processor usage pattern is shown in Fig. 17.1, and demonstrates that the desired throughput varies over time, and the type of computation falls into one of three categories. These three modes of operation are found in most single-user processor systems, including PDAs, notebook computers, and even powerful desktop machines.

Compute-intensive and minimum-latency processes desire maximum performance, which is limited by the peak throughput of the processor,  $T_{MAX}$ . Any increase in  $T_{MAX}$  that the hardware can provide will readily be used by these processes to reduce their latency. Examples of these processes include spreadsheet updates, document spell checks, video decoding, and scientific computation.

Background and high-latency processes only require some fraction of  $T_{MAX}$ . There is no intrinsic benefit to exceeding the real-time latency requirements of these processes since the user will not realize any noticeable improvement. Examples of these processes include video screen updates, data entry, audio codecs, and low-bandwidth input/output (I/O) data transfers.

The third category of computation is system idle, which has zero desired throughput. Ideally, the processor should have zero energy consumption in this mode and therefore be inconsequential; however, in any practical implementation, this is not the case. The section on “Dynamically Varying Voltage” will demonstrate how dynamic voltage scaling can minimize this mode’s energy consumption.

## What Should Be Optimized?

Although compute-intensive and short-latency processes can readily exploit any increase in processor speed, background and long-latency processes do not benefit from any increase in processor speed above and beyond their average desired throughput since the extra throughput cannot be utilized. Thus,  $T_{MAX}$  is

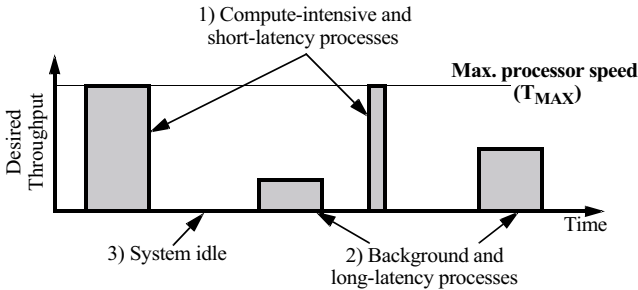

FIGURE 17.1 Processor usage model.

the parameter to be maximized since the user and/or operating environment determines the average throughput of the processor.

The run-time of a portable system is constrained by battery life. To maximize battery life, these systems require minimum energy consumption. Even for wired desktop machines, the drive toward “green” computers is making energy-efficient design a priority. Therefore, the computation per battery-life per watt-hour should be maximized, or equivalently, the average energy consumed per operation should be minimized.

This is in contrast to low-power design, which attempts to minimize power dissipation, typically to meet thermal design limits. Power relates to energy consumption as follows:

$$\text{Power} = \frac{\text{Energy}}{\text{Operation}} \times \text{Throughput} \quad (17.2)$$

Thus, while reducing throughput can minimize power dissipation, the energy/operation remains constant.

## Quantifying Energy Efficiency

An energy efficiency metric must balance the desire to maximize  $T_{\text{MAX}}$ , and minimize the average energy/operation. A good metric to quantify processor energy efficiency is the energy-throughput ratio (ETR) [6]:

$$\text{ETR} = \frac{\text{Energy/Operation}}{\text{Throughput}} = \frac{\text{Power}}{\text{Throughput}^2} \quad (17.3)$$

A lower ETR indicates lower energy/operation for equal throughput or equivalently indicates greater throughput for a fixed amount of energy/operation, satisfying the need to equally optimize  $T_{\text{MAX}}$  and energy/operation. Thus, a lower ETR represents a more energy-efficient solution. The energy-delay product [7] is a similar metric, but does not include the effects of architectural parallelism when the delay is taken to be the critical path delay.

## Common Design Approaches

With the ETR metric, three common design approaches for processor systems can be analyzed, and their impact on energy efficiency quantified.

### Compute ASAP

In this approach, the processor always performs the desired computation at maximum throughput. This is the simplest approach, and the benchmark to compare others against. When an interrupt comes into the processor, it wakes up from sleep, performs the requested computation, then goes back into sleep mode, as shown in Fig. 17.2(a). In sleep mode, the processor’s clock can be halted to significantly reduce idle energy consumption, and restarted upon the next interrupt. This approach is always high throughput, but unfortunately, it is also always high energy/operation.

### Clock Frequency Reduction

A common low-power design technique is to reduce the clock frequency,  $f_{\text{CLK}}$ . This in turn reduces the throughput, and power dissipation, by a proportional amount. The energy consumption remains unchanged, as shown in Fig. 17.2(b), because energy/operation is independent of  $f_{\text{CLK}}$ . This approach actually increases the ETR with respect to the previous approach, and is therefore more energy inefficient, because the processor delivers the same amount of computation per battery life, but at a lower level of peak throughput.

FIGURE 17.2 Throughput and energy/operation for three design approaches: (a) compute ASAP (b) clock frequency reduction, and (c) supply voltage reduction.

FIGURE 17.3 Throughput and energy/operation vs. supply voltage.

### Supply Voltage Reduction

When  $f_{CLK}$  is reduced, the processor's circuits have a longer cycle time to complete their computation in. In CMOS, the common fabrication technology for most processors today, the delay of the circuits increases as the supply voltage,  $V_{DD}$ , decreases. Thus, with voltage scaling, which reduces  $V_{DD}$ , the circuits can be slowed down until they just complete within the longer cycle time. This, in turn, will reduce the energy/operation, which is a quadratic function of  $V_{DD}$ , as shown in Fig. 17.2(c).

Figure 17.3 demonstrates that the throughput and energy/operation can vary more than tenfold over the range of  $V_{DD}$ . The curves are derived from analytical sub-micron CMOS device models [6]. Because throughput and energy/operation roughly track each other, reducing  $V_{DD}$  maintains approximately constant ETR, providing equivalent energy efficiency to the Compute ASAP approach. Thus, lower energy/operation can be achieved, but at the sacrifice of lower peak throughput.

# 17.3 Dynamically Varying Voltage

If both  $V_{DD}$  and  $f_{CLK}$  are dynamically varied in response to computational load demands, then the energy/operation can be reduced for the low computational periods of time, while retaining peak throughput when required. When a majority of the computation does not require maximum throughput, as is typically the case in portable devices, then the average energy/operation can be significantly reduced, thereby increasing the computation per battery life, without degradation of peak processor throughput. This strategy, which achieves the highest possible energy efficiency for time-varying computational loads, is called dynamic voltage scaling (DVS).

## Voltage Scaling Effects on Circuit Delay

A critical characteristic of digital CMOS circuits is shown in Fig. 17.4, which plots simulated maximum  $f_{CLK}$  versus  $V_{DD}$  for various circuits in a 0.6  $\mu\text{m}$  CMOS process [8]. Whether the circuits are simple (NAND gate, ring oscillator) or complex (register file, SRAM), their circuit delays track extremely well over a broad range of  $V_{DD}$ . Thus, as the processor's  $V_{DD}$  varies, all of the circuit delays scale proportionally making CMOS processor implementations very amenable to DVS, however, subtle variations of circuit delay with voltage do exist and primarily effect circuit timing, as discussed in the section on "Design Issues."

## Energy Efficiency Improvement

With DVS, peak throughput can always be delivered on demand by the processor, and remains a fixed value for the processor hardware. The average energy/operation, however, is a function of the computational load. When most of the processor's computation can be operated at low throughput, and low  $V_{DD}$ , the average energy/operation can be reduced tenfold as compared to the Compute ASAP design approach, which always runs the processor at maximum  $V_{DD}$ . This, in turn, increases the ETR tenfold, significantly improving processor energy efficiency.

Figure 17.5 plots the normalized battery run-time, which is inversely proportional to energy/operation, as a function of the fractional amount of computation performed at low throughput. Although a moderate run-time increase (22%) can be achieved with only 20% of the computation at low throughput, DVS yields significant increases when more of the computation can be run at low throughput, with an upper limit in excess of a tenfold increase in battery run-time, or equivalently, more than a tenfold reduction in energy/operation.

DVS can also significantly reduce a processor's energy consumption when it is idling. If the processor is put into its lowest performance mode before entering sleep mode, the energy consumption of all the circuits

FIGURE 17.4 Simulated maximum clock frequency for four circuits in 0.6  $\mu\text{m}$  CMOS.

FIGURE 17.5 Battery run-time vs. workload.

that require continual operation (e.g., bus interface, VCO, interrupt controller, etc.) can be minimized. The processor can quickly ramp up to maximum throughput upon receiving an incoming interrupt.

## Essential Components for DVS

A typical processor is powered by a voltage regulator, which outputs a fixed voltage. However, the implementation of DVS requires a voltage converter that can dynamically adjust its output voltage when requested by the processor to do so. Programmable voltage regulators can be used, but they are not designed to continuously vary their output voltage and degrade the overall system energy efficiency. A custom voltage converter optimized for DVS is described further in the section on “A Custom DVS Processor System.”

Another essential component is a mechanism to vary  $f_{\text{CLK}}$  with  $V_{\text{DD}}$ . One approach is to utilize a look-up table, which the processor can use to map  $V_{\text{DD}}$  values to  $f_{\text{CLK}}$  values, and set the on-chip phase-locked loop (PLL) accordingly. A better approach, which eliminates the need for a PLL, is a ring oscillator matched to the processor’s critical paths, such that as the critical paths vary over  $V_{\text{DD}}$ , so too will  $f_{\text{CLK}}$ .

The processor itself must be designed to operate over the full range of  $V_{\text{DD}}$ , which places restrictions on the types of circuits that can be used and impacts processor verification. Additionally, the processor must be able to properly operate while  $V_{\text{DD}}$  is varying. These issues are described further in the “Design Issues” section.

The last essential component is a DVS-aware operating system. The hardware itself cannot distinguish whether the currently executing instruction is part of a compute-intensive task or a nonspeed critical task. The application programs cannot set the processor speed because they are unaware of other programs running in a multi-tasking system. Thus, the operating system must control processor speed, as it is aware of the computational requirements of all the active tasks. Applications may provide useful information regarding their load requirements, but should not be given direct control of the processor speed.

## Fundamental Trade-Off

Processors generally operate at a fixed voltage and require a regulator to tightly control voltage supply variation. The processor produces large current spikes for which the regulator’s output capacitor supplies the charge. Hence, a large output capacitor on the regulator is desirable to minimize ripple on  $V_{\text{DD}}$ . A large capacitor also helps to maximize the regulator’s conversion efficiency by reducing the voltage variation at the output of the regulator.

The voltage converter required for DVS is fundamentally different from a standard voltage regulator because in addition to regulating voltage for a given  $f_{CLK}$ , it must also change the operating voltage when a new  $f_{CLK}$  is requested. To minimize the speed and energy consumption of this voltage transition, a small output capacitor on the converter is desirable, in contrast to the supply ripple requirements.

Thus, the fundamental trade-off in a DVS system is between good voltage regulation and fast/efficient dynamic voltage conversion. As will be shown in the “Voltage Converter” section, it is possible to optimize the size of this capacitor to balance the requirements for good voltage regulation with the requirements for a good dynamic voltage conversion.

### Scalability with Technology

Although the prototype system described next demonstrates DVS in a 3.3 V, 0.6  $\mu\text{m}$  process technology, DVS is a viable technique for improving processor system energy efficiency well into deep sub-micron process technologies. Maximum  $V_{DD}$  decreases with advancing process technology, seeming to reduce the potential of DVS, but this decrease is alleviated by decreases in the device threshold voltage,  $V_T$ . While the maximum  $V_{DD}$  may be only 1.2 V in a 0.10  $\mu\text{m}$  process technology, the  $V_T$  will be approximately 0.35 V yielding an achievable energy efficiency improvement,  $V_{DD}^2/V_T^2$ , still in excess of a tenfold increase.

## 17.4 A Custom DVS Processor System

DVS has been demonstrated on a complete embedded processor system, consisting of a microprocessor, external SRAM chips, and an I/O interface chip [9]. Running on the hardware is a preemptive, multi-tasking, real-time operating system, which supports DVS via a modular component called the voltage scheduler. Benchmark programs, typical of software that runs on portable devices, were then used to quantify the improvement in energy efficiency possible with DVS on real programs.

### System Architecture

As shown in Fig. 17.6, this prototype system contains four custom chips in a 0.6  $\mu\text{m}$  3-metal  $V_T \approx 1$  V CMOS process: a battery-powered DC-DC voltage converter, a microprocessor, SRAM memory chips, and an interface chip for connecting to commercial I/O devices. The entire system can operate at 1.2–3.8 V and 5–80 MHz, while the energy/operation varies from 0.54 to 5.6 mW/MIP.

The prototype processor, which contains a custom implementation of an ARM8 processor core [10], is a fully functional microprocessor for portable systems. The design contains a multitude of different

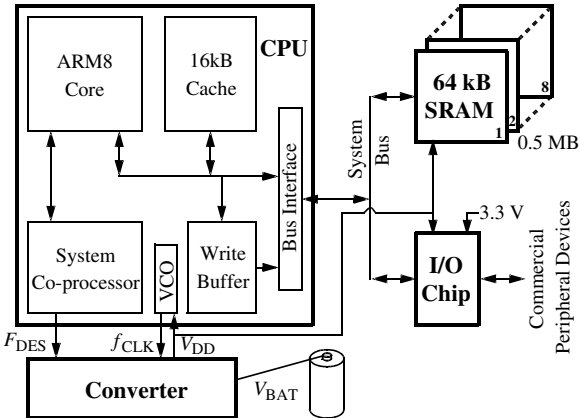

FIGURE 17.6 Prototype DVS processor system architecture.

circuits, including static logic, dynamic logic, CMOS pass-gate logic, memory cells, sense-amps, bus drivers, and I/O drivers. All these circuits have been demonstrated to continuously operate over voltage transients well in excess of  $1\text{ V}/\mu\text{s}$ . While the voltage converter was implemented as a separate chip, integrating it onto the processor die is feasible [11].

To further improve the system's energy efficiency, not only was DVS applied to the processor, but the external SRAM chips and external processor bus, as well. While this system operates off of a single, variable  $V_{\text{DD}}$ , a future processor system could again increase energy efficiency by providing multiple, variable voltages sources. This would allow high-speed, direct-memory accesses to main memory, so that even when the processor core is operating at low speed, high-bandwidth I/O-memory transactions could still occur. Additionally, this would also enable DVS peripheral devices that can adapt their throughput to the processing requirements of the I/O data.

## Voltage Scheduler

The voltage scheduler is a new operating system component for use in a DVS system. It controls the processor speed by writing the desired clock frequency to a system control register, whose value is used by the converter loop to adjust the processor clock frequency and regulated voltage. By optimally adjusting the processor speed, the voltage scheduler always operates the processor at the minimum throughput level required by the currently executing tasks, and thereby minimizes system energy consumption.

The implemented voltage scheduler runs as part of a simple real-time operating system. Because the job of determining the optimal frequency and the optimal task ordering are independent of each other, the voltage scheduler can be separate from the temporal scheduler. Thus, existing operating systems can be straightforwardly retrofitted to support DVS by adding in this new, modular component. The overhead of the scheduler is quite small such that it requires a negligible amount of throughput and energy consumption [12].

The basic voltage scheduler algorithm determines the optimal clock frequency by combining the computation requirements of all the active tasks in the system, and ensuring that all latency requirements are met given the task ordering of the temporal scheduler. Individual tasks supply either a completion deadline (e.g., video frame rate), or a desired rate of execution in megahertz. The voltage scheduler automatically estimates the task's workload (e.g., processing an mpeg frame), measured in processor cycles. The optimal clock frequency in a single-tasking system is simply workload divided by the deadline time, but a more sophisticated voltage scheduler is necessary to determine the optimal frequency for multiple tasks. Workload predictions are empirically calculated using an exponential moving average, and are updated by the voltage scheduler at the end of each task. Other features of the algorithm include the graceful degradation of performance when deadlines are missed, the reservation of cycles for future high-priority tasks, and the filtering of tasks that cannot possibly be completed by a given deadline [13].

Figure 17.7 plots  $V_{\text{DD}}$  for two seconds of a user-interface task, which generally has long-latency requirements. Clock frequency increases with  $V_{\text{DD}}$ , so processor speed can be inferred from this scope trace. The top trace demonstrates the microprocessor running in the typical full-speed/idle operation. A high voltage indicates the processor is actively running at full speed, and low voltage indicates system idle. This trace shows that the user-interface task has bursts of computation, which can be exploited with DVS. The lower trace shows the same task running with the voltage scheduler enabled. In this mode, low voltage indicates both system idle and low-speed/low-energy operation. The voltage spikes indicate when the voltage scheduler has to increase the processor speed in order to meet required deadlines. This comparison demonstrates that much of the computation for this application can be done at low voltage, greatly improving the system's energy efficiency.

## Voltage Converter

The feedback loop for converting a desired operating frequency,  $F_{\text{DES}}$ , into  $V_{\text{DD}}$  is shown in Fig. 17.8, and is built around a buck converter, which is very amenable to high-efficiency, low-voltage regulation [14]. The ring oscillator converts  $V_{\text{DD}}$  to a clock signal,  $f_{\text{CLK}}$ , which drives a counter that outputs a digital

FIGURE 17.7 DVS improvement for UI process.

FIGURE 17.8 Voltage converter negative-feedback loop.

measured frequency value,  $F_{MEAS}$ . This value is subtracted from  $F_{DES}$  to find the frequency error,  $F_{ERR}$ . The loop filter implements a hybrid pulse-width/pulse-frequency modulation algorithm [9], which generates an  $M_P$  or  $M_N$  enable signal. The inductor,  $L_{DD}$ , transfers charge to the capacitor,  $C_{DD}$ , to generate a  $V_{DD}$ , which is fed back to the ring oscillator to close the loop.

The only external components required are a  $4.7 \mu\text{H}$  inductor ( $L_{DD}$ ) placed next to the converter,  $5.5 \mu\text{F}$  ( $C_{DD}$ ) of capacitance distributed near the chips'  $V_{DD}$  pins, and a 1 MHz reference clock. The ring oscillator is placed on the processor chip, and is designed to track the critical paths of the microprocessor over voltage. A beneficial side effect is that the ring oscillator will also track the critical paths over process and temperature variations. The rest of the loop is integrated onto the converter die.

### New Performance Metrics

In addition to the supply ripple and conversion efficiency performance metrics of a standard voltage regulator, the DVS converter introduces two new performance metrics: transition time and transition energy. For a large voltage change (from  $V_{DD1}$  to  $V_{DD2}$ ), the transition time is:

$$t_{\text{TRAN}} \approx \frac{2C_{DD}}{I_{\text{MAX}}} |V_{DD2} - V_{DD1}| \quad (17.4)$$

where  $I_{MAX}$  is the maximum output current of the converter, and the factor of two exists because the current is pulsed in a triangular waveform. The energy consumed during this transition is:

$$E_{TRAN} = (1 - \eta)C_{DD}|V_{DD2}^2 - V_{DD1}^2| \quad (17.5)$$

where  $\eta$  is the efficiency of the DC-DC converter.

A typical capacitance of 100  $\mu\text{F}$  yields a  $t_{TRAN}$  of 520  $\mu\text{s}$  and an  $E_{TRAN}$  of 130  $\mu\text{J}$  for a 1.2–3.8 V transition (for the prototype system:  $I_{MAX} = 1 \text{ A}$ ,  $\eta = 90\%$ ). This long  $t_{TRAN}$  precludes any real-time control or fast interrupt response time, and only allows very coarse speed control. For voltage changes on the order of a context switch (30–100 Hz), the 100  $\mu\text{F}$  capacitor will give rise to 4–13 mW of transition power dissipation. In the prototype system, this was unreasonably large, since the average system power dissipation could be as low as 3.2 mW. To prevent the transition power dissipation from dominating the total system power dissipation, a converter loop optimized for a much smaller  $C_{DD}$  was designed.

Increasing  $C_{DD}$  reduces supply ripple and increases low-voltage conversion efficiency, making the loop a better voltage regulator, while decreasing  $C_{DD}$  reduces transition time and energy, making the loop a better voltage tracking system. Hence, the fundamental trade-off in DVS system design is to make the processor more tolerant of supply ripple so that  $C_{DD}$  can be reduced in order to minimize transition time and energy. The hybrid modulation algorithm of the loop filter maintains good low-voltage conversion efficiency to counter the effect of a smaller  $C_{DD}$  [15].

### Limits to Reducing $C_{DD}$

Decreasing  $C_{DD}$  reduces transition time, and by doing so increases  $dV_{DD}/dt$ . CMOS circuits can operate with a varying supply voltage, but only up to a point, which is process dependent. This is discussed further in the “Design Issues” section.

Decreased capacitance increases supply ripple, which in turn increases processor energy consumption as shown in Fig. 17.9. The increase is moderate at high  $V_{DD}$ , but begins to increase as  $V_{DD}$  approaches  $V_T$  because the negative ripple slows down the processor so much that most of the computation is performed during the positive ripple, which decreases energy efficiency. Loop stability is another limitation on reducing capacitance. The dominant pole in the system is set by  $C_{DD}$  and the load resistance ( $V_{DD}/I_{DD}$ ). The inductor does not contribute a pole because the buck converter operates in discontinuous mode; inductor current is pulsed to deliver discrete quantities of charge to  $C_{DD}$  [9].

As  $C_{DD}$  is reduced the pole frequency increases, particularly at high  $I_{DD}$ . As the pole approaches the sampling frequency, a 1 MHz pole due to a sample delay becomes significant, and will induce ringing. Interaction with higher-order poles will eventually make the system unstable.

Increasing the converter sampling frequency will reduce supply ripple and increase the pole frequency due to the sample delay. Thus, these two limits are not fixed, but can be varied; however, increasing the

FIGURE 17.9 Energy loss due to supply ripple.

FIGURE 17.10 Measured throughput vs. energy/operation.

sampling frequency has two negative side effects. First, low-load converter efficiency will decrease, and  $f_{CLK}$  quantization error will increase. These side effects may be mitigated with a variable sampling frequency that adapts to the system power requirements (e.g.,  $V_{DD}$  and  $I_{DD}$ ). The maximum  $dV_{DD}/dt$  at which the circuits will still operate properly is a hard constraint, but occurs for a much smaller  $C_{DD}$  than the supply ripple and stability constraints.

## Measured Energy Efficiency

Figure 17.10 plots the prototype system's throughput versus its energy/operation for the Dhrystone 2.1 benchmark, which is commonly used to characterize throughput (MIPS), as well as energy consumption (watts/MIP), for microprocessors in embedded applications [16]. To generate the curve, the system is operated at constant  $f_{CLK}$  and  $V_{DD}$  to demonstrate the full operating range of the system. The throughput ranges 6–85 Dhrystone 2.1 MIPS, and the total system energy consumption ranges 0.54–5.6 mW/MIP. At constant  $V_{DD}$ , the ETR is 0.065–0.09 mW/MIP<sup>2</sup>.

With DVS, peak throughput can be delivered upon demand. Thus, the true operating point for the system lies somewhere along the dotted line because 85 MIPS can always be delivered when required. When only a small fraction of the computation requires peak throughput, the processor system can deliver 85 MIPS while consuming, on average, as little as 0.54 mW/MIP. This yields an ETR of 0.006 mW/MIP<sup>2</sup>, which is more than a tenfold improvement compared to when the system is operating with a fixed voltage.

To evaluate DVS on real programs, three benchmark programs were chosen that represented software applications that are typically run on notebook computers or PDAs. Existing benchmarks (e.g., SPEC, Dhrystone MIPS, etc.) are not applicable because they only measure the peak performance of the processor. New benchmarks were selected, which combine computational requirements with realistic latency constraints, and include video decoding (MPEG), audio decoding (AUDIO), and an address-book user interface program (UI) [9].

As expected, the compute-intensive MPEG benchmark only has an 11% energy reduction from DVS, but DVS demonstrates significant improvement for the less compute-intensive AUDIO and UI benchmarks, which have a 4.5 times and 3.5 times energy reduction, respectively. The voltage scheduler's heuristic algorithm has a difficult time optimizing for compute-intensive code, so it performs extremely well on nonspeed critical applications. Thus, DVS provides significant reduction in energy consumption, with no loss of performance, for real software that is commonly run on portable electronic devices.

# 17.5 Design Issues

By following a simple set of rules and design constraints, the design of DVS circuits moderately increases design validation and reduces energy-efficiency when measured at a fixed voltage; however, these constraints are heavily outweighed by the enormous increase in energy efficiency afforded by DVS.

## Design over Voltage

A typical processor targets a fixed supply voltage, and is designed for  $\pm 10\%$  maximum voltage variation. In contrast, a DVS processor must be designed to operate over a much wider range of supply voltages, which impacts both design implementation and verification time. However, with a few exceptions, the design of a DVS-compatible processor is similar to the design of any other high-performance processor.

## Circuit Design Constraints

To maximize the achievable energy efficiency, only circuits that can operate down to  $V_T$  should be used. NMOS pass gates are often used in low-power design due to their small area and input capacitance [17], but they are limited by not being able to pass a voltage greater than  $V_{DD} - V_T$ , such that a minimum  $V_{DD}$  of  $2V_T$  is required for proper operation. Since throughput and energy consumption vary by a factor of 4 over the voltage range  $V_T$  to  $2V_T$ , using NMOS pass gates restricts the range of operation by a significant amount, and are not worth the moderate improvement in energy efficiency. Instead, CMOS pass gates, or an alternate logic style, should be utilized to realize the full voltage range of DVS.

The delay of CMOS circuits tracks over voltage such that functional verification is only required at one operating voltage. The one possible exception is any self-timed circuit, which is a common technique to reduce energy consumption in memory arrays. If the self-timed path layout exactly mimics that of the circuit delay path as was done in the prototype processor, then the paths will scale similarly with voltage and eliminate the need to functionally verify over the entire range of operating voltages.

## Circuit Delay Variation

Although circuit delay tracks well over voltage, subtle delay variations exist and do impact circuit timing. To demonstrate this, three chains of inverters were simulated whose loads were dominated by gate, interconnect, and diffusion capacitance respectively. To model paths dominated by stacked devices, a fourth chain was simulated consisting of 4 PMOS and 4 NMOS transistors in series. The relative delay variation of these circuits is shown in Fig. 17.11 for which the baseline reference is an inverter chain with a balanced load capacitance similar to the ring oscillator.

The relative delay of all four circuits is a maximum at only the lowest or highest operating voltages. This is true even including the effect of the interconnect's RC delay. Because the gate dominant curve is

FIGURE 17.11 Relative CMOS circuit delay variation over supply voltage.

FIGURE 17.12 Sources of noise margin degradation.

FIGURE 17.13 Noise margin vs. supply voltage.

convex, combining it with one or more of the other effects' curves may lead to a relative delay maxima somewhere between the two voltage extremes, but all the other curves are concave and roughly mirror the gate dominant curve such that this maxima will be less than a few percent higher than at either the lowest or highest voltage, and therefore insignificant. Thus, timing analysis is only required at the two voltage extremes, and not at all the intermediate voltage values.

As demonstrated by the series dominant curve, the relative delay of four stacked devices rapidly increases at low voltage, and larger stacks will further increase the relative delay [18]. Thus, to improve the tracking of circuit delay over voltage, a general design guideline is to limit the number of stacked devices, except for circuits whose alternative design would be significantly more expensive in area and/or power (e.g., memory address decoder).

### Noise Margin Variation

Figure 17.12 demonstrates the two primary ways that noise margin is degraded. The first is capacitive coupling between an aggressor signal wire that is switching and an adjacent victim wire. When the aggressor and victim signals have the same logic level, and the aggressor transitions between logic states, the victim signal can also incur a voltage change. Switching current spikes on the power distribution network, which has resistive and inductive losses, induces supply bounce. If a gate's output signal is the same voltage as the supply that is bouncing, the voltage spike transfers directly to the output signal. If the voltage change on the gate output for either case is greater than the noise margin, the victim signal will glitch and potentially lead to functional failure.

For the case of capacitive coupling, the amplitude of the voltage spike on the victim signal is proportional to  $V_{DD}$  to first order. As such, the important parameter to analyze is noise margin divided by  $V_{DD}$  to normalize out the dependence on  $V_{DD}$ . Figure 17.13 plots two common measures of noise margin versus  $V_{DD}$ ,

**FIGURE 17.14** Normalized noise margin reduction due to supply bounce.

the noise margin of a standard CMOS inverter, and a more pessimistic measure of noise margin,  $V_T$ . The relative noise margin is a minimum at high voltage, such that signal integrity analysis to ensure there is no glitching only needs to consider a single value of  $V_{DD}$ . If a circuit passes signal integrity analysis at maximum  $V_{DD}$ , it is guaranteed to pass at all other values of  $V_{DD}$ .

Supply bounce occurs through resistive ( $IR$ ) and inductive ( $dI/dt$ ) voltage drop on the power distribution network both on chip and through the package pins. Figure 17.14 plots the relative normalized  $IR$  and  $dI/dt$  voltage drops as a function of  $V_{DD}$ . It is interesting to note that the worst-case condition occurs at high voltage, and not at low voltage, since the decrease in current and  $dI/dt$  more than offsets the reduced voltage swing. Given a maximum tolerable noise margin reduction, only one operating voltage needs to be considered, which is maximum  $V_{DD}$ , to determine the maximum allowed resistance and inductance for the global power grid and package parasitics.

## Design over Varying Voltage

One approach to designing a processor system that switches voltage dynamically is to halt processor operation during the switching transient. The drawback to this approach is that interrupt latency increases and potentially useful processor cycles are discarded. Since static CMOS gates are quite tolerable of a varying  $V_{DD}$ , there is no fundamental need to halt operation during the transient. When the gate's output is low, it will remain low independent of  $V_{DD}$ , but when the output is high, it will track  $V_{DD}$  via the PMOS device(s). Simulation demonstrated that for a minimum-sized PMOS device in our  $0.6\ \mu\text{m}$  process, the RC time constant of the PMOS drain-source resistance and the load capacitance is a maximum of 5 ns, which occurs at low voltage. Thus, static CMOS gates track quite well for a  $dV_{DD}/dt$  in excess of  $100\ \text{V}/\mu\text{s}$ , and because all logic high nodes will track  $V_{DD}$  very closely, the circuit delay will instantaneously adapt to the varying supply voltage. Since the processor clock is derived from a ring oscillator also powered by  $V_{DD}$ , its output frequency will dynamically adapt as well, as shown in Fig. 17.15.

Yet, constraints are necessary when using a design style other than static CMOS as well as limits on allowable  $dV_{DD}/dt$ . The prototype processor design contains a variety of different styles, including static CMOS logic, as well as dynamic logic, CMOS pass-gate logic, memory cells, sense-amps, bus drivers, and I/O drivers. The maximum  $dV_{DD}/dt$  that the circuits in this  $0.6\ \mu\text{m}$  process technology can tolerate is approximately  $5\ \text{V}/\mu\text{s}$ , which is well above the maximum  $dV_{DD}/dt$  ( $0.2\ \text{V}/\mu\text{s}$ ) of the prototype voltage converter.

## Dynamic Logic

Dynamic logic styles are often preferable over static CMOS as they are more efficient for implementing complex logic functions. They can be used with a varying  $V_{DD}$ , but require some additional design considerations. One failure mode can occur while the circuit is in the evaluation state and the gate inputs are low such that the output node is undriven at a value  $V_{DD}$ . If  $V_{DD}$  ramps down by more than a diode drop by the end of the evaluation state, the drain-well diode will become forward biased. Current may

FIGURE 17.15 Ring oscillator adapting to varying supply voltage (simulated).

be injected into the parasitic PNP transistor of the PMOS device and induce latch-up [19]. This condition occurs when

$$\frac{dV_{DD}}{dt} \leq \frac{-V_{BE}}{t_{CLK|AVE}/2} \quad (17.6)$$

where  $t_{CLK|AVE}$  is the average clock period as  $V_{DD}$  varies by a diode voltage drop,  $V_{BE}$ . Since the clock period is longest at lowest voltage, this is evaluated as  $V_{DD}$  ranges from  $V_{MIN} + V_{BE}$  to  $V_{MIN}$ , where  $V_{MIN} = V_T + 100$  mV. For our  $0.6 \mu\text{m}$  process, the limit is  $-20$  V/ $\mu\text{s}$ . Another failure mode occurs if  $V_{DD}$  ramps up by more than  $V_{Tp}$  by the end of the evaluation state, and the output drives a PMOS device resulting in a false logic low, giving a functional error. This condition occurs when

$$\frac{dV_{DD}}{dt} \geq \frac{-V_{Tp}}{t_{CLK|AVE}/2} \quad (17.7)$$

and  $t_{CLK|AVE}$  is evaluated as  $V_{DD}$  varies from  $V_{MIN}$  to  $V_{MIN} + V_{Tp}$ , since this condition is also most severe at low voltage. For our  $0.6 \mu\text{m}$  process, the limit is  $24$  V/ $\mu\text{s}$ .

These limits assume that the circuit is in the evaluation state for no longer than half the clock period. If the clock is gated, leaving the circuit in the evaluation state for consecutive cycles, these limits drop proportionally. Hence, the clock should only be gated when the circuit is in the precharge state. These limits may be increased to that of static CMOS logic using a small bleeder PMOS device to hold the output at  $V_{DD}$  while it remains undriven. The bleeder device also removes the constraint on gating the clock, and since the bleeder device can be made quite small, there is insignificant degradation of circuit delay due to the PMOS bleeder fighting the NMOS pull-down devices. A varying  $V_{DD}$  will magnify the charge-redistribution problem of dynamic logic such that the internal nodes of NMOS stacks should be properly precharged [19].

### Tri-State Buses

Tri-state buses that are not constantly driven for any given cycle suffer from the same two failure modes as seen in dynamic logic circuits due to their floating capacitance. The resulting  $dV_{DD}/dt$  can be much lower if the number of consecutive undriven cycles is unbounded. Tri-state buses can only be used if one of two design methods is followed.

The first method is to ensure by design that the bus will always be driven. Although this is done easily on a tri-state bus with only two drivers, this may become expensive to ensure by design for a large number of drivers,  $N$ , which requires routing  $N$ , or  $\log(N)$ , enable signals.

FIGURE 17.16 SRAM cell and basic sense-amp topology.

The second method is to use weak, cross-coupled inverters that continually drive the bus. This is preferable to just a bleeder PMOS as it will also maintain a low voltage on the floating bus. Otherwise, leakage current may drive the bus high while it is floating for an indefinite number of cycles. The size of these inverters can be quite small, even for a large bus. For our 0.6  $\mu\text{m}$  process, the inverters could be designed to tolerate a  $dV_{\text{DD}}/dt$  in excess of 75  $\text{V}/\mu\text{s}$  with negligible increase in delay, while increasing the energy consumed driving the bus by only 10%.

### SRAM

SRAM is an essential component of a processor. It is found in the processor's cache, translation look-aside buffer (TLB), and possibly in the register file(s), prefetch buffer, branch-target buffer, and write buffer. Because all these memories operate at the processor's clock speed, fast response time is critical, which demands the use of a sense-amp. The static and dynamic CMOS logic portions (e.g., address decoder, word-line driver, etc.) of the memory respond to a changing  $V_{\text{DD}}$  similar to the ring oscillator, as desired.

To first-order, the delay of both the six-transistor SRAM cell and the basic sense-amp topology (Fig. 17.16), track changes in  $V_{\text{DD}}$  much like the delay of static CMOS logic. Second-order effects cause the SRAM cell behavior to deviate when  $dV_{\text{DD}}/dt$  is in excess of 50  $\text{V}/\mu\text{s}$  for our 0.6  $\mu\text{m}$  process [20]. However, the limiting second-order effect occurs within the sense-amp because the common-mode voltage between *Bit* and *nBit* does not change with  $V_{\text{DD}}$  as it varies during the sense-amp evaluation state.

Figure 17.17 plots the relative delay variation of the sense-amp compared against the relative delay variation for static CMOS for different rates of change on  $V_{\text{DD}}$ . It demonstrates that the delay does shift to first order, but that for negative  $dV_{\text{DD}}/dt$ , the sense-amp slows down at a faster rate than static CMOS. For the prototype processor design, the sense-amp delay was approximately 25% of the cycle time. The critical path containing the sense-amp was designed with a delay margin of 10%, such that the maximum increase in relative delay of the sense-amp as compared to static CMOS that could be tolerated was 40%.

This set the ultimate limit on how fast  $V_{\text{DD}}$  could vary in our 0.6  $\mu\text{m}$  process

$$|dV_{\text{DD}}/dt| \leq 5 \text{ V}/\mu\text{s} \quad (17.8)$$

This limit is proportional to the sense-amp delay, such that for improved process technology and faster cycle times, this limit will improve. What must be avoided are more complex sense-amps whose aim is

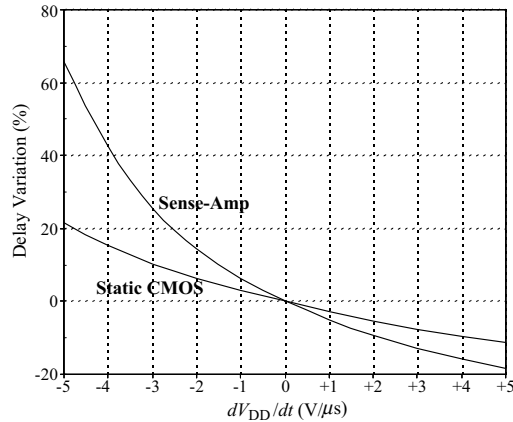

FIGURE 17.17 Sense-amp delay variation with varying supply voltage.

to improve response time and/or lower energy consumption for a fixed  $V_{DD}$ , but fail for varying  $V_{DD}$ , such a charge-transfer sense-amp [21].

## 17.6 Conclusions

DVS is a powerful design technique that can provide a tenfold increase in the energy efficiency of battery-powered processors, without sacrificing peak throughput. DVS is amenable to standard digital CMOS processes, with a few additional circuit design constraints. Existing operating systems can be retrofitted to support DVS, with little modification, as the voltage scheduler can be added to the operating system in a modular fashion. The prototype system has demonstrated that when running real programs, typical of those run on notebook computers and PDAs, DVS provides a significant reduction in measured system energy consumption, thereby considerably extending battery life.

Although DVS was not even considered feasible in commercial products three or four years ago, the rapidly evolving processor industry has begun to adopt various forms of DVS

- In 1999, Intel introduced SpeedStep<sup>®\*</sup>, which runs the processor at two different voltages and frequencies, depending upon whether the notebook computer is plugged into an AC outlet, or running off of its internal battery [22].
- In 2000, Transmeta introduced LongRun<sup>®\*</sup>, which dynamically varies voltage and frequency over the range of 1.2–1.6 V and 500–700 MHz, providing a 1.8 times variation in processor energy consumption. Control of the voltage/frequency is in firmware, which monitors the amount of time the operating system is sleeping [23].
- In 2000, AMD introduced PowerNow!<sup>®\*</sup>, which dynamically varies voltage and frequency over the range of 1.4–1.8 V and 200–500 MHz, providing a 1.7 times variation in processor energy consumption. Control of the voltage/frequency is implemented via a software driver that monitors the operating system's measure of CPU utilization [24].
- In 2001, Intel Inc. introduced the XScale<sup>®\*</sup> processor, which is essentially the second generation StrongArm<sup>®\*</sup> processor. It can dynamically operate over the voltage and frequency range of 0.7–1.75 V and 150–800 MHz, providing a 6.3 times variation in processor energy consumption, the most aggressive range announced to date. By further advancing the energy-efficiency of the original StrongArm, this device will be able to deliver 1000 MIPS with average power dissipation as low as 50 mW at 0.7 V, yielding an ETR as low as 0.05  $\mu$ W/MIP<sup>2</sup> [25].

### 18.1 Introduction

---

For innovative portable and wireless devices, systems on chip (SoCs) containing several processors, memories, and specialized modules are obviously required. Performance and also low power are main issues in the design of such SoCs. In deep submicron technologies, SoCs contain several millions of transistors and have to work at lower and lower supply voltages to avoid too high power consumption. Consequently, digital libraries as well as ROM and SRAM memories have to be designed to work at very low supply voltages and to be very robust while considering wire delays, signal input slopes, noise, and crosstalk effects.

Are these low-power SoCs only constructed with low-power processors, memories, and logic blocks? If the latter are unavoidable, many other issues are quite important for low-power SoCs, such as the way to synchronize the communications between processors as well as test procedures, online testing, software design and development tools. This chapter is a general framework for the design of low-power SoCs, starting from the system level to the architecture level, assuming that the SoC is mainly based on the reuse of low-power processors, memories, and standard cell libraries.

# 18.2 Power Reduction from High to Low Level

Design methodologies at different abstraction levels such as systems, architectures, logic design, basic cells as well as layout, have to take into account the power consumption. The main goals of such design methods are the  $V_{dd}$  reduction, the activity reduction as well as the capacitance reduction [1–7]. One has to ask the following question: What are the results of several years of research, applications, industrial designs in low power?

Two ways to consider this:

- What are the new or effective design techniques to reduce power?
- What is the status of the CAD tools regarding low power, as it is well known that such tools are required today to layout several millions of transistors on a single chip?

## Design Techniques for Low Power

Future SoCs will contain several different processor cores on a single chip. It results in parallel architectures, which are known to be less power hungry than fully sequential architectures based on a single processor [8]. The design of such architectures has to start with very high-level models in languages such as System C, SDL, or MATLAB. The very difficult task is then to translate such very high-level models in application software in C and in RTL languages (VHDL, Verilog) to be able to implement the system on several processors. One could think that many tasks running on many processors require a multitask but centralized operating system (OS), but regarding low power, it would be better to have tiny OS (2 K or 4 K instructions) for each processor [9], assuming that each processor executes several tasks. Obviously, this solution is easier as each processor is different even if performances could be reduced due to the inactivity of a processor that has nothing to do at a given time frame.

One has to note that most of the power can be saved at the highest levels. At the system level, partition, activity, number of steps, simplicity, data representation, and locality (cache or distributed memory instead of a centralized memory) have to be chosen (Fig. 18.1). These choices are strongly application dependent. Furthermore, these choices have to be performed by the SoC designer, and he has to be power conscious.

At the architecture level, many low-power techniques have been proposed (Fig. 18.1). The list could be gated clocks, pipelining, parallelization, very low  $V_{dd}$ , several  $V_{dd}$ , variable  $V_{dd}$  and  $V_T$ , activity estimation and optimization, low-power libraries, reduced swing, asynchronous, adiabatic. Some are used in industry, but some are not, such as adiabatic and asynchronous techniques. At the lowest levels, for instance a low-power library, only a moderate factor (about 2) in power reduction can be reached. At the logic and layout level, the choice of a mapping method to provide a netlist and the choice of a low-power library are crucial. At the physical level, layout optimization and technology have to be chosen.

High level	LP systems, LP software, processor types, processors versus random logic, parallel machines, high-level power estimation		
	Activity reduction	$V_{dd}$ reduction	Capacitance reduction
Architecture	LP Codes asynchronous	Parallelization adiabatic	Simplicity
Circuit layout	Gated clock	Low $V_T$	Low-power library

FIGURE 18.1 Overview of low-power techniques.

## Some Basic Rules

There are some basic rules that can be proposed to reduce power consumption at system and architecture levels:

- Reduction of the number  $N$  of operations to execute a given task.
- Sequencing that is too high always consumes more than the same functions executed in parallel.
- Obviously, parallel architectures provide better clock per instruction (CPI), as well as pipelined and RISC architectures.
- The lowest  $V_{dd}$  for the specific application has to be chosen.
- The goal is to design a chip that just fits to the speed requirements [10].

The main point is to think about systems, with power consumption reduction in mind. According to the mentioned basic rules, how to design a SoC that uses parallelism, at the right supply voltage, while minimizing the steps to perform a given operation or task.

The choice of a given processor or a random logic block is also very important. A processor results in a quite high sequencing while a random logic block works more in parallel for a same specific task. The processor type has to be chosen according to the work to be performed; if 16-bit data are to be used, it is not a good idea to choose a less expensive 8-bit controller and to work in double precision (high sequencing).

## CAD Tools

Each specialized processor embedded in a SoC will be programmed in C and will execute after compilation its own code. Low-power software techniques have to be applied to each piece of software, including pruning, inlining, loop unrolling, and so on. For reconfigurable processor cores, retargetable compilers have to be available. The parallel execution of all these task have to be synchronized through communication links between processors and peripherals. It results that the co-simulation development tools have to deal with several pieces of software running on different processors and communicating between each other. Such a tool has to provide a high-level power estimation tool to check which are the power hungry processors, memories or peripherals as well as the power hungry software routines or loops [11]. Such a tool is far from being commercially available. Embedded low-power software emerges as a key design problem. The software content of SoC will increase as well as the cost of its development.

Generally speaking, the available CAD tools for SoC chips have been designed for robust and reliable synchronous designs. It means that even gated clocks, low  $V_{dd}$ , several  $V_{dd}$ , are not or not yet supported, and that asynchronous and adiabatic will not be supported in the near future. It is a major problem, because CAD tools are far behind (10 years) the 2000 year requirements. Furthermore, little money is invested in CAD tools. It could be a stopper for some low-power methods. One can conclude that if power can be saved at a high level (factor 10 to 100 or more!) while using conventional CAD tools, it could be the way to go; however, power conscious SoC designers are required [12].

## 18.3 Large Power Reduction at High Level

---

As mentioned previously, a large part of the power can be saved at high level. Factors of 10 to 100 or more are possible; however, it means that the resulting system could be quite different, with less functionality or less programmability. The choice among various systems is strongly application dependent. One has to think about systems and low power to ask good questions of the customers and to get reasonable answers. Power estimation at high level is a very useful tool to verify the estimated total power consumption. Before starting a design for a customer, it is mandatory to think about the system and what is the goal about performances and power consumption. Several examples will be provided because this way of thinking is application dependent.

## RF Devices

An FM radio can be designed with an analog FM receiver as well as with analog and digital (random logic) demodulations, but a software radio has also been proposed. Such a system converts the FM signal directly into digital with very high-speed ADCs and does the demodulation work with a microprocessor. Such a solution is interesting as the same hardware can be used for any radio, but one can be convinced that a very high-speed ADC is a very consuming block, as well as a microprocessor that has to perform the demodulation (16-bit ADC can consume 1–10 W at 2.2 GHz [13]). In [13], some examples are provided for a digital baseband processor, achieving 1500 mW if implemented with a DSP processor and only 10 mW if implemented with a direct mapped ASIC. The latter case provides a factor of 150 in power reduction.

The transmission of data from one location to another by RF link is more and more power consuming if the distance between the two points is increased. The power (although proportional to the distance at square in ideal case) is practically proportional to the distance at power 3 or even power 4 due to noise, interferences, and other problems. If three stations are inserted between the mentioned points, and assuming a power of 4, the power can be reduced by a factor 64.

## Low-Power Software

Quite a large number of low-power techniques have been proposed for hardware, but relatively fewer for software. Hardware designers are today at least conscious that power reduction of SoCs is required for most applications. However, it seems that it is not the case for software people. Furthermore, a large part of the power consumption can be saved while modifying the application software.

For embedded applications, it is quite often the case that an industrial existing C code has to be used to design an application (for instance, MPEG, JPEG). The methodology consists in improving the industrial C code by

1. pruning, some parts are removed.
2. clear separation of (a) the control code, (b) the loops, and (c) the arithmetic operations.

Several techniques can be used to optimize the loops. In some applications, the application is 90% of the time running in loops. Three techniques can be used efficiently, such as loop fusion (loops executed in sequence with the same indices can be merged), loop tiling (to avoid fetching all the operands from the data cache for each loop iteration, so some data used by the previous iteration can be reused for the next iteration), and loop unrolling.

To unroll a loop is to repeat the loop body  $N$  times if there are  $N$  iterations of the loop. The code size is increased, but the number of executed instructions is reduced, as the loop counter (initialization, incrementation, and comparison) is removed.

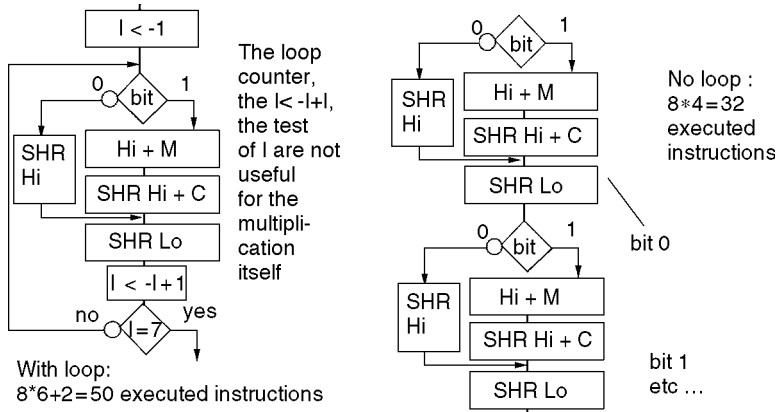

A small loop executed eight times, for instance an  $8 \times 8$  multiplication, results in at least 40 executed instructions, while the loop counter has to be incremented and tested. If the loop is unrolled, the code size is larger, but the number of executed instructions is reduced to about 24 (Fig. 18.2). This example illustrates a general rule: less sequencing in the software at the price of more hardware, i.e., more instructions in the program memory. Table 18.1 also shows that a linear routine (without loops) is executed with fewer instructions than a looped routine at the price of more instructions in the program.

## Processors, Instructions Sets, and Random Logic

A processor-based implementation results in very high sequencing. It is due to the processor architecture that is based on the reuse of the same operators, registers, and memories. For instance, only one step ( $N = 1$ ) is necessary to up-date a hardware counter. For its software counterpart, the number of steps is much higher, while executing several instructions with many clocks in sequence. This simple example shows that the number of steps executed for the same task can be very different depending on the architecture.

The instruction set can also contain some instructions that are very useful but expensive to implement in hardware. An interesting comparison is provided by the multiply instruction that has been implemented in the CoolRISC 816 (Table 18.2). Generally, 10% of the instructions are multiplications in a given embedded code. Assume 4 K instructions, i.e., 400 instructions (10%) for multiply, resulting in 8 multiply (each multiply requires about 50 instructions), so a final code of 3.6 K instructions. This is why the CoolRISC 816 contains a hardware  $8 \times 8$  multiplier.

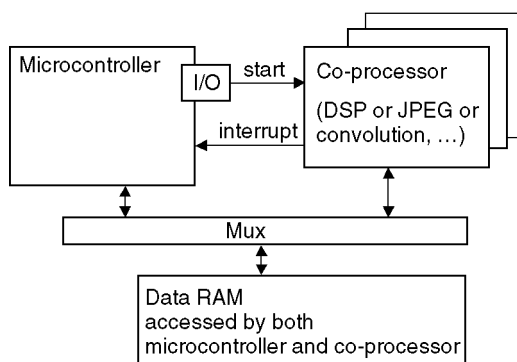

## Processor Types

Several points must be fulfilled in order to save power. The first point is to adapt the data width of the processor to the required data. It results in increased sequencing to manage, for instance, 16-bit data on a 8-bit microcontroller. For a 16-bit multiply, 30 instructions are required (add-shift algorithm) on a 16-bit processor, while 127 instructions are required on a 8-bit machine (double precision). A better architecture is to have a  $16 \times 16$  bit parallel-parallel multiplier with only one instruction to execute a multiplication.

Another point is to use the right processor for the right task. For control tasks, DSP processors are largely inefficient. But conversely, 8-bit microcontrollers are very inefficient for DSP tasks! For instance, to perform a JPEG compression on a 8-bit microcontroller requires about 10 millions of executed instructions for a  $256 \times 256$  image (CoolRISC, 10 MHz, 10 MIPS, 1 s per image). It is quite inefficient. Factor 100 in energy reduction can be achieved with JPEG dedicated hardware. With two CSEM-designed

Huffman co-processor	3.8 per pixel	130 MHz	20 $\mu$ AMHz
JPEG compression	3.8 per pixel	100 MHz	130 $\mu$ AMHz

**FIGURE 18.3** Microcontroller and co-processor.

co-processors working in pipeline, i.e., a DCT co-processor based on an instruction set (program memory based) and a Huffman encoder based on random logic, finite state machines, one has the following results (Table 18.3, synthesized by Synopsys in 0.25  $\mu$ m TSMC process at 2.5 V) 400 images can be compressed per second with a 13 mA power consumption. At 1.05 V, 400 images can be compressed per second with a 1 mA power consumption, resulting in quite a large number of 80,000 compressed images per watt (1000 better than a programmed-based implementation).

Figure 18.3 shows an interesting architecture to save power. For any application there is some control that is performed by a microcontroller (the best machine to perform control). But in most applications, there is also a main task to execute such as DSP tasks, convolutions, JPEG, or other tasks. The best architecture is to design a specific machine (co-processor) to execute such a task. So this task is executed by the smallest and the most energy efficient machine. Most of the time, both microcontroller and co-processors are not running in parallel.

## Low-Power Memories

Memory organization is very important in systems on a chip. Generally, memories consume most of the power. So it comes immediately that memories have to be designed hierarchically. No memory technology can simultaneously maximize speed and capacity at lowest cost and power. Data for immediate use is stored in expensive registers, in cache memories, and less used data in large memories.

For each application, the choice of the memory architecture is very important. One has to think of hierarchical, parallel, interleaved, and cache memories (sometimes several levels of cache) to try to find the best trade-off. The application algorithm has to be analyzed from the data point of view, the organization of the data arrays, and how to access these structured data.

If a cache memory is used, it is possible, for instance, to minimize the number of cache miss while using adequate programming as well as a good data organization in the data memory. For instance, in inner loops of the program manipulating structured data, it is not equivalent to write (1)  $d_0 i$  then  $d_0 j$  or (2)  $d_0 j$  then  $d_0 i$  depending on how the data are located in the data memory.

Proposing a memory-centric view (as opposed to the traditional CPU-centric view) to SoC design has become quite popular. It is certainly of technological interest. It means, for instance, that the DRAM memory is integrated on the same single chip; however, it is unclear if this integration inspires any truly

FIGURE 18.4 Energy-flexibility gap.

new architecture paradigms. We see it as more of a technological implementation issue [14]. It is, however, crucial to have most of the data on-chip, as fetching data off-chip at high frequency is a very high power consumption process.

### The Energy-Flexibility Gap

Figure 18.4 shows that the flexibility [13], i.e., to use a general purpose processor or a specialized DSP processor, has a large impact on the energy required to perform a given task compared to the execution of the same given task on dedicated hardware.

## 18.4 Low-Power and Reliability Issues in SoCs

For SoCs, very important design problems have to be solved. They are mainly the silicon complexity (reliability, power consumption, interconnect delays), the system complexity (logic, MPU, memories, RF, FPGA, RF, MEMS), the design procedures (300–800 people for the design of a single chip, IP reuse, design levels), verification and test. The total number of transistors on a single chip could be over one billion (predicted [15] to be between 4 to 19 billions in 2014 depending in the circuit type). Some partial answers have been given to the complexity problem, such as design reuse. The SIA Roadmap [15] predicts that in 2012 reuse of processors, logic blocks, and peripherals, would reach about 90% of the embedded logic on the chip.

### Low-Power SoC Architectures

Low-power SoCs will be based on low-power components, such as processor cores, memories, and libraries, that are available with good performances, i.e., 20,000–100,000 MIPS/watt [16] for some cores (using low-power techniques such as gated clocks); however, memories are the main consumers on a SoC and several techniques at the architecture and electrical levels have to be applied to reduce their power consumption (generally based on caches, DWL, bitline splitting, low swing).

The 1997 SIA Roadmap [15] recognizes that, in 2007, asynchronous design will be used in many designs. If  $\partial$  is the distance travelled by a signal in one clock cycle, due to higher frequencies and increasing interconnect delays, a chip will contain several time zones of sizes  $\partial \times \partial$ . Due also to the increasing die size, this number of time zones will grow very rapidly with the new technologies, up to 10,000 zones in 2012. To synchronize 10,000 time zones is a true asynchronous problem [15]. This is why asynchronous design is strongly required for chip architectures in the future [17].

Asynchronous architectures are often presented as being capable of reducing significantly the power consumption [17]. Looking at the results from many papers, it turns out that the largest power savings are obtained with circuits or applications that present a very irregular behavior. An irregular behavior

FIGURE 18.5 Comparison of the power consumption of asynchronous vs. synchronous architectures.

is, for instance, a processor that presents a tricky instruction set with multi-bytes instructions executed in a various number of cycles and phases. Or an application for which the controller has to very often stop and restart depending on the application. A very regular behavior is a 32-bit RISC core for which all instructions are always executed in one clock. Figure 18.5 illustrates this basic law [18]. Basically, SoCs will present more of an irregular behavior than a regular one.

At the architecture level, power and  $V_{dd}$  management with behavior prediction of the user will be used extensively, as well as low-power communication protocols between the various processors on a single chip. These protocols have to be kept simple and will be asynchronous due to the fact that the various cores will be clocked (if not asynchronous cores) with many different frequencies.

### Low-Power Design and Testability Issue

At the low-level, low-power libraries and logic synthesis embedded with place and route are required, as well as estimation of interconnect delays with copper, low-k, and SOI; however, the main issue is  $V_{dd}$  as low as 0.6 to 0.3 V in 2014. With very deep submicron technologies and very low  $V_{dd}$ , the static power will increase significantly due to low  $V_t$ . Several techniques with double  $V_t$ , source impedance, well polarization, dynamic regulation of  $V_t$  are today under investigation and will be necessarily used in the future.

SoCs testability and debug, when the first silicon has been returned from the foundry, are important issues. Generally, the mean time to fix a bug is one week. Today, it is not possible to determine if more bugs will be present in a one-billion transistor chip, and if a one-week fix per bug is realistic or not; however, it has to be mentioned that it could be much more difficult to fix a bug in IP blocks that you have not designed. It is estimated that half of the total design effort will be devoted to verification tasks, including debugging of the embedded software [15].

## 18.5 Low-Power Microcontroller Cores

The most popular 8-bit microcontroller is the Intel 8051, but each instruction is executed in at least 12 clock cycles resulting in poor performances in MIPS (million of instructions per second) and MIPS/watt. MIPS performances of microcontrollers are not required to be very high. Consequently, short pipelines and low operating frequencies are allowed if, however, the number of CPI is low. Such a low CPI has been used for the CoolRISC microcontroller [19,20]. The CoolRISC 88 is an 8-bit core with eight registers and the CoolRISC 816 is an 8-bit core with 16 registers.

### CoolRISC Microcontroller Architecture

The CoolRISC is a 3-stage pipelined core. The branch instruction is executed in only one clock. In that way, no load or branch delay can occur in the CoolRISC core, resulting in a strictly  $CPI = 1$  (Fig. 18.6). It is not the case of other 8-bit pipelined microprocessors (PIC, Nordic  $\mu$ RISC, Scenix, MCS-151, and 251). It is known that the reduction of CPI is the key to high performances. For each instruction, the first half clock is used to precharge the ROM program memory. The instruction is read and decoded in

The critical path:  
 - precharge ROM  
 - read ROM  
 - branch decoder  
 - address multiplexer

However, at 50 MHz, one clock = 20 ns

 for an 8-bit microcontroller

FIGURE 18.6 No branch delay.

FIGURE 18.7 Microphotograph of CoolRISC 88.

the second half of the first clock. As shown in Fig. 18.6, a branch instruction is also executed during the second half of this first clock, which is long enough to perform all the necessary transfers. For a load/store instruction, only the first half of the second clock is used to store data in the RAM memory. For an arithmetic instruction, the first half of the second clock is used to read an operand in the RAM memory or in the register set, the second half of this second clock to perform the arithmetic operation, and the first half of the third clock to store the result in the register set. Figure 18.7 is a CoolRISC 88 test chip.

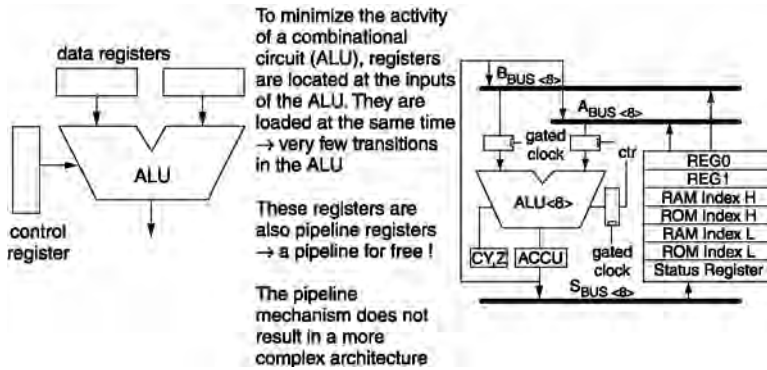

Another very important issue in the design of 8-bit microcontrollers is the power consumption. The gated clock technique has been extensively used in the design of the CoolRISC cores (Fig. 18.8). The ALU, for instance, has been designed with input and control registers that are loaded only when an ALU operation has to be executed. During the execution of another instruction (branch, load/store), these registers are not clocked thus no transitions occur in the ALU (Fig. 18.8). This reduces the power consumption. A similar mechanism is used for the instruction registers, thus in a branch, which is executed only in the first pipeline stage, no transitions occur in the second and third stages of the pipeline. It is interesting to see that gated clocks can be advantageously combined with the pipeline architecture; the input and control registers implemented to obtain a gated clocked ALU are naturally used as pipelined registers.

## IP “Soft” Cores

The main issue in the design of “soft” cores [21] is reliability. In deep submicron technologies, gate delays are smaller and smaller compared to wire delays. Complex clock trees have to be designed using Synopsys to satisfy the required timing, mainly the smallest possible clock skew, and to avoid any timing violations.

**TABLE 18.4** Power Consumption of the Same Core with Various Test Benches and Skew

Skew	Test Bench A	Test Bench B
10 ns	0.44 mW/MHz	0.76 mW/MHz
3 ns	0.82 mW/MHz	1.15 mW/MHz

**FIGURE 18.8** Gated-clock ALU.

Furthermore, “soft” cores have to present a low power consumption to be attractive to the possible licensees. If the clock tree is a major issue to achieve the required clock skew, its power consumption could be larger than desired. Today, most IP cores are based on a single-phase clock and are based on D-flip-flops. As shown in the following example, the power consumption is largely dependent on the required clock skew.

As an example, a DSP core synthesized with the CSEM low-power library in TSMC 0.25  $\mu\text{m}$ . The test bench A contains only a few multiplication operations, while the test bench B performs a large number of MAC operations (Table 18.4). Results show that if the power is sensitive to the application program, it is also quite sensitive to the required skew: 100% of power increase from 10 ns to 3 ns skew.

The clocking scheme of IP cores is therefore a major issue. Another approach other than the conventional single-phase clock with D-flip-flops (DFF) is presented in this paper. It is based on a double-latch approach with two nonoverlapping clocks. This clocking scheme has been used for the 8-bit CoolRISC microcontroller IP core [16] as well as for other cores, such as a DSP core and other execution units [22]. The advantages as well as the disadvantages will be presented.

## Latch-Based Designs

Figure 18.9 shows the double-latch concept that has been chosen for such IP cores to be more robust to the clock skew, flip-flop failures, and timing problems at very low voltage [16]. The clock skew between various  $\emptyset 1$  (respectively  $\emptyset 2$ ) pulses have to be shorter than half a period of CK. However, one requires two clock cycles of the master clock CK to execute a single instruction. It is why one needs, for instance, in technology TSMC 0.25  $\mu\text{m}$ , 120 MHz to generate 60 MIPS (CoolRISC with CPI = 1), but the two  $\emptyset i$  clocks and clock trees are at 60 MHz. Only a very small logic block is clocked at 120 MHz to generate two 60 MHz clocks.

The design methodology using latches and two nonoverlapping clocks has many advantages over the use of DFF methodology. Due to the nonoverlapping of the clocks and the additional time barrier caused by having two latches in a loop instead of one DFF, latch-based designs support greater clock skew, before failing, than a similar DFF design (each targeting the same MIPS). This allows the synthesizer and router to use smaller clock buffers and to simplify the clock tree generation, which will reduce the power consumption of the clock tree.

FIGURE 18.9 Double-latch clocking schemes.

FIGURE 18.10 Time borrowing.

With latch-based designs, the clock skew becomes relevant only when its value is close to the nonoverlapping of the clocks. When working at lower frequency and thus increasing the nonoverlapping of clocks, the clock skew is never a problem. It can even be safely ignored when designing circuits at low frequency, but a shift register made with DFF can have clock skew problems at any frequency.

Furthermore, if the chip has clock skew problems at the targeted frequency after integration, one is able, with a latch-based design, to reduce the clock frequency. It results that the clock skew problem will disappear, allowing the designer to test the chip functionality and eventually to detect other bugs or to validate the design functionality. This can reduce the number of test integrations needed to validate the chip. With a DFF design, when a clock skew problem appears, you have to reroute and integrate again. This point is very important for the design of a chip in a new process not completely or badly characterized by the foundry, which is the general case as a new process and new chips in this process are designed concurrently for reducing the time to market.

Using latches for pipeline structure can also reduce power consumption when using such a scheme in conjunction with clock gating. The latch design has additional time barriers, which stop the transitions and avoid unneeded propagation of signal and thus reduce power consumption. The clock gating of each stage (latch register) of the pipeline with individual enable signals, can also reduce the number of transitions in the design compared to the equivalent DFF design, where each DFF is equal to two latches clocked and gated together.

Another advantage with a latch design is the time borrowing (Fig. 18.10). It allows a natural repartition of computation time when using pipeline structures. With DFF, each stage of logic of the pipeline should ideally use the same computation time, which is difficult to achieve, and in the end, the design will be limited by the slowest of the stage (plus a margin for the clock skew). With latches, the slowest pipeline stage can borrow time from either or both the previous and next pipeline stage. And the clock skew only reduces the time that can be borrowed. An interesting paper [23] has presented time borrowing with DFF, but such a scheme needs a complete new automatic clock tree generator that does not minimize the clock skew but uses it to borrow time between pipeline stages.

Using latches can also reduce the number of MOS of a design. For example, a microcontroller has  $16 \times 32$ -bits registers, i.e., 512 DFF or 13,312 MOS (using DFF with 26 MOS). With latches, the master part of the registers can be common for all the registers, which gives 544 latches or 6528 MOS (using latches with 12 MOS). In this example, the register area is reduced by a factor of 2.

FIGURE 18.11 Latch-based clock gating.

FIGURE 18.12 Power consumption comparison of “soft” CoolRISC cores.

## Gated Clock with Latch-Based Designs

The latch-based design also allows a very natural and safe clock gating methodology. Figure 18.11 shows a simple and safe way of generating enable signals for clock gating. This method gives glitch-free clock signals without the adding of memory elements, as it is needed with DFF clock gating.

Synopsys handles the proposed latch-based design methodology very well. It performs the time borrowing well and appears to analyze correctly the clocks for speed optimization. So it is possible to use this design methodology with Synopsys, although there are a few points of discussion linked with the clock gating.

This clock gating methodology cannot be inserted automatically by Synopsys. The designer has to write the description of the clock gating in his VHDL code. This statement can be generalized to all designs using the above latch-based design methodology. We believe Synopsys can do automatic clock gating for pure double latch design (in which there is no combinational logic between the master and slave latch), but such a design causes a loss of speed over similar DFF design.

The most critical problem is to prevent the synthesizer from optimizing the clock gating AND gate with the rest of the combinational logic. To ensure a glitch-free clock, this AND gate has to be placed as shown in Fig. 18.11. This can be easily done manually by the designer by placing these AND gates in a separate level of hierarchy of his design or placing a “don’t touch” attribute on them.

## Results

A synthesizable by Synopsys CoolRISC–DL 816 core with 16 registers has been designed according to the proposed double latch (DL) scheme (clocks Ø1 and Ø2) and provides the estimated (by Synopsys) following performances (only the core, about 20,000 transistors) in TSMC 0.25  $\mu\text{m}$ :

- 2.5 V, about 60 MIPS (but 120 MHz single clock) (It is the case with the core only, if a program memory with 2 ns of access time is chosen, as the access time is included in the first pipeline stage, the achieved performance is reduced to 50 MIPS.)
- 1.05 V, about 10  $\mu\text{W}/\text{MIPS}$ , about 100,000 MIPS/watt (Fig. 18.12)

The core “DFF+Scan” is a previous CoolRISC core designed with flip-flops [19,20]. The CoolRISC-DL “double latch” cores [16] with or without special scan logic provide better performances.

# 18.6 Low-Power Memories

As memories in SoCs are larger and larger, the ratio between power consumption of memories to the power consumption of embedded processors is significantly increased. Several solutions have been proposed at the memory architecture level, such as, for instance, cache memories, loop buffers, and hierarchical memories, i.e., to store a frequently executed piece of code in a small embedded ROM memory and large but rare executed pieces of code in a large ROM memory [19,20]. It is also possible to read the large ROM in two or four clock cycles as its read access time is too large for the chosen main frequency of the microprocessor.

## Cache Memories for Microcontrollers

Cache memories are widely used for high-performance microprocessors. In SoCs, application software is stored in embedded memories, ROM, flash or EEPROM. If a conventional  $N$ -way set-associative cache is used, one has to compare the energy used for a ROM access and the energy for a SRAM cache access. While reading  $N$  tags and  $N$  blocks of the selected cache line just to select one instruction (hundreds of bits), one can see that a conventional cache consumes much more power than a ROM access.

The only way to save power is to use unconventional cache memories such as small L0 caches or buffers, which store only some instructions that are reused frequently from the cache. Such a scheme is used for some DSP processors to capture loops. Furthermore, the tags are read first and in case of a hit, only one way is accessed. So this mechanism avoids reading  $N$  blocks in parallel and saves power. Before fetching a block in the cache, one has to check if the instruction is already in the buffer in order to stop the access to the cache or to the ROM if there is a buffer hit (Fig. 18.13). Obviously, the hit rate of such a cache cannot be as high as for a  $N$ -way set associative cache of the same size.

To improve the hit rate, one has a supplementary bit (flag) per instruction generated by the compiler (or manually generated) in the main memory indicating (if activated) that this instruction has to be stored in the L0 cache. If this bit is "0", the instruction, when fetched from L1 cache, is not stored in the L0 cache. It results in the fact that instructions not often used do not pollute the L0 cache (Fig. 18.13). Furthermore, with quite small caches (32–64 instructions), one has also to choose between cacheable instructions, which ones are the most useful to write in cache to reach the highest hit rate. Many algorithms working on program traces have been studied to maximize the number of instruction fetches per write in the cache. The results are strongly dependent on the applications, i.e., a scientific code is better than a control code (Table 18.5).

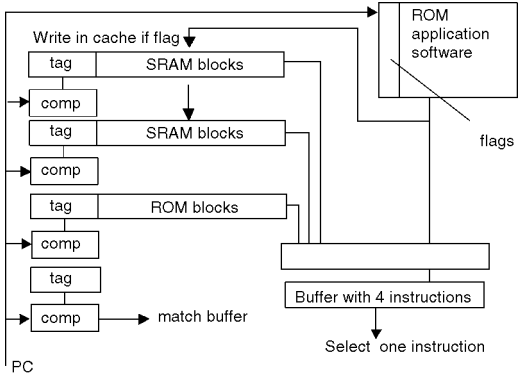

FIGURE 18.13 CoolCache for the CoolRISC microcontroller.

**TABLE 18.5** CoolCache Results

Watch application	68%	-93%	82%	41%

**FIGURE 18.14** Old ROM memory structure.

Another idea is to search for instructions or routines that are obviously always in the cache during the program execution (or nearly always in the cache). So it is quite interesting to replace a part of the SRAM cache that is not written by a ROM structure (Fig. 18.13). In so doing, the power consumption is reduced, as a ROM access is less consuming than a RAM access. Furthermore, a ROM cell is smaller than a RAM cell, so there is no need to write something in the memory and a ROM memory is faster than a RAM. Another advantage is the fact that instructions stored in ROM are always in the ROM; it could be interesting for reactivity and real-time routines for which the execution time does not need to be dependent on the fact that this routine is already in or not in the cache.

### Electrical Design of Low-Power ROM Memories

Few papers describe very low-power ROM structures. A ROM memory is an array of transistors (a transistor means a logical bit “0”). Each bit is connected to a bitline to read the ROM and controlled by a wordline.

Figure 18.14 shows an old design of a ROM memory. Precharge techniques are used for both the decoder and bit array. After the address is provided, the decoder (NAND gates) is precharged to “1” and the bit array is precharged to “0” through the output multiplexer (PROM = 1). When PROM = 0, the ROM is read. If the P-MOS in the array is there, the bitline is charged to “1,” otherwise it keeps its “0” value. Such a memory is very slow: NAND gates for the decoder, P-MOS for the array and long bitlines.

Existing ROM memories use a similar scheme: in a first step the bitlines are precharged to “1,” and in the next step a wordline is selected. If there is a transistor (bit is “0”) at the intersection of the selected wordline and a bitline, this bitline is discharged. The value of the selected word can therefore be read on the bitlines. Many techniques have been used to speed-up existing ROM memories: NOR gates, N-MOS for the array, to split the memory in several arrays, divided word lines (DWL), to divide the bit line, to precharge only the useful bitlines, partial swing with sense amplifiers. Two of these techniques are described in the following text.

Because a large part of the access time is due to the discharge of the bitline, split bitlines are generally used. Figure 18.15 presents the split bitlines principle. Each bitline is split in sub-bitlines that are

**TABLE 18.6** ROM Memories Power Consumption Comparison

**FIGURE 18.15** Split bitlines.

connected to the main bitline (only a wire) with an additional transistor. The selection of these transistors depends on address bits. Only one of the sub-bitlines can be connected to the main bitline. Since only a small fraction of the bit array transistor drains are connected to a given sub-bitline, the capacitance to be discharged is significantly reduced. The problem is that the capacitance of the main bitline is discharged through two transistors in series. Then, in order to have a speed gain, the additional transistors (which connect the sub-bitlines to the main bitlines) must be large. The number of large transistors is the same as the number of bitlines. So, for 1000 bitlines, one has to drive 1000 transistors. It is therefore quite difficult to reduce the access time and the power consumption.

Another solution is also shown in Figure 18.15. The drains of the bit array transistors are connected directly to a sub-bitline that is a single metal line. Figure 18.15 shows three metal lines and therefore three sub-bitlines. To access the ROM, one has to precharge to “1” the three metal lines, and when a transistor of a bit array is selected, only one of the three metal lines switch to “0” (if a “0” is read). A NAND gate can detect the read value. In this solution, each “read” bitline is split only “physically” in the layout, not “logically” as in other solutions.

The second technique aims at removing the sense amplifiers. It allows the ROM memory to be capable of working at any supply voltage. Noise problems are therefore removed, as sense amplifiers are very sensitive to noise. Furthermore, it is a very simple solution, as there is no need to detect when the read operation is finished to disable the sense amplifiers; however, if sense amplifiers are removed, bitlines switch with full swings. One could think that power consumption is largely increased, but the results show that power consumption is reduced. Table 18.6 shows the results in power and speed in a 0.25  $\mu\text{m}$  process.

## Electrical Design of Low-Power SRAM Memories

Low power and fast SRAM memories have been described in many papers [24]. Very advanced technologies have been used with double  $V_T$ . RAM cells are designed with high  $V_T$  and selection logic with low  $V_T$  transistors. Some techniques such as low swing and hierarchical sense amplifiers have been used. One can also use the fact that a RAM memory is read 85% of the time and written only 15% of the time.

Low-power RAM memories designed by CSEM also use the split bitlines described for the ROM. However, the RAM cell is based on nonsymmetrical ways to read and to write the memory. The patented

idea is to write in a conventional way while using the true and inverted bitlines, but to read only through a single bitline (Fig. 18.16).

The advantages are the following:

- As it is the case in the conventional scheme, it is possible to write at low  $V_{dd}$  since both true and inverted bitlines on both sides of the cell are used.
- The use of only one bitline for reading (instead of two) decreases the power consumption.
- The read condition (to achieve a read and not to overwrite the cell) has only to be effective on one side of the cell, so some transistors can be kept minimal. It decreases the capacitance on the inverted-bitline and the power consumption when writing the RAM. Furthermore, minimal transistors result in a better ratio between cell transistors when reading the memory, resulting in a speed-up of the read mechanism.
- Due to a read process only on one side of the cell, one can use the split bitlines concept more easily (Fig. 18.15).

Table 18.7 shows some results. As mentioned, the CSEM SRAM memory achieves a full swing without any sense amplifier.

## 18.7 Low-Power Standard Cell Libraries

At the electrical level, digital standard cells have been designed in a robust branch-based logic style, such as hazard-free D-flip-flops [7,25]. Such libraries with 60 functions and 220 layouts have been used for industrial chips. The low-power techniques used were the branch-based logic style that reduces parasitic capacitances and a clever transistor sizing. Instead, to enlarge transistors to have more speed, parasitic capacitances were reduced by reducing the sizes of the transistors on the cell critical paths. If several years ago, power consumption reductions achieved compared to other libraries were about a factor of 3–5, it

is today only about a factor of 2 due to a better understanding of power consumption problems of library designers.

Today, logic blocks are automatically synthesized from a VHDL description while considering a design flow using a logic synthesizer such as Synopsys. Furthermore, deep submicron technologies with large wire delays imply a better robustness, mainly for sequential cells sensitive to the clock input slope. Fully static and branch-based logic style has been found as the best; however, a new approach has been proposed that is based on a limited set of standard cells. As a result, the logic synthesizer is more efficient because it has a limited set of cells well chosen and adapted to the considered logic synthesizer. With significantly less cells than conventional libraries, the results show speed, area, and power consumption improvements for synthesized logic blocks. The number of functions for the new library has been reduced to 22 and the number of layouts to 92. Table 18.8 shows that, for a similar silicon area, delays with the new library are reduced. Table 18.9 shows that, for a similar speed, silicon area is reduced for the new library. Furthermore, as the number of layouts is drastically reduced, it takes less time to design a new library for a more advanced process.

Overall, the main issue in the design of future libraries will be the static power. For  $V_{\text{dd}}$  as low as 0.6–0.3 V in 2014, as predicted by the Roadmap [15],  $V_T$  will be reduced accordingly in very deep submicron technologies. Consequently, the static power will increase significantly due to these low  $V_T$  [3]. Several techniques with double  $V_T$ , source impedance, well polarization, dynamic regulation of  $V_T$  [4] are today under investigation and will be necessarily used in the future. This problem is crucial for portable devices that are often in standby mode in which the dynamic power is reduced to zero. It results that the static power becomes the main part of the total power. It will be a crucial point in future libraries for which more versions of the same function will be required while considering these static power problems. A same function could be realized, for instance, with low or high  $V_T$  for double  $V_T$  technologies, or several cells such as a generic cell with typical  $V_T$ , a low-power cell with high  $V_T$ , and a fast cell with low  $V_T$ .

### 19.1 Introduction

---

Recently low-power design has become a very important and critical issue to enhance the portable multimedia market. Therefore, various approaches to explore low power design have been made. The implementation can be categorized into system level, algorithm level, architecture level, circuit level, and process/device level. [Figure 19.1](#) shows the relative impact on power consumption of each phase of the design process. Essentially higher-level categories have more effect on power reduction. This section describes the impact of each level on low-power design.

### 19.2 System Level Impact

---

The system level is the highest layer. Therefore, it strongly influences power consumption and distribution by partitioning system factors.

Reference [1], InfoPad of University of California, Berkeley, demonstrated a low-power wireless multimedia access system. Heavy computation resources (functions) and large data storage devices such as hard disks are moved to the backbone server and InfoPad itself works as just a portable terminal device. This system level partitioning realizes Web browser, X-terminal, voice-recognition, and other application with low power consumption because energy hungry factors were moved from the pad to the backbone. And reference [2] demonstrates the power consumption of the InfoPad chipset to be just 5 mW.

### 19.3 Algorithm Level Impact

---

The algorithm level is the second to the system level, which defines a detailed implementation outline of a required original function. This level has quite a large impact on power consumption. It is because the algorithm determines how to solve the problem and how to reduce the original complexity. Thus, the algorithm layer is key to power consumption and efficiency.

FIGURE 19.1 Each level impact for low-power design.

A typical example of algorithm contribution is motion estimation of MPEG encoder. Motion estimation is an extremely critical function of MPEG encoding. Implementing fundamental MPEG2 motion estimation using a full search block matching algorithm requires huge computations [3,4]. It reaches 4.5 teraoperations per second (TOPS) if realizing a very wide search range ( $\pm 288$  pixels horizontal and  $\pm 96$  pixels vertical), on the other hand the rest of the functions take about 2 GOPS. Therefore motion estimation is the key problem to solve in designing a single chip MPEG2 encoder LSI. Reference [5] describes a good example to dramatically reduce actual required performance for motion estimation with a very wide search range, which was implemented as part of a 1.2 W single chip MPEG2 MP@ML video encoder. Two adaptive algorithms are applied. One is 8:1 adaptive subsampling algorithm that adaptively selects subsampled pixel locations using characteristics of maximum and minimum values instead of fixed subsampled pixel locations. This algorithm effectively chooses sampled pixels and reduces the computation requirements by seven-eighths. Another is an adaptive search area control algorithm, which has two independent search areas with H:  $\pm 32$  and V:  $\pm 16$  pixels in full search block matching algorithm for each. The center locations of these search areas are decided based on a distribution history of the motion vectors and this algorithm substantially expands the search area up to H:  $\pm 288$  and V:  $\pm 96$  pixels. Therefore, the total computation requirement is reduced from 4.5 TOPS to 20 GOPS (216:1), which is possible to implement on a single chip. The first search area can follow a focused object close to the center of the camera finder with small motion. The second one can cope with a background object with large motion in camera panning. This adaptive algorithm attains high picture quality with very wide search range because it can efficiently grasp moving objects, that is, get correct motion vectors. As shown in this example, algorithm improvement can drastically reduce computation requirement and enable low power design.

## 19.4 Architecture Level Impact

The architecture level is the next to the algorithm level, also in terms of impact on power consumption. At the architecture level there are still many options and wide freedom in implementation. The architecture level is explained as CPU (microprocessor), DSP (digital signal processor), ASIC (dedicated hardwired logic), reconfigurable logic, and special purpose DSP.

The CPU is the most widely used general-purpose architecture as shown in Fig. 19.2. Fundamentally anything can be performed by software. It is the most inefficient in power, however. The main features of the CPU are the following: (1) It is completely sequential in operation with instruction fetch and decode in every cycle. Basically this is not essential for computation itself and is just overhead. (2) There is no dedicated address generator for memory access. The regular ALU is used to calculate memory address. Throughput of data feeding is not, every cycle, based on load/store architecture via registers (RISC-based architecture). This means cycles are consumed for data movement and not just for computation itself. (CISC allows memory access operation, but this doesn't mean it is more effective; it is a different story, not explained in detail here.) (3) Many temporal storage operations are included in computation procedure.

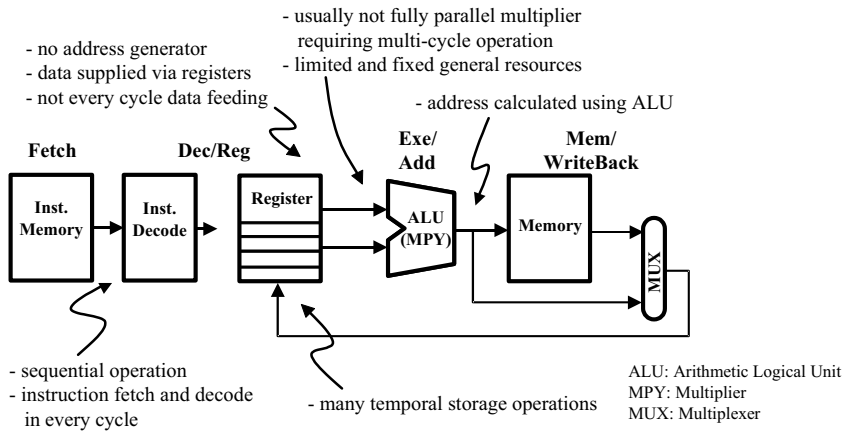

FIGURE 19.2 CPU structure.

FIGURE 19.3 Dynamic instruction statistics.

This is a completely justified overhead. (4) Usually, a fully parallel multiplier is not used, causing multi-cycle operation. This also consumes more wasted power because clocking, memory, and extra circuits are activated in multiple for one multiply operation. (5) Resources are limited and prefixed. This results in overhead operations to be executed as general purpose. Figure 19.3 shows dynamic run time instruction statistics [6]. This indicates that essential computation instructions such as arithmetic operation occupy just 33% of the entire dynamic run time instruction stream. The data moving and control-like branches take two-thirds, which is large overhead consuming extra power.

The DSP is an enhanced processor for multiply-accumulate computation. It is general-purpose in structure and more effective for signal processing than the CPU. But still it is not very power efficient. Figure 19.4 shows the basic structure and its features are as follows. (1) The DSP is also sequential in operation with instruction fetch and decode in every cycle similar to the CPU. It causes overhead in the same way, but as an exception DSP has a hardware loop, which eliminates continued instruction fetch in repeated operations, improving power penalty. (2) Many temporal storage operations are also used. (3) Resources are limited and prefixed for general purpose as well. This is a major reason for causing temporal storage operations. (4) Fully parallel multiplier is used making one cycle operation possible. And also accumulator with guardbits is applied, which is very important to accumulate continuously without accuracy degradation and undesired temporal storing to registers. This improves power efficiency for multiply-accumulate-based

FIGURE 19.4 DSP structure.

FIGURE 19.5 ASIC structure.

computations. (5) It is equipped with dedicated address generators for memory access. This realizes more complex memory addressing without using regular ALU and consuming extra cycles, and two data can be fed in every cycle directly from memory. This is very important for DSP operation. Features (4) and (5) are advantages of the DSP in improving power efficiency over the CPU.

We define the ASIC as dedicated hardware here. It is the most power efficient because the structure can be designed for the specific function and optimized. Figure 19.5 shows the basic image and the features are as follows: (1) Required functions can be directly mapped in optimal form. This is the essential feature and source of power efficiency by minimizing any overheads. (2) Temporal storage operation can be minimized, which is large overhead in general purpose architectures. Basically this comes from feature (1). (3) It is not sequential in operation. Instruction fetch and decode are not required. This eliminates fundamental overhead of general-purpose processors. (4) Function is fixed as design. There is no flexibility. This is the most significant drawback of dedicated hardware solutions.

There is another category known as reconfigurable logic. Typical architecture is field programmable gate array (FPGA). This is gate level fine-grained programmable logic. It consists of programmable network structure and logic blocks that have a look-up table (LUT)-based programmable unit, flip-flop, and selectors as shown in Fig. 19.6. The features are: (1) It is quite flexible. Basically, the FPGA can be configured to any dedicated function if integrated gate capacity is enough to map it; (2) Structure can be optimized without being limited to prefixed data width and variation of function unit like a general 32-bit ALU of CPU. Therefore, FPGA is not used only for prototyping but also where high performance and high throughput are targeted. (3) It is very inefficient in power. Switch network for fine-grain level flexibility causes large power overhead. Each gate function is realized by LUT programmed as truth table, for example NAND, NOR, and so on. Power consumption of interconnect takes 65% of the chip, while logic part consumed only 5% [7]. This means major power of FPGA is burned in unessential portion.

FIGURE 19.6 FPGA simplified structure.

FIGURE 19.7 IIR comparison.

FPGA sacrifices power efficiency in order to attain wide range flexibility. It is a trade-off between flexibility and power efficiency. Lately, however, there is another class of reconfigurable architecture. It is coarse-grained or heterogeneous reconfigurable architecture. Typical work is Maia of Pleiades project, U.C. Berkeley [8–12]. This architecture consists of heterogeneous modules that are mainly coarse-grain similar to ALU, multiplier, memory, etc. The flexibility is limited to some computation or application domain but power efficiency is dramatically improved. This type of architecture might gain acceptance because of strong demand for low power and flexibility.

Figure 19.7 shows cycle comparison to execute fourth order infinite impulse response (IIR) for CPU, DSP, ASIC, and reconfigurable logic. ASIC and reconfigurable logic are assumed as two parallel implementations. CPU takes more overhead than DSP, which is enhanced for multiply computation as mentioned previously. Also, dedicated hardware structures such as ASIC and reconfigurable logic can reduce computational overhead more than others.

The last one is the special purpose DSP for MPEG2 video encoding. Figure 19.8 shows an example of programmable DSP for MPEG2 video encoding [13]. This architecture applied 3-level parallel processing of macro-block level, block level, and pixel level in reducing performance requirement from 1.1 GHz to

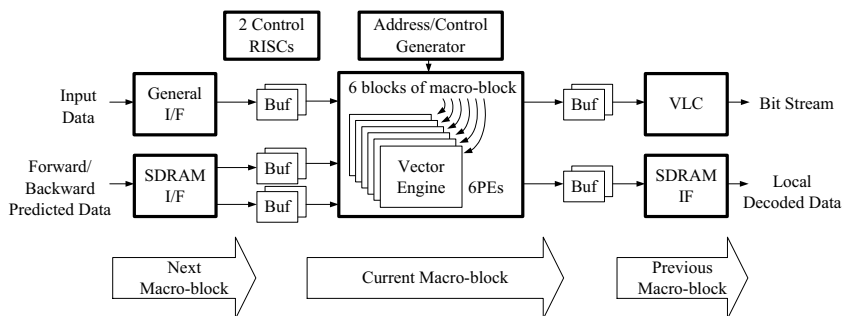

FIGURE 19.8 Special purpose DSP for MPEG2 video encoding.

81 MHz with 13 operations in parallel on an average. The macro-blocks are processed in 3-stage pipeline with MIMD controlled by two RISCs. The 6 blocks of macro-block are handled by 6 vector processing engines (PEs) assigned to each block with SIMD way. The pixels of block are computed by the PE that consists of extended ALU, multiplier, accumulator, three barrel-shifters with truncating/rounding function and 6-port register file. This specialized DSP performs MPEG2 MP@ML video encoding at 1.3 W/3 V/0.4  $\mu\text{m}$  process with software programmability. The architecture improvement for dedicated application can reduce performance requirement and overhead of general-purpose approach and plays an important role for low-power design.

## 19.5 Circuit Level Impact

The circuit level is the most detailed implementation layer. This level is explained as module level such as multiplier or memory and basement level like voltage control that affects wide range of the chip. The circuit level is quite important for performance but usually has less impact on power consumption than previous higher levels. One reason is that each component itself is just a part of the entire chip. Therefore, it is needed to focus on critical and major factors (most power hungry modules, etc.) in order to contribute to power reduction for chip level improvement.

### Module Level

The module level is each component like adder, multiplier, and memory, etc. It has relatively less impact on power compared to algorithm and architecture level as mentioned above. Even if power consumption of one component is reduced to half, it is difficult to improve the total chip power consumption drastically in many cases. On the other hand, it is still important to focus on circuit level components, because the sum of all units is the total power. Especially memory components occupy a large portion of many chips. Two examples of module level are shown here.

Usually there occur many glitches in logic block causing extra power at average 15 to 20% of the total power dissipation [14]. Multiplier has a large adder-based array to sum partial products, which generates many glitches. Figure 19.9 is an example of multiplier improvement to eliminate those glitches [13]. There are time-skews between X-side input signals and Y-side Booth encoded signals (Booth select) creating many glitches at Booth selectors. These glitches propagate in the Wallace tree and consume extra power. The glitch preventive booth (GPB) scheme (Figure 19.9) blocks X-signals until Booth encoded signals (Y-signals) are ready by delaying the clock in order to synchronize X-signals and Y-signals. During this blocking period, Booth selectors keep previous data as dynamic latches. This scheme reduces Wallace tree power consumption by 44% without extra devices in the Booth selectors.

Another example is a memory power reduction [13]. Normally in ASIC embedded SRAM, the whole memory cell array is activated. But actually utilized memory cells whose data are read out are just part

FIGURE 19.9 Glitch preventive booth (GPB) multiplier.

FIGURE 19.10 Column selective wordline (CSW) SRAM.

of them. This means large extra power is dissipated in memory cell array. Figure 19.10 shows column selective wordline (CSW) scheme. The wordline of each row address is divided into two that are controlled by column address LSB corresponding to odd and even column. And memory cells of each row address are also connected to wordline corresponding to odd or even column. Therefore, simultaneously activated memory cells are reduced to 50% and it saves SRAM power by 26% without using section division scheme.

## Basement Level

The basement level is another class. This is categorized as circuit level but affects whole or wide area of the chip like unit activation scheme as chip level control strategy or voltage management scheme. Therefore, it can make a much larger impact on the power than the module level.

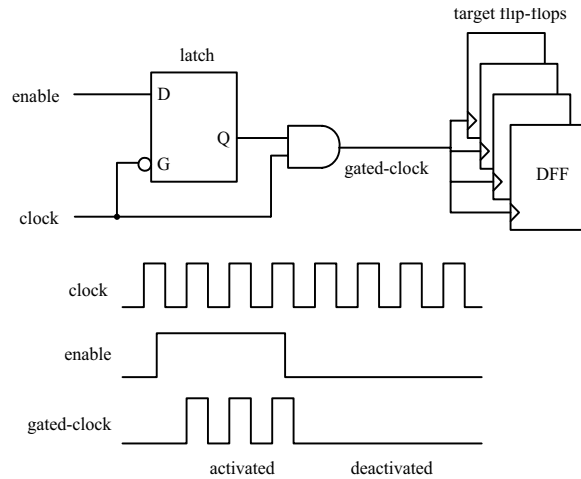

FIGURE 19.11 Gated-clock.

FIGURE 19.12 Frequency and voltage scaling.

Figure 19.11 describes the gated-clock scheme, which is very popular, and is the basic scheme to reduce power consumption. Activation of clock for target flip-flops is controlled by enable signal that is asserted only when needed. The latch of Fig. 19.4 prevents clock from glitch. This scheme is used to inactivate blocks or units when they are not used. Unless clocks are controlled on demand, all clock lines and inside of flip-flops are toggled and also unnecessary data propagate into circuit units through flip-flops, which causes large waste in power all over the chip. The gated-clock used to be handled manually by designer; today, however, it can be generated automatically in gate compilation and also static timing analysis can be applied without special care at latch by EDA tool. This means the gated-clock has become a very common and important scheme.

The operating voltage is conventionally fixed at the standard voltage like 5 V or 3.3 V. But when the system runs at multiple performance requirements, frequency can be varied to meet each performance. At this time, the operating voltage can be also changed to the minimum to attain that frequency. The power consumption is a quadratic function of voltage, therefore to control voltage has a very big impact and is quite an effective method of power reduction. Figure 19.12 shows an effect of scaling with frequency and voltage. Scaling with only frequency reduces power consumption in just proportion to frequency. On the other hand, scaling with frequency and voltage achieves drastic power saving because of quadratic effect of voltage reduction. It is really important to handle the voltage as a design parameter and not as

a fixed given standard. References [15,16] are examples called dynamic voltage scaling (DVS), which demonstrated actual benchmark programs running on a processor system with dynamically varied frequency and voltage based on required performance, and indicate energy efficiency improvement by factor of 10 among audio, user interface, and MPEG programs.

## 19.6 Process/Device Level Impact

---

The process and device are the lowest level of implementation. This layer itself does not have drastic impact directly. But when it leads to voltage reduction, this level plays a very important role in power saving.

Process rule migration rate is about 30% ( $\times 0.7$ ) per generation. And supply voltage is also reduced along with process shrinking after submicron generation, therefore capacitance scaling with voltage reduction makes good contribution on power.

Wire delay has become a problem because wire resistance and side capacitance are increasing along with process shrinking. To relieve this situation, inter-metal dielectric using low-k material and copper (Cu) interconnect have been utilized lately [17–19]. Still, however, dielectric constant of low-k is about 3.5–2.0 depending on materials while 4.0 for  $\text{SiO}_2$ , so this capacitance reduction does not a great impact on power because it affects just wire capacitance reduction as part of the whole chip. On the other hand, this can improve interconnect delay and chip speed allowing lower voltage operation at the same required speed. This accelerates power reduction with effect of quadratic function of voltage.

Silicon-on-insulator (SOI) is one of the typical process options for low power. The SOI transistor is isolated by  $\text{SiO}_2$  insulator, so junction capacitance is drastically reduced. This lightens charge/discharge loads and saves power consumption. Partial depletion (PD)-type SOI and full depletion (FD)-type SOI are used. The FD type can realize a steep subthreshold slope of about 60–70 mV/dec while the bulk one is 80–90 mV/dec. This helps reduction of threshold voltage ( $V_{th}$ ) at the same subthreshold leakage by 0.1–0.2 V, therefore operating voltage can be lowered while maintaining the same speed. References [20–22] are examples of PD type approach that demonstrate 20–35% performance improvement for microprocessor. Reference [23] is FD type approach also applied to microprocessor.

## 19.7 Summary

---

The impact on low-power design with each implementation classes of system level, algorithm level, architecture level, circuit level, and process/device level was described. Basically, higher levels affect power consumption more than lower levels because higher levels have more freedom in implementation. The key point for lower level to improve power consumption is its relationship with voltage reduction.

### 20.1 Introduction

---

Estimation of average power consumption is one of the main concerns in today's VLSI (very large scale integrated) circuit and system design [18,19]. This is mainly due to the recent trend towards portable computing and wireless communication systems. Moreover, the dramatic decrease in feature size, combined with the corresponding increase in the number of devices in a chip, make the power density larger. For a portable system to be practical, it should be able to operate for an extended period of time without the need to recharge or replace the battery. In order to achieve such an objective, power consumption in portable systems has to be minimized.

Power consumption also translates directly into excess heat, which creates additional problems for cost-effective and efficient cooling of ICs. Overheating may cause run-time errors and/or permanent damage, and hence, affects the reliability and the lifetime of the system. Modern microprocessors are indeed *hot*: Intel's Pentium 4 consumes 50 W, and Digital's Alpha 21464 (EV8) chip consumes 150 W, Sun's UltraSPARC III consumes 70 W [14]. In a market already sensitive to price, an increase in cost

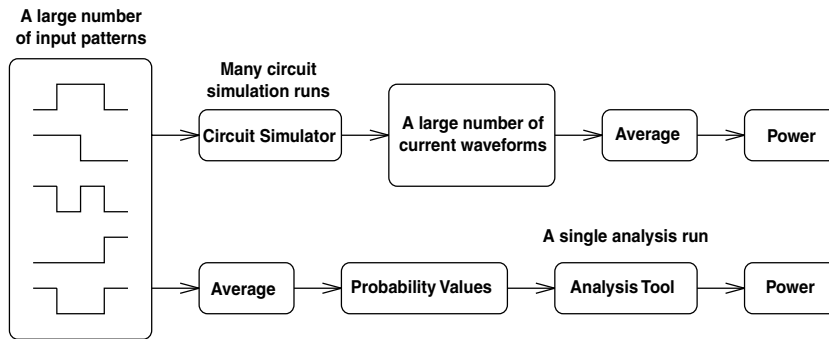

FIGURE 20.1 Probabilistic and simulation-based power estimation.

from issues related to power dissipation are often critical. Thus, shrinking device geometries, higher clocking speeds, and increased heat dissipation create circuit design challenges.

The Environmental Protection Agency's (EPA) constant encouragement for *green machines* and its Energy Star program are also pushing computer designers to consider power dissipation as one of the major design constraints. Hence, there is an increasing need for accurate estimation of power consumption of a system during the design phase so that the power consumption specifications can be met early in the design cycle and expensive redesign process can be avoided.

Intuitively, a straightforward method to estimate the average power consumption is by simulating the circuits with all possible combinations of valid inputs. Then, by monitoring power supply current waveforms, the power consumption under each input combination can be computed. Eventually, the results are averaged. The advantage of this method is its generality. This method can be applied to different technologies, design styles, and architectures; however, the method requires not only a large number of input waveforms combination, but also *complete and specific* knowledge of the input waveforms. Hence, the simulation method is prohibitively expensive and impractical for large circuits.

In order to solve the problem of input pattern dependence, *probabilistic techniques* [21] are used to describe the set of *all possible input combinations*. Using the probabilistic measures, the signal activities can be estimated. The calculated signal activities are then used to estimate the power consumption [1,3,6,12]. As illustrated in Fig. 20.1 [2], probabilistic approaches average all the possible input combinations and then use the probability values as inputs to the analysis tool to estimate power. Furthermore, the probabilistic approach requires only one simulation run to estimate power, so it is much faster than the simulation-based approaches, which require several simulation runs. In practice, some information about the typical input waveforms are given by the user, which make the probabilistic approach a *weakly pattern dependent* approach.

Another alternative method to estimate power is the use of *statistical techniques*, which tries to combine the speed of the probabilistic techniques with the accuracy of the simulation-based techniques. Similar to other simulation-based techniques, the statistical techniques are slower compared to the probabilistic techniques, as it needs to run a certain number of samples before simulation converges to the user-specified accuracy parameters.

This chapter is organized as follows. Section 20.2 describes how power is consumed in CMOS circuits. Probabilistic and statistical techniques to estimate power are presented in sections 20.3 and 20.4, respectively. Both techniques consider the temporal and spatial correlations of signals into account. Experimental results for both techniques are presented in section 20.5. Section 20.6 summarizes and concludes this chapter.

## 20.2 Power Consumption

Power dissipation in a CMOS circuit consists of the following components: static, dynamic, and direct path power. Static power component is due to the leakage current drawn continuously from the power supply. The dynamic power component is dependent on the supply voltage, the load capacitances, and the frequency of operation. The direct path power is due to the switching transient current that exists

for a short period of time when both PMOS and NMOS transistors are conducting simultaneously when the logic gates are switching.

Depending on the design requirements, there are different power dissipation factors that need to be considered. For example, the peak power is an important factor to consider while designing the size of the power supply line, whereas the average power is related to cooling or battery energy consumption requirements. We focus on the average power consumption in this chapter. The peak power and average power are defined in the following equations:

$$P_{\text{peak}} = I_{\text{peak}} \cdot V_{\text{supply}} \quad \text{and} \quad P_{\text{average}} = \frac{1}{T} \int_0^T (I_{\text{supply}}(t) \cdot V_{\text{supply}}) dt$$

## Static Power Component

In CMOS circuit, no conducting path between the power supply rails exists when the inputs are in an equilibrium state. This is due to the complimentary feature of this technology: if the NMOS transistors in the pull-down network (PDN) are conducting, then the corresponding PMOS transistors in the pull-up network (PUN) will be nonconducting, and vice-versa; however, there is a small static power consumption due to the leakage current drawn continuously from the power supply. Hence, the static power consumption is the product of the leakage current and the supply voltage ( $P_{\text{static}} = I_{\text{leakage}} \cdot V_{\text{supply}}$ ), and thus depends on the device process technology.

The leakage current is mainly due to the *reverse-biased parasitic diodes* that originate from the *source-drain* diffusions, the *well* diffusion, and the transistor *substrate*, and the *subthreshold current* of the transistors. Subthreshold current is the current which flows between the drain and source terminals of the transistors when the gate voltage is smaller than the threshold voltage ( $V_{\text{gs}} < V_{\text{th}}$ ). For today and future technologies, the subthreshold current is expected to be the dominant component of leakage current. Accurate estimation of leakage current has been considered in [13].

Static power component is usually a minor contributor to the overall power consumption. Nevertheless, due to the fact that static power consumption is always present even when the circuit is idle, the minimization of the static power consumption is worth considered by completely turning off certain sections of a system that are inactive.

## Dynamic Power Component

Dynamic power consumption occurs only when the logic gate is switching. The two factors that make up the dynamic power consumption are the charging and discharging of the output load capacitances and the switching transient current. During the low-to-high transition at the output node of a logic gate, the load capacitance at the output node will be charged through the PMOS transistors in PUN of the circuit. Its voltage will rise from GND to  $V_{\text{supply}}$ . An amount of energy,  $C_{\text{load}} \cdot V_{\text{supply}}^2$ , is drawn from the power supply. Half of this energy will then be stored in the output capacitor, while the other half is dissipated in the PMOS devices. During the high-to-low transition, the stored charge is removed from the capacitor, and the energy is dissipated in the NMOS devices in the PDN of the circuit. [Figure 20.2](#) illustrates the charging and the discharging paths for the load capacitor. The load capacitance at the output node is mainly due to the gate capacitances of the circuits that are being driven by the output node (i.e., the number of fanouts of the output node), the wiring capacitances, and the diffusion capacitances of the driving circuit.

Each switching cycle, which consists of charging and discharging paths, dissipates an amount of energy equals to  $C_{\text{load}} \cdot V_{\text{supply}}^2$ . Therefore, to calculate the power consumption, we need to know how often the gate switches. If the number of switching in a time interval  $t$  ( $t \rightarrow \infty$ ) is  $B$ , then the average dynamic power consumption is given by

$$P_{\text{dynamic}} = \frac{1}{2} \cdot C_{\text{load}} \cdot V_{\text{supply}}^2 \cdot B \cdot \frac{1}{t} = \frac{1}{2} \cdot C_{\text{load}} \cdot V_{\text{supply}}^2 \cdot A$$

FIGURE 20.2 The charging and discharging paths.

FIGURE 20.3 Switching current spikes.

where  $A = B/t$  is the number of transitions per unit time.

During the switching transient, both the PMOS and NMOS transistors conduct for a short period of time. This results in a short-circuit current flow between the power supply rails and causes a direct path power consumption. The direct path power component is dependent on the input rise and fall time. Slow rising and falling edges would increase the short-circuit current duration. In an unloaded inverter, the transient switching current spikes can be approximated as triangles, as shown in Figure 20.3 [16]. Thus, the average power consumption due to direct-path component is given by

$$P_{\text{direct-path}} = I_{\text{avg}} \cdot V_{\text{supply}}$$

where

$$I_{\text{avg}} = 2 \left[ \frac{1}{T} \int_{t_1}^{t_2} I(t) dt + \frac{1}{T} \int_{t_2}^{t_3} I(t) dt \right]$$

The saturation current of the transistors determines the peak current, and the peak current is directly proportional to the size of the transistors.

## Total Average Power

Putting together all the components of power dissipation, the total average power consumption of a logic gate can be expressed as follows:

$$P_{\text{total}} = P_{\text{dynamic}} + P_{\text{direct-path}} + P_{\text{static}} = \frac{1}{2} \cdot C_{\text{load}} \cdot V_{\text{supply}}^2 \cdot A + I_{\text{avg}} \cdot V_{\text{supply}} + I_{\text{leakage}} \cdot V_{\text{supply}} \quad (20.1)$$

Among these components, dynamic power is by far the most dominant component and accounts for more than 80% of the total power consumption in modern day CMOS technology. Thus, the total average power for all logic gates in the circuits can be approximated by summing up all the dynamic component of each of the logic gate,

$$P_{\text{total}} = \frac{1}{2} \cdot V_{\text{supply}}^2 \cdot \sum_{i=1}^n C_{\text{load}_i} \cdot A_i$$

where  $n$  is the number of logic gates in the circuit.

## Power Due to the Internal Nodes of a Logic Gate

The power consumption due to the internal nodes of the logic gates has been ignored in the above analysis, which causes inaccuracy in the power consumption result. The internal node capacitances are primarily due to the source and drain diffusion capacitances of the transistors, and are not as large as the output node capacitance. Hence, total power consumption is still dominated by the charging and discharging of the output node capacitances. Nevertheless, depending on the applied input vectors and the sequence in which the input vectors are applied, the power consumption due to the internal nodes of logic gates may contribute a significant portion of the total power consumption. Experimental results in section 20.5 show that the power consumption due to the internal nodes can be as high as 20% of the total power consumption for some circuits.

The impact of the internal nodes in the total power consumption is most significant when the internal nodes are switching, but the output node remains unchanged, as shown in Fig. 20.4. The internal capacitance,  $C_{\text{internal}}$ , is being charged, discharged, and recharged at time  $t_0$ ,  $t_1$ , and  $t_2$ , respectively. During this period of time, power is dissipated solely due to charging and discharging of the internal node.

FIGURE 20.4 Charging and discharging of internal node.

In order to obtain a more accurate power estimation result, the internal nodes have to be considered. In taking the internal nodes of the logic gates into consideration, the overall total power consumption equation is modified to

$$P_{\text{total}} = \sum_{i=1}^n \left( \frac{V_{\text{supply}}^2}{2} \cdot C_{\text{load}_i} \cdot A_i + \sum_{j=1}^m \frac{V_j^2}{2} \cdot C_{\text{internal}_j} \cdot A_j \right) \tag{20.2}$$

where  $m$  is the number of internal nodes in the  $i$ th logic gate. Note that output node voltages can only have two possible values:  $V_{\text{supply}}$  and GND; however, each internal node voltage can have multiple possible values ( $V_j$ ) due to charge sharing, and threshold voltage drop. In order to accurately estimate power dissipation, we should be able to accurately estimate the switching activities of all the internal nodes of a circuit.

### 20.3 Probabilistic Technique to Estimate Switching Activity

Probabilistic technique has been used to solve the strong input pattern dependence problem in estimating the power consumption of CMOS circuits. The probabilistic technique, based on zero-delay symbolic simulation, offers a fast solution for calculating power. The technique is based on an algorithm that takes the switching activities of the primary inputs of a circuit specified by the users. The probabilistic analysis relies on propagating the probabilistic measures, such as *signal probability* and *activity*, from the primary inputs to the internal and output nodes of a circuit.

To estimate the power consumption, probabilistic technique first calculates the *signal probability* (probability of being logic high) of each node. The *signal activity* is then computed from the signal probability. Once the signal activity has been calculated, the average power consumption can then be obtained by using Eq. (20.2).

The primary inputs of a combinational circuit are modeled to be *mutually independent strict-sense-stationary (SSS) mean-ergodic 1-0 processes* [3]. Under this assumption, the probability of the primary input node  $x$  to assume logic high,  $P(x(t))$ , becomes constant and independent of time, and denoted by  $P(x)$ , the *equilibrium signal probability* of node  $x$ . Thus,  $P(x)$  is the average fraction of clock cycles in which the equilibrium value of node  $x$  is of logic high.

The activity at primary input node  $x$  is defined by

$$\lim_{n \rightarrow \infty} \frac{n_x(T)}{T}$$

where  $n_x$  is the number of time the node  $x$  switches in the time interval of  $(-T/2, T/2)$ . The activity  $A(x)$  is then the average fraction of clock cycles in which the equilibrium value of node  $x$  is different from its previous value ( $A(x)$  is the probability that node  $x$  switches). Figure 20.5 illustrates the signal probability and activity of two different signals.

FIGURE 20.5 Signal probability and activity.

## Signal Probability Calculation

In calculating the signal probability, we first need to determine if the input signals (random variables) are independent. If two signals are correlated, they may never be in logic high together, or they may never be switching at the same time. Due to the complexities of the signals flow, it is not easy to determine if two signals are independent. The primary inputs may be correlated due to the feedback loop. The internal nodes of the circuit may be correlated due to the reconvergent fanouts, even if the primary inputs are assumed to be independent. The reconvergent fanouts occur when the output of a node splits into two or more signals that eventually recombine as inputs to certain nodes downstream. The exact calculation of the signal probability has been shown to be *NP-hard* [3].

The probabilistic method in estimating power consumption uses *signal probability* measure to accurately estimate *signal activity*. Therefore, it is important to accurately calculate signal probability as the accuracy of subsequent steps in computing activity depends on how accurate the signal probability calculation is. In implementing the probabilistic method, we adopted the general algorithm proposed in [4] and used the data structure similar to [5].

The algorithm used to compute the signal probability is given as follows:

- *Inputs*: Circuit network and signal probabilities of the primary inputs.
- *Output*: Signal probabilities of all nodes in the circuit.
- *Step1*: Initialize the circuit network by assigning a unique variable, which corresponds to the signal probability, to each node in the circuit network.
- *Step 2*: Starting from the primary inputs and proceeding to the primary outputs, compute the *symbolic probability expression* for each node as a function of its inputs expressions.
- *Step 3*: Suppress all exponents in the expression to take the spatial signal correlation into account [4].

### Example

Given  $y = ab + ac$ . Find signal probability  $P(y)$ .

$$\begin{aligned}
 P(y) &= P(ab) + P(ac) + P(abac) \\
 &= P(a)P(b) + P(a)P(c) - P^2(a)P(b)P(c) \\
 &= P(a)P(b) + P(a)P(c) - P(a)P(b)P(c)
 \end{aligned}$$

## Activity Calculation

The formulation to determine an exact expression to calculate *activity* of static combinational circuits has been proposed in [6]. The formulation considers spatio-temporal correlations into account and is adopted in our method. If a clock cycle is selected at random, then the probability of having a transition at the leading edge of this clock cycle at node  $y$  is  $A(y)/f$ , where  $A(y)$  is the number of transition per second at node  $y$ , and  $f$  is the clock frequency. This normalized probability value,  $A(y)/f$ , is denoted as  $a(y)$ . The exact calculation of the *activity* uses the concept of *Boolean difference*. In the following sections, the Boolean difference is first introduced before applying it in the exact calculation of the activity of a node.

### Boolean Difference

The Boolean difference of  $y$  with respect to  $x$  is defined as follows:

$$\frac{\partial y}{\partial x} = y|_{x=1} \oplus y|_{x=0}$$

The Boolean difference can be generalized to  $n$  variables as follows:

$$\frac{\partial^n}{\partial x_1 \dots \partial x_n} y|_{b_1 \dots b_n} = y|_{(x_1=b_1) \dots (x_n=b_n)} \oplus y|_{(x_1=b_1) \dots (x_i=b_i) \dots (x_n=b_n)}$$

where  $n$  is a positive integer,  $b_n$  is either logic high or low, and  $x_n$  are the distinct mutually independent primary inputs of node  $y$ .

### Activity Calculation Using Boolean Difference

Activity  $a(y)$  at node  $y$  in a circuit is given by [1]

$$a(y) = \sum_{i=1}^n P\left(\frac{\partial y}{\partial x_i}\right) \cdot a(x_i) \quad (20.3)$$

where  $a(x_i)$  represents switching activity at input  $x_i$ , while  $P(\partial y/\partial x_i)$  is the probability of sensitizing input  $x_i$  to output  $y$ .

Equation (20.3) does not take simultaneous switching of the inputs into account. To consider the simultaneous switching, the following modifications have to be made:

- $P(\partial y/\partial x_i)$  is modified to  $P(\partial y/\partial x_i | x_i^\dagger)$ , where  $x_i^\dagger$  denotes that input  $x_i$  is switching.
- $a(x_i)$  is modified to  $\{a(x_i) \prod_{j \neq i, 1 \leq j \leq n} (1 - a(x_j))\}$

#### Example

For a Boolean expression  $y$  with three primary inputs  $x_1, x_2, x_3$ , the activity  $a(y)$  is given by the sum of three cases, namely,

- when only one input is switching:

$$\sum_{i=1}^3 P\left(\frac{\partial y}{\partial x_i} \Big|_{x_i^\dagger}\right) \left( a(x_i) \prod_{j \neq i, 1 \leq j \leq n} (1 - a(x_j)) \right)$$

- when two inputs are switching:

$$\frac{1}{2} \left( \sum_{1 \leq i < j \leq 3} \left( P\left(\frac{\partial^2 y}{\partial x_i \partial x_j} \Big|_{x_i^\dagger x_j^\dagger}\right) + P\left(\frac{\partial^2 y}{\partial x_i \partial x_j} \Big|_{x_i^\dagger \bar{x}_j}\right) \right) \left( a(x_i) a(x_j) \prod_{k \in \{1,2,3\} - \{i,j\}} (1 - a(x_k)) \right) \right)$$

- and when all three inputs are switching simultaneously:

$$\begin{aligned} & \frac{1}{2^2} \left( P\left(\frac{\partial^3 y}{\partial x_1 \partial x_2 \partial x_3} \Big|_{x_1^\dagger x_2^\dagger x_3^\dagger}\right) + P\left(\frac{\partial^3 y}{\partial x_1 \partial x_2 \partial x_3} \Big|_{x_1^\dagger \bar{x}_2 \bar{x}_3}\right) + P\left(\frac{\partial^3 y}{\partial x_1 \partial x_2 \partial x_3} \Big|_{\bar{x}_1 x_2^\dagger x_3^\dagger}\right) \right) \\ & + P\left(\frac{\partial^3 y}{\partial x_1 \partial x_2 \partial x_3} \Big|_{\bar{x}_1 \bar{x}_2 x_3^\dagger}\right) \left( \prod_{k=1}^3 a(x_k) \right) \end{aligned}$$

The activity calculation using Boolean difference can now be readily extended to the general case of  $n$  inputs.

### Activity Calculation Using Signal Probability

The calculation of the activity of a node using the Boolean difference is computationally intensive. The complexity and computation time grow exponentially with the number of inputs. Hence, an alternative, and more efficient method to compute the activity using signal probability can be used instead.

Let  $P(y(t))$  be the signal probability at time  $t$ . The probability of a given node  $y$  is not switching at time  $t$  is  $P(y(t-T)y(t)) = P(y(t)) - \frac{1}{2}a(y) = P(y) - \frac{1}{2}a(y)$ . Hence,  $a(y) = 2(P(y) - P(y(t-T)y(t)))$ . To calculate the activity  $a(y)$  from the pre-computed signal probability  $P(y)$ , we must first calculate  $P(y(t-T)y(t))$ .

**Example**

Given  $y = x_1 + x_2$ . Find  $P(y(t - T)y(t))$  and  $a(y)$ .

$$P(y) = P(x_1) + \overline{P(x_1)}P(x_2) \quad \text{and} \quad \overline{P(x_1)} = P(\overline{x_1}) = 1 - P(x_1)$$

$P(y(t - T)y(t))$  is given by the *product of two terms*, namely

$$P(x_1(t - T)) + \overline{P(x_1(t - T))}P(x_2(t - T)) \quad \text{and} \quad P(x_1(t)) + \overline{P(x_1(t))}P(x_2(t))$$

Expanding the product of these two terms, we obtain the following four terms:

$$\begin{aligned} &P(x_1(t - T))P(x_1(t)) + P(x_1(t - T))\overline{P(x_1(t))}P(x_2(t)) + \overline{P(x_1(t - T))}P(x_1(t))P(x_2(t - T)) \\ &+ \overline{P(x_1(t - T))}P(x_1(t))P(x_2(t - T))P(x_2(t)) \\ &= P(x_1(t - T)x_1(t)) + P(x_1(t - T)\overline{x_1(t)})P(x_2(t)) + P(\overline{x_1(t - T)}x_1(t))P(x_2(t - T)) \\ &\quad + P(\overline{x_1(t - T)}x_1(t))P(x_2(t - T)x_2(t)) \\ &= P(x_1) - \frac{1}{2}a(x_1) + \frac{1}{2}a(x_1)P(x_2) + \frac{1}{2}a(x_1)P(x_2) + \left(1 - P(x_1) - \frac{1}{2}a(x_1)\right)\left(P(x_2) - \frac{1}{2}a(x_2)\right) \end{aligned}$$

After rearranging the above equation, we obtain

$$a(y) = (1 - P(x_1))a(x_2) + (1 - P(x_2))a(x_1) - \frac{1}{2}a(x_1)a(x_2).$$

**Partitioning Algorithm**

Accurate calculation of the *symbolic probability* is important to subsequent computation of the *activity* at internal node of a circuit; however, not only the *exact* calculation of the symbolic probability is *NP-hard*, but also the size of symbolic probability expression grows exponentially with the number of the inputs. Thus, a technique to partition the circuit network by utilizing the circuit topology information is used [6]. Using this partitioning scheme, the size of the probability expression is limited as each node in the circuit network is now only dependent upon its *minimum set of topologically independent inputs (MSTII)*. MSTII is a set of independent inputs (or internal nodes) that *logically* determines the logic function of a node. This partitioning scheme can trade off accuracy with computation speed and data storage size.

Figure 20.6 shows the MSTII of a logic gate Z. The MSTII of  $y_1$ ,  $x_4$ ,  $w$ , and  $x_7$  are used instead of  $x_1$ ,  $x_2, \dots, x_7$ . Hence, we only deal with four inputs instead of the original seven.

FIGURE 20.6 MSTII of a logic gate.

## Power Estimation Considering the Internal Nodes

In the previous analysis, we only considered the activity at the output of a logic gate; however, complex CMOS logic gates have internal nodes that are associated with capacitances that may charge/discharge based on the inputs applied to the logic gate. The power consumption due to the internal nodes in the logic gates may play an important role in determining the total power consumption for a certain sequence of input vectors. In order to improve the accuracy of the probabilistic, let us include the power consumed by the internal nodes of logic gates.

The algorithm to compute the power consumption due to the internal node is given as follows [7]:

- *Inputs*: Functional expression of the node in terms of its inputs, input signal probabilities, and activities.
- *Output*: Normalized power estimation measure,  $\phi$  (described later in the section on “Normalized Power Measure”).
- *Step 1*: Factorize the functional expression.
- *Step 2*: Determine the position of each internal node.
- *Step 3*: Compute the probability of the conducting path: from the internal node  $i$  to  $V_{\text{supply}}$  ( $P_{V_{\text{supply}}}^i$ ), and to GND ( $P_{V_{\text{gnd}}}^i$ ).
- *Step 4*: Compute the activity obtained from  $\min(P_{V_{\text{supply}}}^i)(P_{V_{\text{gnd}}}^i)$ .
- *Step 5*: Compute the normalized power measure.

### Factorization of the Functional Expression

For a given functional expression of a node in term of its inputs, we need to factorize and simplify the expression to obtain a compact and optimal expression, and thus an optimal implementation of the logic gate. The functional expression is used to determine the position of the internal nodes of the logic gate. The output node of the logic gate will not be affected whether the factorized expression is used or not. However, the number of internal nodes of the logic gate depends on the functional expression used.

#### Example

Given  $X = \overline{ABF} + \overline{ABE} + \overline{DF} + \overline{CF} + \overline{DE} + \overline{CE}$ .

If the expression is directly implemented as static CMOS complex gate, then a total of 13 internal nodes exist in the logic gate. Some of these internal nodes are redundant and can be eliminated if the factorized expression is used instead. The factorized expression is  $X = (\overline{AB} + \overline{C} + \overline{D})(\overline{E} + \overline{F})$ , and has only five internal nodes. Figure 20.7 shows the implementation of both the factorized and unfactorized expressions.

### The Position of the Internal Nodes

The position of the internal nodes can be determined while implementing the given functional expression of a node in static CMOS. Internal nodes exist whenever there is an AND or an OR function exist as both functions have at least two inputs. Inside an AND (OR) function, the internal nodes are found in the PUN (PDN). In both functions, the number of the inputs to the logic gate determines the number of the internal nodes. If there are  $n$  inputs to the logic gate, then  $(n - 1)$  internal nodes must exist inside the logic gate. In implementing the functional expressions, the complemented input signals are assumed to be available.

### The Conducting Paths to the Supply Rails

After determining the position of the internal nodes inside the logic gate, the probabilities of the conducting paths from each internal node to the supply rails (both to  $V_{\text{supply}}$  and GND) are then computed. The probability of the conducting path from an internal node to  $V_{\text{supply}}$ (GND) signifies the probability of charging (discharging) the capacitance in that internal node. The probability of charging and discharging the internal node capacitances is then used to calculate the *activity* of the internal nodes. The *signal probability* of each of the internal nodes is calculated using the algorithm outlined in the previous section, which takes spatio-temporal correlation among signals into account.

FIGURE 20.7 Unfactorized and factorized functional expression.

**Example**

Given a 2-input NAND gate  $Y = \overline{AB}$  as shown in Fig. 20.8. The probabilities of the conducting paths from the internal node to  $V_{supply}$  and to GND are  $P(\overline{AB})$  and  $P(B)$ , respectively.

**Internal Nodes Activity Computation**

The activities of each internal node are calculated using the probabilities of the conducting paths from the internal nodes to the supply rails. The minimum of the two probabilities is used to compute the activity of the internal node because no effective charging/discharging will occur once this minimum threshold value is reached. For example, if within a period of 10 clock cycles, the probability of charging process is 0.5 (5 out of 10 clock cycles are conducting), and the probability of discharging process is 0.3, then the charging and discharging processes can only take place for 3 out of 10 clock cycles. The extra 2 charging cycles will have no effect on the outcome, as the internal node capacitance remains charged. Hence, only a previously charged (discharged) capacitance can be discharged (charged).

**Normalized Power Measure**

The normalized power measure is computed from the activity of each of the internal nodes. At the logic gate output, the total normalized power measure is computed by  $\phi = \sum_i fanout_i \times a(i)$  where  $fanout_i$  is the number of gate being driven by the output node  $i$  ( $C_{load-i}$  is assumed to be proportional to  $fanout_i$ ). At the internal nodes, the normalized power measure is computed by  $\phi_{internal} = \sum_i C_{int_i} \times a_{internal}(i)$ . The results for the power estimation using the probabilistic technique will be given in section 20.5.

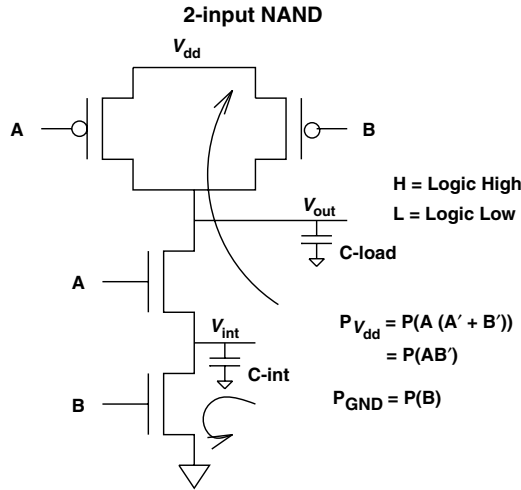

FIGURE 20.8 Charging and discharging paths of the internal node.

## 20.4 Statistical Technique

Statistical technique for estimating power consumption is a simulation-based approach. To improve the accuracy of this method, we need to run all possible sets of input combinations exhaustively for an indefinitely long period of time. Thus, this method is prohibitively expensive and impractical for very large circuits. The main advantage of this technique is that the existing simulators can be used readily. Furthermore, issues such as glitch generation and propagation, spatio-temporal correlations among signals are all automatically taken into account. The generality of this technique still attracts much interest, but Monte Carlo-based approaches [8,20] can be used to determine the number of simulation runs for a given error that can be tolerated.

We adopted a statistical sampling technique using Monte Carlo approach as proposed in [8], and included the internal node analysis to further improve the accuracy. To estimate the power consumption in the circuit, the statistical technique first generates random input vectors that conform to the user-specified signal probability and activity. The circuit is then simulated using the randomly generated input vectors. For each simulation run in time period  $T$ , the cumulative power dissipation is monitored by counting the number of transitions of each node (*sample*) in the circuit. The simulation run is then repeated  $N$  times until the monitored power dissipation converges to the user-specified error and confidence levels. The average number of transitions (*sample mean*),  $\bar{n}$ , at each node is then obtained. The activity of each node is computed by  $\bar{n}/T$ .

Because the signal probability and activity of the primary inputs are only needed, this technique is essentially *weakly pattern-dependent*. Monte Carlo method has an attractive property that it is *dimension independent*, meaning that the number of simulation runs needed does not depend on the circuit size. A good random input generator and an efficient stopping criterion are important for the Monte Carlo method. These issues are presented in the following sections.

### Random Input Generator

The input vector is considered to be a Markov process [9], meaning that the present input waveform only depends on the value of the waveform in the prior immediate clock cycle, and not on the values of the other previous clock cycles. The implementation is based on Markov process, so the length of time

between successive transitions is a random variable with an *exponential* distribution [10]. Another implication of Markov process is that the pulse width distribution of the input waveform is a *geometric* distribution. The conditional probabilities of the input waveforms switching are then given as:  $P(0|1) = T/\mu_1$  and  $P(1|0) = T/\mu_0$  where  $T$  is the clock pulse period,  $\mu_1$  is the mean of high pulse width ( $P(x)/a(x)$ ), and  $\mu_0$  is the mean of low pulse width ( $2[1 - P(x)]/a(x)$ ). Also,  $P(0|0) = 1 - P(1|0)$  and  $P(1|1) = 1 - P(0|1)$ . The random number generator uses the above criteria to decide whether the input signals switch or not.

## Stopping Criteria

The number of simulation runs needed to converge the result determines the speed of the statistical technique. Hence, efficient stopping criteria are needed. The decision is made based on the mean and standard deviation of the monitored power consumption at the end of every simulation run.

For large sample  $N$ , the sample mean,  $\bar{n}$  approaches  $\eta$ , the true average number of transitions in  $T$ , and the sample standard deviation,  $s$ , also approaches  $\sigma$ , the true standard deviation [10]. According to the *Central Limit Theorem*,  $\bar{n}$  has the mean  $\eta$  with the distribution approaching *normal* distribution for large  $N$  ( $N \geq 30$ ). It follows that for  $(1 - \alpha)$  confidence level,  $-z_{\alpha/2} \cdot \sigma \leq \eta - \bar{n} \leq z_{\alpha/2} \cdot \sigma$ , where  $z_{\alpha/2}$  is the point where the area to its right under the standard normal distribution curve is equal to  $\alpha/2$ .

Since  $\sigma \approx s/\sqrt{N}$  for large  $N$ , and with confidence  $(1 - \alpha)$ , then

$$\frac{|\eta - \bar{n}|}{\bar{n}} \leq \frac{s \cdot z_{\alpha/2}}{\bar{n} \sqrt{N}} \quad (20.4)$$

If  $\varepsilon_1$  is a small positive number and the number of sample is

$$N \geq \left( \frac{s \cdot z_{\alpha/2}}{\bar{n} \varepsilon_1} \right)^2 \quad (20.5)$$

then  $\varepsilon_1$  sets the upper bound for Eq. (20.4):

$$\frac{|\eta - \bar{n}|}{\bar{n}} \leq \frac{s \cdot z_{\alpha/2}}{\bar{n} \sqrt{N}} \leq \varepsilon_1 \quad (20.6)$$

Equation (20.6) can also be expressed as the deviation percentage from the population mean  $\eta$ :

$$\frac{|\eta - \bar{n}|}{\bar{n}} \leq \varepsilon_1 \quad \text{translates into} \quad \frac{|\bar{n} - \eta|}{\eta} \leq \frac{\varepsilon_1}{1 - \varepsilon_1} = \varepsilon \quad (20.7)$$

where  $\varepsilon$  is the user-specified percentage error tolerance.

Equation (20.5) thus provides the stopping criterion for the percentage error tolerance in Eq. (20.7) for  $(1 - \alpha)$  confidence. The problem with this stopping criterion is that for small  $\bar{n}$ , a large number of samples  $N$  are required, as shown in Eq. (20.5), so it becomes too expensive to guarantee percentage error accuracy in this case. The nodes with small  $\bar{n}$  (or  $\bar{n} < \eta_{\min}$ , where  $\eta_{\min}$  is the user-specified minimum threshold value) are called *low-activity* nodes. Large value of  $N$  means that these low-activity nodes will take a much longer time to converge. Yet, these low-density nodes have the least effect on circuit power and reliability. To improve the convergence time without any significant effect in the overall result, an *absolute error bound*,  $\eta_{\min} \cdot \varepsilon_1$ , is used instead of the *percentage error bound*,  $\varepsilon$  [9]. The absolute error bounds for low-density nodes are always *less than* the absolute error bounds for high-activity nodes.

Therefore, when dealing with low-activity nodes, instead of using Eq. (20.5), the following stopping criterion is used

$$N \geq \left( \frac{s \cdot z_{\alpha/2}}{\eta_{\min} \epsilon_1} \right)^2 \quad (20.8)$$

For  $(1 - \alpha)$  confidence level, the accuracy for the low-density nodes is given by  $|\eta - \bar{n}| \leq s z_{\alpha/2} / \sqrt{N} \leq \eta_{\min} \epsilon_1$ .

During the simulation run, after  $N$  exceeds 30, Eq. (20.5) is used as a stopping criterion as long as  $\bar{n} \geq \eta_{\min}$ . Otherwise, Eq. (20.8) is used instead.

## Power Estimation due to the Internal Nodes

We included the capability of estimating internal nodes power dissipation in the Monte Carlo technique. The algorithm to compute the internal nodes power is as follows [7]:

- *Inputs:* Functional expression of the node in terms of its inputs, and user-specified accuracy parameters
- *Output:* Normalized power measure  $\phi$
- *Step 1:* Factorize the functional expression
- *Step 2:* Generate a graph to represent the expression
- *Step 3:* Simulate the circuit with random input
- *Step 4:* Update conducting path (event-driven process)
- *Step 5:* Sum all charges in the discharging path
- *Step 6:* Accumulate all the sum

The given functional expression of a node is expressed in terms of its inputs. The factorization process, the same as in the probabilistic technique, is to ensure that the expression is compact and does not contain any redundant items.

### Graph Generation

A graph to represent the factorized expression is generated to be used as the data structure in estimating power dissipation. The nodes of the graph represent all the nodes in the logic gate, such as supply rails, output node, and all the internal nodes inside the logic gate. The edges of the graph represent the inputs to the logic gate between the nodes. Information of the internal nodes capacitances and voltages are stored in nodes structure of the graph. Once the graph is generated, the circuit is simulated with randomly generated input vectors conforming to the user-specified input signal probability and activity.

Note that in the case of the probabilistic method, a graph is not used, as there is no need for such data structure. In the probabilistic method, the signal probability and activity of each node are calculated as we traverse level by level from primary inputs of the circuit network to the outputs. The calculated values are then stored in the data structure within the node itself. In the statistical technique, however, the graph is needed to store the simulation run results. An example of a generated graph for a given factorized functional expression  $X = (\overline{AB} + \overline{C} + \overline{D})(\overline{E} + \overline{F})$  is shown in Fig. 20.9.

### Updating Conducting Paths

The path in the graph needs to be updated whenever a change in the input signals occurs. The change in the input signals is defined as an *event*. To improve the computation speed, the updating process of the path is being done only when an event occurs. Hence, the path updating process is said to be an *event-driven* process.

The path in the graph that needs to be updated may change from conducting to nonconducting or vice-versa, depending on the event which occurs. If the path becomes nonconducting, then the nodes at

FIGURE 20.9 A logic gate and its corresponding graph.

both ends of disjointed segments of the path become isolated and assumed to retain their voltage values. On the other hand, if a conducting path joins the disjointed segments, then all the nodes along the conducting paths must be updated to a new equilibrium value. If the conducting path to the  $V_{supply}$  ( $V_{gnd}$ ) exists, then all nodes along the path will be charged (discharged).

The algorithm for path updating process is as follows. When input node  $i$  switches from OFF to ON:

1. If a conducting path from the internal node to Gnd exists:
  - collect all the node charges along the path
  - set all the node voltages to  $V_{low}$  ( $V_{low}$  for nodes in NMOS and PMOS are 0 and  $V_{thp}$ , respectively).
2. If a conducting path to  $V_{supply}$  exists:
  - set all the node voltages to  $V_{high}$  ( $V_{high}$  for nodes in NMOS and PMOS are  $(V_{supply} - V_{thn})$  and  $V_{supply}$ , respectively).

$V_{thp}$  and  $V_{thn}$  are PMOS and NMOS threshold voltage, respectively. The internal nodes in PUN among PMOS devices will be fully charged to  $V_{supply}$ , but will only be discharged to  $V_{thp}$ . Similarly, the internal nodes in PDN among NMOS devices will be fully discharged to  $V_{gnd}$ , but will only be charged to  $(V_{supply} - V_{thn})$ . This is because the transistors will be cut-off when the gate to source voltage is less than the threshold voltage.

Along the discharging path (conducting path to the GND), all the charges in the internal nodes are added together. The sum of the charges is accumulated over all simulation runs. The normalized power measure is directly derived from this accumulated sum of charges as  $\phi_{internal} = Q_{total} \cdot V_{supply}/run\text{-time}$ .

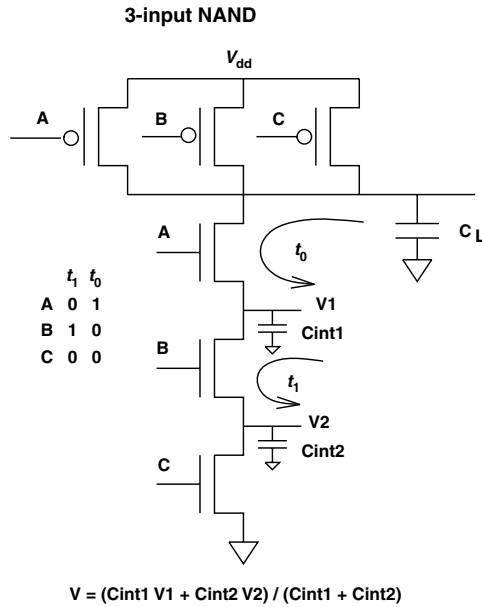

FIGURE 20.10 Charge-sharing.

### Charge-Sharing among the Internal Nodes

Charge-sharing among the internal nodes occurs when the conducting path that connects the nodes is not connected to either  $V_{supply}$  or GND. The nodes along the path are then isolated from the supply rails, and will not be charged or discharged. These isolated nodes will come to a new equilibrium state, a value between  $V_{supply}$  and GND. In the isolated state, the capacitances of the internal nodes are connected in parallel, and share the charges among themselves, thus the term charge-sharing. The new equilibrium voltage among the internal nodes is

$$V = \frac{\sum_{j=1}^n (C_j V_j)}{\sum_{j=1}^n C_j} \quad (20.9)$$

where  $n$  is the number of isolated nodes, and  $V_j$  is the initial voltage across the internal node capacitance  $C_j$ . An example of the charge-sharing process is illustrated in Fig. 20.10. The event occurs when inputs  $A$  and  $B$  switch at time  $t_1$ . The internal nodes are then isolated from  $V_{supply}$  and GND. The new equilibrium voltage between the two isolated internal capacitances is calculated to be

$$V = \frac{C_{int1} \cdot V_1 + C_{int2} \cdot V_2}{C_{int1} + C_{int2}}$$

## 20.5 Experimental Results

Both the probabilistic and the statistical techniques have been implemented in C within University of California at Berkeley's SIS [17] environment. SIS is an interactive tool for synthesis and optimization of logic circuits. The test circuits used in obtaining the results are the benchmarks presented at ISCAS in 1985 [11]. These circuits are combinational circuits and Table 20.1 shows the number of primary inputs, outputs, nodes, and circuit level of each benchmark circuit.

## Results Using Probabilistic Technique

The signal probability and activity for the primary inputs are both specified to be 0.5. The load capacitance at the output nodes is specified to a unit capacitance and the internal node capacitances are specified to one-half unit capacitance. The maximum number of inputs allowed for each partition level is 10 inputs. The simulations are run on SPARCstation 5, and the results are shown in [Table 20.2](#). Power dissipation due to the internal node ranges from 9.38% to 22.4% of the overall power consumption. Hence, the internal nodes power is a significant portion of the total power consumption. The result is given in term of power measure  $\phi$  (switching activity  $\times$  fanouts).

## Results Using Statistical Technique

Similar to the probabilistic technique, the signal probability and activity for the primary inputs are specified to be 0.5. The sample period of each simulation run is specified to be 100 unit clock cycles. The relative error is specified to be 30%, and the minimum threshold is specified to be 3%. In the simulation, 5 V power supply is used. The threshold voltages for both PMOS and NMOS devices are specified to be 1 V. The results are tabulated in [Table 20.3](#).

The experiment shows that the percentage of internal nodes power consumption to overall power consumption ranges from 7.75% to 18.59%. The result of the same simulation with the charge-sharing option being switched off is shown in [Table 20.4](#).

The computation time is faster by up to 10% for certain cases when the simulation is run with the charge-sharing option switched off. The percentage of internal power to overall power only changes by 0.1% to 0.2% when charge sharing is not taken into consideration, so neglecting the charge-sharing effect among the internal node capacitances will not affect the overall result significantly.

## Comparing Probabilistic with Statistical Results

Figure 20.11 illustrates the percentage total power consumption due to internal nodes as obtained from both probabilistic and statistical techniques [15]. A dashed line and a solid line for statistical and probabilistic techniques represent the results, respectively. On an average, the result from the statistical technique is slightly lower than the result obtained from the probabilistic approach. The discrepancy arises from various different sets of simplifying assumptions used in both techniques. Nevertheless, both results track one another closely.

Figure 20.12 illustrates the run time of the probabilistic and statistical techniques [15]. The vertical axis is in log scale. The probabilistic technique, as expected, runs one or two magnitude order faster than the statistical technique. The statistical technique needs a number of simulation runs before the result

converges to the specified parameters, whereas the probabilistic technique only needs one run to obtain the result. This accounts for the difference in the computational time.

Figure 20.13 shows the total power consumption measure of both probabilistic and statistical techniques [15]. The results of both methods follow one another very closely. The vertical axis is plotted in log scale. The dashed line represents the result for statistical technique and the solid line represents the result for probabilistic technique.

## 20.6 Summary and Conclusion

---

In this chapter, estimation of activity and thus power consumption are presented. Probabilistic and statistical techniques, which take spatio-temporal correlations into account, are used. The probabilistic method uses a zero-delay model. If a nonzero model is used instead, the accuracy of the probabilistic method improves, but the underlying method and concept outlined for simplified zero-delay model still applies, i.e., the probability of some inputs switching simultaneously will change and thus causes a change in the calculated switching activity. The statistical method uses the inherent gate delay during the simulation run. Both probabilistic and statistical techniques include the effect of power consumption due to the internal nodes, which improves the accuracy of the methods by 7.75–22.4%. The power estimation methods allow circuit designers to analyze and optimize the designs for power consumption early in the design cycle. This is a critical requirement for today's demanding power-sensitive applications, such as portable computing and communication systems.

### 21.1 Introduction

---

Power dissipation is one of the most important design considerations for portable systems as well as desktop and server computers. For portable systems, long battery life is a necessity. There is only a fixed amount of energy stored in the battery; the lower the system dissipation, the longer the battery life. For desktop and server computers, cost is of utmost importance. Heat generation is proportional to power dissipation. Systems with high power dissipation require an expensive cooling system to remove the heat. CMOS is the technology used for implementing the vast majority of computing systems. In CMOS systems, dynamic power is the dominant dissipation factor, which is consumed for switching circuit nodes between 0 V and a voltage  $V$  from a dc supply source. Dynamic power dissipation is generally denoted by  $fCV^2$ , where  $f$  is the operating frequency and  $C$  is the effective switching capacitance per cycle. As CMOS technology advances, both the operating frequency  $f$  and the switching capacitance  $C$  increase resulting in increasingly higher power dissipation. The typical approach to reduce power dissipation is to lower the supply voltage  $V$  [1]. Despite the quadratic dependence of power to the voltage, the reduction of the voltage is not sufficient to surpass the increase of the frequency and capacitance [2].

Adiabatic charging [3] is an alternative approach to reduce energy dissipation below the  $CV^2$  barrier. The basic idea of adiabatic charging is to employ an ac (i.e., time-varying) source to gradually charge and discharge circuit nodes. Examples of ac sources that can be used for adiabatic charging include a voltage-ramp source, a sinusoidal source, or a constant-current source. In time-varying supplies, energy dissipation is controlled by varying the charging time. For instance, if a capacitance  $C$  is charged from

0 V to a voltage  $V$  in time  $T$  through a resistance  $R$  from a voltage-ramp source, the energy dissipated in the resistance,  $E_{vrs}$ , is [4,5]:

$$E_{vrs} = \left( \frac{RC}{T} - \left( \frac{RC}{T} \right)^2 + \left( \frac{RC}{T} \right)^2 e^{-\frac{T}{RC}} \right) CV^2 \quad (21.1)$$

For  $T \rightarrow 0$ , the voltage-ramp source becomes equivalent to a dc source. Indeed, for  $T \rightarrow 0$  Eq. (21.1) reduces to:

$$E_{dcs} = \frac{1}{2} CV^2 \quad (21.2)$$

which denotes the energy required to charge a capacitance  $C$  from a dc source of voltage  $V$ . For  $T \gg RC$ , Eq. (21.1) can be approximated by [6,7]:

$$E_{ccs} = \left( \frac{RC}{T} \right) CV^2 \quad (21.3)$$

Equation (21.3) gives the energy dissipated in the resistance  $R$  if a constant-current source is used to charge the capacitance  $C$  to voltage  $V$  in time  $T$ . It can be proved [8] that constant-current charging results in minimum energy dissipation for a given charging time  $T$ . Constant-current charging represents the ideal case. For practical purposes, it can be approximated with a sinusoidal source. In this case, although the energy dissipation increases by a constant shape factor [3], the inverse relationship between energy dissipation and charging time still holds.

The implementation of viable CMOS energy-recovery systems based on adiabatic charging has not been a trivial task. First, adiabatic charging is associated with some circuit overhead, which potentially cancels out the energy savings from adiabatic charging. Second, a key factor to implement an energy-recovery system is the efficiency of the time-varying voltage source. Proposals for exploiting adiabatic charging range from extreme reversible logic systems that theoretically can achieve asymptotically zero energy dissipation [3,9] to more practical partial adiabatic approaches [10–16]. The former requires the most overhead, both at the logic level and at the supply source level. The latter results in energy losses asymptotic to  $CV_{th}^2$  or  $CVV_{th}$  depending on the specific approach, where  $V_{th}$  is the FET threshold voltage. Their overhead is mostly at the logic level. Some of them can operate from a single time-varying supply source [15,16].

In this chapter, we focus on clock-powered logic, which is a systematic approach for designing overall energy-efficient CMOS VLSI systems that use adiabatic charging and energy recovery. The motivation behind clock-powered logic is that the distribution of circuit nodes, excluding  $V_{dd}$  and GND, for many VLSI chips can be relatively identified as either large capacitance or small capacitance. Clock-powered logic is a node-selective adiabatic approach, in which energy recovery through adiabatic charging is applied to only those nodes that are deemed to be large capacitance. The circuitry overhead for energy recovery and the adiabatic-charging process is amortized by the large capacitive load since energy savings is proportional to the load. Nodes that are deemed small capacitance can be powered as they usually are in CMOS circuits, e.g., precharging, pass-transistors networks, and static pull-up and pull-down networks that draw power from a dc supply.

This article is organized as follows: First, section 21.2 reviews clock-powered logic followed by a presentation of ac supply sources that can be used for adiabatic charging in section 21.3. In section 21.4, an energy-recovery (E-R) latch is presented. The E-R latch is a key circuit used to pass energy from the ac supply source to circuit data nodes and vice versa. Section 21.5 describes in detail how adiabatically-charged nodes interface with logic blocks powered from a dc supply voltage. In section 21.6, the drive part of the E-R latch is compared to conventional drivers for energy versus delay performance through HSPICE simulations. In section 21.7, two generations of clock-powered microprocessors are presented and compared against an equivalent fully dissipative design. Finally, section 21.8 presents the conclusions.

## 21.2 Overview of Clock-Powered Logic<sup>1</sup>

The overall organization for a clock-powered microsystem is shown in Fig. 21.1. Adiabatic charging requires a time-varying voltage signal as a source of ac power. Rather than introduce a new power supply, this power source can be naturally supplied in a synchronous digital system through the clock rails. Depending on the implementation, the E-R clock driver may or may not be on the same chip as the clock-powered logic. The clock phases that are generated by the clock driver synchronize the operation of the clock-powered logic as well as power the large-capacitance nodes through special latches, called E-R latches. E-R latches operate in synchrony with the clock phases, so their placement effects the timing and partitioning of logic functions into logic blocks. Placement of the E-R latches is determined not only by the location of the large capacitance nodes, but also by system-level factors such as circuit latencies and overall timing, e.g., pipelining.

Data representation is different between clock-powered and dc-powered signals. Nodes that are dc-powered are logically valid when their voltage levels are sufficiently close to the voltages supplied by the power rails, i.e.,  $V_{dd}$  and GND. Clock-powered signals are valid only when the clock phase is valid. The presence of a pulse that is coincident with a clock phase defines a logic value of one. The absence of a pulse defines a logic value of zero. When the clock phase is zero, the logical value of the clock-powered signal is undefined.

The co-existence of clock-powered and dc-powered nodes necessitates signal conversion from pulses to levels and vice versa. Levels are converted to pulses in the E-R latches, which receive dc-powered signals as inputs and pass clock pulses to the output. As discussed in detail later in this chapter, depending on the style of the logic blocks, either pulses are implicitly converted to levels, or, special pulse-to-level converters must be introduced between the E-R latches and the logic blocks.

The total average energy dissipation per cycle,  $E_{tot}$ , of clock-powered microsystems consists of two terms and is given by:

$$E_{tot} \sim \sum_i a_i \frac{R_i C_i}{T_s} C_i V_\phi^2 + \sum_j a_j C_j V_{dd}^2 \quad (21.4)$$

The first term models the clock-powered nodes that are adiabatically switched for  $T_s \gg R_i C_i$ . The second term models the dc-powered nodes that are conventionally switched. In Eq. (21.4),  $a_i$  and  $a_j$  denote the switching activity for clock- and dc-powered nodes, respectively;  $C_i$  and  $C_j$  denote the capacitance of clock- and dc-powered nodes, respectively;  $R_i$  is the effective resistance of the charge-transfer path between the clock driver and the clock-powered nodes;  $T_s$  is the transition time of the clock signal;  $V_\phi$  is the clock voltage swing; and  $V_{dd}$  the dc supply voltage.

The benefit of applying clock-powered logic can be readily evaluated from Eq. (21.4). Capacitance information can be extracted from layout, assuming the various parasitic and device capacitances have been accurately characterized. Activity data for the different nodes can be determined for specified input data sets from switch-level and circuit-level simulation. As shown later, in clock-powered microprocessors,

<sup>1</sup>Portions in sections 21.2, 21.4, 21.6 and subsection "Static Logic" reprinted, with permission, from [23] © 1999 IEEE.

a small fraction of circuit nodes that are clock powered accounts for most of the power dissipation if they were powered from a dc supply voltage.

Equation (21.4) also defines the absolute maximum degree to which adiabatic charging can be used to reduce dissipation. As the clock transition time approaches infinity, the first term of Eq. (21.4) approaches zero and the dissipation is solely determined by the second term.  $R_\phi$ , the effective resistance of the charge-transfer path, is the difficult parameter to quantify. It depends upon the circuit topology of the E-R latch as shown in detail in section 21.4.

### 21.3 Clock Driver

Two known circuit types can be used as clock drivers in a clock-powered system: *resonant* [3,17] and *stepwise* [8]. For the purposes of this text, only resonant drivers will be presented due to their superior energy efficiency.

A simple resonant clock driver can be built from an LRC circuit that generates sinusoidal pulses. Such a circuit can be formed with two nFETs ( $M_1$  and  $M_2$ ) and an inductor ( $L$ ) (Fig. 21.2). The capacitor  $C_\phi$  represents the clock load. The resistance of the clock line is assumed negligible compared to the on-resistance of  $M_1$ . Two nonadiabatically-switched control signals drive  $M_1$  and  $M_2$ . The circuit generates sinusoidal pulses if operated as follows. Assume that  $\phi$  is at 0 V, i.e.,  $C_\phi$  is discharged and that both  $M_1$  and  $M_2$  are off. Then  $M_1$  is turned on and  $M_1$ ,  $L$ , and  $C_\phi$  form an LRC circuit that produces a sinusoidal pulse with width  $2\pi(LC_\phi)^{1/2}$  and amplitude approximately  $2 \cdot V_{dc}$ .  $M_1$  should be turned off exactly at the end of the pulse. Then  $M_2$  is turned on and fully discharges  $\phi$ . Two such circuits can be synchronized to generate two nonoverlapping phases. If  $T_s$  is the pulse switching time, it can be shown [3] that the energy for switching  $\phi$  scales as  $T_s^{-1/2}$  instead of  $T_s^{-1}$  solely because  $M_1$  and  $M_2$  are controlled by nonadiabatically-switched signals.

The LRC clock driver can be further simplified by eliminating the series nFET  $M_1$  and using a single signal to control the pull-down nFET (Fig. 21.3). When the nFET is on, a current is built in the inductor while  $\phi$  is clamped at 0 V. When the nFET is turned off, the current flows to the load  $C_\phi$ , generating a sinusoidal pulse. The energy dissipation for switching  $C_\phi$  still scales as  $T_s^{-1/2}$  because the nFET is driven by a nonadiabatically-switched signal; however, two such circuits can combine as shown in Fig. 21.4 to form an all-resonant configuration [18] that generates two almost nonoverlapping clock phases (Fig. 21.5). The energy for switching the clock loads in the all-resonant configuration scales as  $T_s^{-1}$  since the control signals are adiabatically switched.

FIGURE 21.2 A simple LRC resonant clock driver ([18] © 1996 IEEE).

FIGURE 21.3 A single-phase resonant clock driver ([28] © 1997 IEEE).

FIGURE 21.4 An all-resonant, dual-rail LC oscillator used as a clock driver ([18] © 1996 IEEE).

FIGURE 21.5 A scope trace of the almost nonoverlapping, two-phase clock waveforms ([28] © 1997 IEEE).

The main advantage of resonant clock drivers is their high energy efficiency since, for all-resonant configurations, the energy dissipation for driving the clock loads can scale as the inverse of the switching time. Nevertheless, these all-resonant configurations pose design challenges when frequency stability is important. Their frequency and, therefore, the system frequency depends on their loads. For the all-resonant two-phase clock driver, two types of potential load imbalances occur: between the two phases and between different cycles for the same phase. First, loads should be approximately evenly distributed between the two phases. Otherwise, inductors with different inductance and/or two different supply voltages should be used so that  $\phi_1$  and  $\phi_2$  have the same width and amplitude. Second, for clock-powered microsystems, clock loads are data dependent. Therefore, the load may vary from cycle to cycle for the same phase, resulting in a data-dependent clock frequency. A simple solution for this problem is to use dual-rail clock-powered signaling, which ensures that half of clock-powered nodes switch per cycle. The drawback of such a clock-powered system is its high switching capacitance. For the purposes of this research, the all-resonant clock driver (Fig. 21.4) has been sufficient and highly energy efficient. Resonant clock drivers can also be designed with transmission lines [17] instead of inductors.

## 21.4 Energy-Recovery Latch

The E-R latch serves two purposes: to latch the input data, and, conditionally on the latched datum, to transfer charge from a clock line to a load capacitance  $C_L$  and back again. Consequently, the E-R latch consists of two stages: the *latch* and the *driver* (Fig. 21.6(a)). The latch-stage design is not important for clock-powered logic and can be chosen to meet other system requirements. Suitable latch designs are the 3-transistor dynamic latch consisting of a pass transistor and an inverter, and the doubled N-C<sup>2</sup>-MOS latch [19]. The driver stage is based on the bootstrapped clocked buffer (CB) [20] implemented in CMOS. The driver choice is discussed later in this section. The E-R latch operates from a two-phase, nonoverlapping clocking scheme (Fig. 21.6(b)): the input is latched on  $\phi_L$  and the output is driven during  $\phi_D$ . The two clock phases swing from 0 to voltage  $V_\phi$ . A symbol used to denote the clocked buffer part of the E-R latch is shown in Fig. 21.6(c).

**FIGURE 21.6** (a) E-R latch, (b) timing diagram when  $D_{in}$  is high, and (c) symbol that denotes a clocked buffer pulsed on  $\phi_D$ .

Without loss of generality, the latch-stage output  $\bar{D}_{inL}$  is assumed in negative polarity. The latch stage and the inverter  $I_1$  are powered from a dc supply with voltage  $V_{dd}$ . The gate of transistor  $M_1$  connects to a dc supply with voltage  $V_{iso}$ . This dc supply dissipates no power since it is connected only to pass-transistor gates.  $V_{iso}$  is equal to  $V_{dd} + V_{tE}$ , where  $V_{tE}$  is the nFET effective threshold voltage, so that the boot node  $bn$  can be charged close to the maximum possible voltage  $V_{dd}$ . During  $\phi_L$ ,  $D_{in}$  is stored on the gate capacitance of  $M_2$  (the boot node). If  $D_{in}$  is low, then the clamp transistor  $M_3$  holds the output to ground. If  $D_{in}$  is high (Fig. 21.6b), then  $bn$  charges to  $V_{dd}$  through the isolation transistor  $M_1$ . When the positive edge of  $\phi_D$  occurs, the voltage of  $bn$  bootstraps to well above  $V_\phi$  due to the gate-to-channel capacitance of  $M_2$ . Then the output charges to  $V_\phi$  from the clock line  $\phi_D$  through the bootstrap transistor  $M_2$ . Charge returns to the clock line through the same path at the end of  $\phi_D$ . The timing sketch of Fig. 21.6(b) indicates  $V_{dd}$  (i.e., the voltage that  $V_{bn}$  is charged to) as being less than  $V_\phi$ . Although this is possible and happens in certain cases, it is not necessary. Voltages  $V_{dd}$  and  $V_\phi$  can be decided based on the logic style and the system requirements.

The dc supply  $V_{iso}$  is introduced so that the transistor  $M_2$  is always actively driven. Phase  $\phi_L$  could be used instead of  $V_{iso}$  to drive the transistor  $M_1$  [21]. If this were the case, when  $\phi_D$  occurred and  $bn$  was at 0 V, the voltage of  $bn$  would bootstrap to above 0 V and short-circuit current would flow from  $\phi_D$  to ground through the transistors  $M_2$  and  $M_3$ .

The E-R latch is small in area. The size of  $M_1$  is made small to minimize the parasitic capacitance of node  $bn$ .  $M_3$  can also be small since it only clamps the output to ground to avoid coupling to the output when  $bn$  is 0 V. It does not discharge the load capacitance. On the other hand, the size of the device  $M_2$  is critical. Two criteria are used for sizing  $M_2$ . First, the ratio of the gate capacitance of  $M_2$  to the parasitic capacitance of the node  $bn$  should be large enough to allow the voltage of  $bn$  to bootstrap to at least  $V_\phi + V_{tE}$ . This criterion applies for small capacitance loads and/or slow systems. Second, the transistor  $M_2$  should be large enough to meet the system frequency and energy savings specifications. A detailed analytical model for obtaining the on-resistance  $R_b$  of the bootstrap transistor has been derived elsewhere [22,23]. This model can be used for sizing these transistors based on the load capacitance  $C_L$  and the desired  $R_b C_L / T_s$  ratio for a given switching time  $T_s$ .

The key feature of E-R latches for low power is that they pass clock power. Therefore, an energy-efficient charge-steering device is essential. In addition to a bootstrap transistor, other charge-steering topologies are a nonbootstrapped pass transistor and a transmission gate (T-gate). The pass transistor would require its gate to be overdriven, which would impose constraints on the allowable voltage levels. The pass-transistor gate would be powered from the dc supply  $V_{dd}$ , and  $V_{dd}$  would need to be at least  $V_\phi + V_{tE}$ . Otherwise the output would not be fully charged to  $V_\phi$ . The T-gate would fully charge the output, but it would require a pFET connected in parallel to the nFET; however, since pFETs carry less current per unit gate area than nFETs, the combined nFET and pFET width of the T-gate would be larger

than the width of an equal-resistance bootstrapped transistor. The larger gate capacitance of the charge-steering device translates directly into a higher, nonadiabatic, energy dissipated to control it.

The criterion for the charge-steering device is to minimize the dissipation by maximizing the energy that is recovered. The total dissipation required to operate the charge-steering device has two terms: one for the control charge and one for the controlled charge. For all the above CMOS charge-steering topologies, there exists an inverse dependency between the control energy and the loss in the switch. To reduce the total E-R latch dissipation, the charge-steering topology that experiences the smallest loss for a specified control energy should be selected. It was found [24] that bootstrapping is the most suitable charge-steering implementation in the CMOS technology. Effective bootstrapping makes the switch-transistor gate voltage rise high enough above the highest applied clock voltage to keep the channel conductance high, and consequently the instantaneous loss low, even for the maximum clock voltage. The output swing is thus fully restored to the clock amplitude.

## 21.5 Interfacing Clock-Powered Signals with CMOS Logic

This section shows how the E-R latch can be used in conjunction with the major CMOS logic styles (precharged, pass-transistor, and static logic) for the implementation of complete clock-powered microsystems. All three logic styles need to be modified so that they comply with the clock-powered approach requirements. First, logic should be operated from two nonoverlapping clock phases that are available only in positive polarity. To switch clock-powered nodes adiabatically, the two clock phases must have a switching time longer than the minimum obtainable from the process technology. Clock complements are not available, due to problems related to the efficiency of the clock driver. Second, clock-powered signals are pulses that need to be converted to levels. As we see next, this conversion happens inherently for precharged and pass-transistor logic, while pulse-to-level converters are required for static logic.

### Precharged Logic

Precharged logic works straightforwardly with clock-powered signals. These signals are valid during one clock phase and low during the other phase. Therefore, they can drive gates that are precharged during the other phase; however, precharging with pFETs is problematic for two reasons. First, the clock complements are not available. Second, the clock phases may have slow edges. Assume that the same clock phase  $\phi_1$  is used to precharge the gate through a pFET and power its inputs (Fig. 21.7a). The symbol “ $\wedge$ ” indicates clock-pulsed signals in conjunction with the driving clock phase. Precharged gates driven by clock-pulsed signals do not need protection nFETs in their pull-down stacks since the input signals are low during precharge. Without loss of generality, assume that both pFETs and nFETs have the same threshold voltage magnitude  $V_{th}$ . Then, when  $a_{in}$  is high, there will be a short-circuit current drawn while the clock phase transits from  $V_{dd} - V_{th}$  to  $V_{th}$ . This current may be significant due to the slow clock edges, since it scales linearly to the input switching time [25]. The short-circuit current interval is marked in

FIGURE 21.7 Precharging with (a) a pFET and (b) an nFET.

the timing diagram of Fig. 21.7(a). Also note that the point  $V_{dd} - V_{th}$  is chosen assuming that  $V_{dd}$  is higher than  $V_{\phi}$ , which may not be the case.

One solution to this problem is to set  $V_{dd}$  to  $2V_{th}$ , which would impose restrictions on the system's operating voltage, and hence on its maximum frequency. Another solution is to precharge with an nFET driven by the other phase (Fig. 21.7(b)). This would require  $V_{\phi}$  to swing between 0 V and  $V_{dd} + V_{th}$ ; otherwise, the inverter would experience a short-circuit current. A keeper pFET driven by  $a_{out}$  (shown with dashed lines in Fig. 21.7(b)) can restore the voltage level of the precharged gate if necessary. The latter solution is more attractive because, despite the restrictions between the supply voltage  $V_{dd}$  and the clock voltage swing  $V_{\phi}$ , it provides a wider range of operating points. Moreover, it dictates that the clock-powered nodes be in higher energy levels than the dc-powered nodes, but the effect is mitigated when dissipation is considered because energy is recovered from the high-energy, clock-powered nodes.

If  $V_{\phi}$  swings from 0 V to  $V_{dd} + V_{th}$ , then a latch-stage that can be used for the E-R latch is the 3-transistor dynamic latch (Fig. 21.8). If necessary, the dynamic node  $D_{inL}$  can be staticized with an inverter. Alternatively, a keeper pFET driven by  $\bar{D}_{inL}$  can restore the voltage at node  $D_{inL}$ .

Figure 21.9 shows how an E-R latch drives a precharged gate and how the output of the gate is stored in an E-R latch. The gate precharges on  $\phi_1$  and evaluates on  $\phi_2$ . Although for simplicity Fig. 21.9 shows a single gate, precharged gates can be arranged in domino style; the outputs of the final stage are stored in E-R latches. The precharged gates and the E-R latch inverters are powered from the same dc supply with voltage  $V_{dd}$ .

## Pass-Transistor Logic

The E-R latch design used with precharged logic (Fig. 21.8) can operate with pass-transistor logic as well (Fig. 21.10). As in precharged logic, the magnitude of clock voltage swing  $|V_{\phi}|$  is equal to  $V_{dd} + V_{th}$ . Pass-transistor gates are driven by clock-powered signals. Transistor chains can be driven either by clock-powered signals (i.e., signal  $w_o$  in Fig. 21.10) or by dc-powered signals. When transistor chains are driven by clock-powered signals, the output of the first transistor (signal  $u_i$  in Fig. 21.10) is a dc-level signal, due to the threshold voltage drop of the pass transistor. Therefore, dc-level signals are steered through transistor chains. The higher voltage swing of the clock-powered signals allows the dc-level signals to be passed at their full swing. Furthermore, some energy along the transistor-chain path can be recovered if the path is driven by a clock-powered signal; however, for typical pass-transistor gate configurations, HSPICE simulations indicate that most of the injected energy would be trapped in the path.

FIGURE 21.10 E-R latches used with pass-transistor logic ([28] © 1997 IEEE).

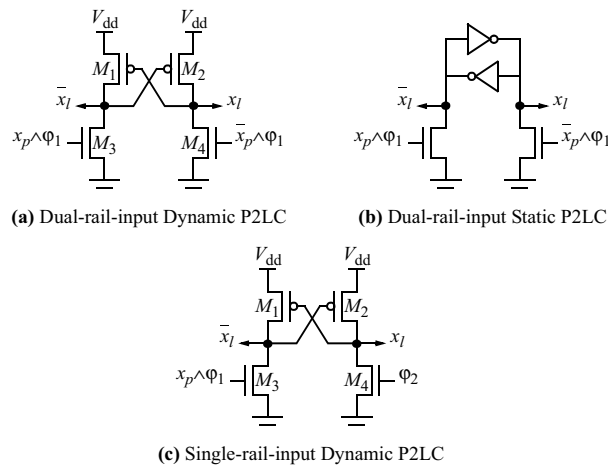

FIGURE 21.11 Various pulse-to-level converter designs.

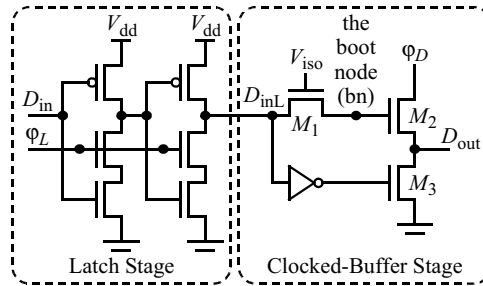

## Static Logic

As was previously discussed, clock-powered signals can be used directly with precharged and pass-transistor logic. First, no pulse-to-level conversion is required; second, the latch-stage of the E-R latch consists of a 3-transistor dynamic latch. The limitation for these logic styles is that the clock voltage swing  $V_\phi$  should be equal to  $V_{dd} + V_{th}$ . This subsection investigates how clock-powered signals can operate with static logic. The main problem with static logic is that clock-powered signals may have long transition times. Therefore, they cannot drive static gates directly, because these gates would experience short-circuit current even if  $V_\phi$  were larger than  $V_{dd}$ . To solve this problem, pulse-to-level converters (P2LC) must be introduced between the E-R latches and the static logic blocks. A similar static-dissipation problem arises for conventional static-logic systems with multiple supply voltages; the outputs of low-supply-voltage gates cannot drive high-supply-voltage gates directly, because short-circuit current would be drawn in the high-supply-voltage gates. To solve this problem, low-to-high voltage converter designs have been proposed [26]. These low-to-high voltage converters can be slightly modified to operate as pulse-to-level converters (Fig. 21.11).

The first design (Fig. 21.11(a)) is a dual-rail-input, dynamic P2LC (DD P2LC). On every  $\phi_1$ , exactly one of  $x_p$  or  $\bar{x}_p$  is pulsed, setting the outputs  $x_l$  or  $\bar{x}_l$  accordingly. Assume that  $\bar{x}_l$  is high and  $x_l$  is low. If  $\bar{x}_p$  is pulsed, then  $x_l$  and  $\bar{x}_l$  remain unchanged. If  $x_p$  is pulsed, then transistor  $M_3$  turns on, discharging  $\bar{x}_l$ . This turns on  $M_2$ , which charges  $x_l$  to  $V_{dd}$ , cutting off  $M_1$ . At the end of the operation, the outputs  $x_l$  and  $\bar{x}_l$  have been flipped. The second design (Fig. 21.11(b)) is a dual-rail-input, static P2LC (DS P2LC).

**TABLE 21.1** Characteristics of Pulse-to-Level Converters

Converter	Input Form	Output Timing	Description
DD P2LC	Dual rail	Valid on driving phase, stable on other phase	Nonrefreshed dynamic
DS P2LC	Dual rail	Valid on driving phase, stable on other phase	Nonrefreshed static
SD P2LC	Single rail	Valid on driving phase, reset on other phase	Refreshed dynamic

**FIGURE 21.12** Potential E-R latch for static logic.

The only difference between the two designs is that the nodes  $x_i$  and  $\bar{x}_i$  of the DS P2LC are staticized. This converter can be used in cases where its inputs  $x_p$  and  $\bar{x}_p$  are not pulsed on every cycle. The third design (Fig. 21.11(c)) is a single-rail-input, dynamic P2LC (SD P2LC). In this case,  $\phi_2$  acts similar to a precharge phase, resetting the SD P2LC to low state (i.e.,  $x_i$  is low and  $\bar{x}_i$  is high). On  $\phi_1$ , if  $x_p$  is high, the SD P2LC is set to high. Otherwise, it remains low. The SD P2LC converter does not need to be staticized because it is refreshed on every  $\phi_2$ . If the output of the SD P2LC is required to be stable on  $\phi_2$ , it should be latched on  $\phi_1$ . This is not necessary for DD and DS P2LC since their outputs would not change until after the next  $\phi_1$ .

Table 21.1 summarizes the characteristics of all three P2LC types. All three circuits inherently operate as level-to-level converters as well, which allows  $V_\phi$  and  $V_{dd}$  to be independent from each other. Consequently, these voltages can be selected based solely on system and process specifications.

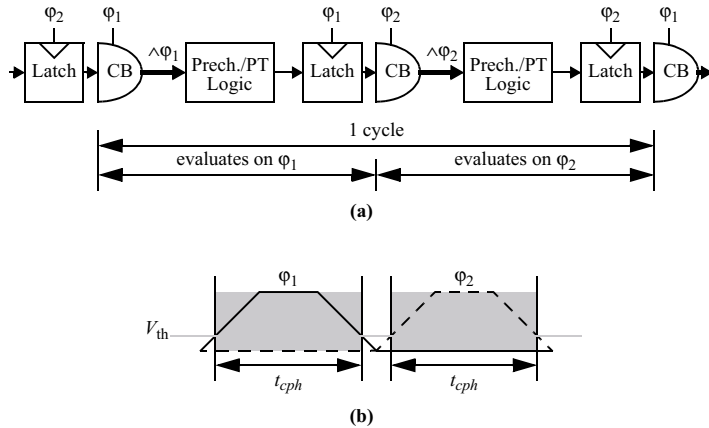

The 3-transistor dynamic latch, which is suitable for use with precharged and pass-transistor logic, requires that  $V_\phi$  depend on  $V_{dd}$  (i.e.,  $V_\phi$  must be at least equal to  $V_{dd} + V_{th}$ ). This dependency is not important with precharged and pass-transistor logic because it is primarily imposed by these logic styles; however, static logic allows  $V_\phi$  and  $V_{dd}$  to be independent from each other. Using the 3-transistor dynamic latch with static logic would impose unnecessary restrictions on the voltage levels of the clock phases and the dc supply.

Figure 21.12 shows a potential E-R latch design that is better suited to static logic. The latch stage consists of a 6-transistor dynamic latch [19]. During  $\phi_L$ , the input  $D_{in}$  gets propagated through the two latch gates. When  $\phi_L$  is low, propagation is blocked on either the first or the second latch gate, depending on the transition of  $D_{in}$ . The 6-transistor dynamic latch does not impose any voltage restrictions, although it is larger and slower than its 3-transistor counterpart. The clocked-buffer stage is slightly different from that of the E-R latch presented in Fig. 21.8 to accommodate the polarity change of its input.

## Clock-Powered Microsystems

This subsection shows how clock-powered microsystems can be built, investigates timing implications for the various styles of clock-powered logic, and discusses the energy dissipation of clock-powered microsystems.

**FIGURE 21.13** (a) Clock-powered precharged and pass-transistor logic arranged in pipeline stages and (b) net computation time within a cycle.

Precharged and pass-transistor clock-powered logic microsystems are built in similar ways. Each logic block evaluates within a phase (Fig. 21.13(a)). Logic block outputs are latched at the same phase. Logic blocks start computing when the input clock-powered signals are charged to  $V_{th}$ . In order for the output to be latched in time, computation should finish before the falling edge of the clock phase crosses the  $V_{th}$  voltage level (Fig. 21.13(b)). Therefore, precharged and pass-transistor logic blocks perform useful computations for less than half of the cycle time. However, precharged logic blocks are not totally idle the rest of the time, since these blocks are precharged during the phase in which they do not evaluate. Furthermore, clock-powered signals drive only the first gate level of precharged logic blocks. Precharged gates inside the logic blocks are arranged in domino form. During the evaluate phase, either the clock-powered block inputs are pulsed or they remain at 0 V, depending on their values. Therefore, once the computation is fired, these inputs are no longer needed. Thus, the energy return time of the pulsed inputs is totally hidden because of the nature of domino precharged logic. On the other hand, clock-powered signals that drive pass-transistor gates are required to remain valid throughout the entire computation time.

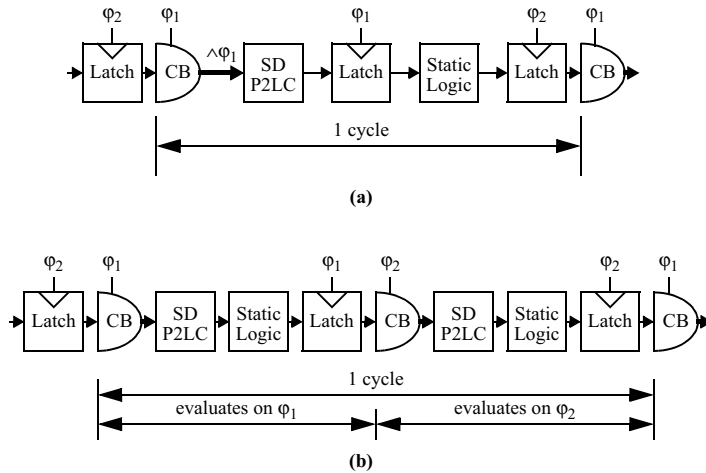

The way that static clock-powered logic is arranged into pipeline stages depends on the converters that are used. Both static and dynamic dual-rail-input converters (i.e., DD and DS P2LC) can drive static logic blocks directly. The inputs of these converters change once every cycle. Therefore, almost a full cycle is allotted for the static logic blocks to compute (Fig. 21.14(a)), disregarding the converter latency. Assuming that the inputs of the DS or DD converters are pulsed on  $\phi_1$ , then the output of the static logic block is latched at the end of  $\phi_2$  (Fig. 21.14(b)).

As illustrated earlier, single-rail-input dynamic P2LCs operate like precharged gates because they are reset during the phase that their input is not valid. Therefore, the outputs of SD P2LCs are valid only for one phase, i.e., the phase in which their inputs are valid. One way to arrange them in pipeline stages is to latch their outputs, and then use the latch outputs to drive static logic blocks (Fig. 21.15(a)). Essentially, the SD P2LC output is transmitted through the latch at the beginning of the phase and remains stable when the phase goes away. The net computation time is as shown in Fig. 21.14(b). Alternatively, SD P2LC outputs can drive static logic blocks directly and the outputs of the static logic blocks can be latched at the end of the phase (Fig. 21.15(b)). This requires logic blocks to be split into smaller pieces with half latency. Operation is similar to the precharged clock-powered logic, and the net computation time is as shown in Fig. 21.13(b). The energy return time is totally hidden for static clock-powered logic, since clock-powered signals are not needed when they have been converted to levels.

For low-power operation, the rise and fall times of the clock phases must be longer than the practically obtainable minimum transition times. The consequence of stretching the rise time is that, within a clock cycle, the logic will activate later than it would from a minimal-transition-time input signal. A consequence

**FIGURE 21.14** (a) Clock-powered static logic arranged in pipeline stages with DD/DS P2LC and (b) net computation time within a cycle.

**FIGURE 21.15** Clock-powered static logic arranged on pipeline stages with SD P2LC (a) for cycle- and (b) for phase-granularity computations.

of stretching the fall time is that the input cutoff voltage for the E-R latch will occur earlier in the clock phase. The net result is that for a fixed cycle time, the amount of computation that can be done during a cycle is decreased to reduce energy dissipation. For phase-granularity computations (i.e., mostly pre-charged and pass-transistor logic—Fig. 21.13(b)), the slow clock phase edges reduce the computation time four times within a cycle as opposed to twice per cycle for cycle-granularity computations (i.e., static logic—Fig. 21.14(b)). The benefit of phase-granularity computations is that more opportunities for energy recovery are available, since nodes can be clock-pulsed on both phases. This also results in balanced capacitance for both clock phases, which may be required for high-efficiency clock drivers; however, phase capacitance can be balanced for cycle-granularity computations if a phase-granularity computation is introduced in a sequence of pipeline stages. For example, assume a system with  $N$  pipeline stages. Also assume that a phase-granularity computation is introduced after the  $N/2$  pipeline stage while the rest of the stages are cycle-granularity computations. Then the clock-powered nodes of the first  $N/2$  stages would be driven by one phase, whereas the clock-powered nodes of the final  $N/2$  stages would be driven by the other phase.

## 21.6 Driver Comparison

In clock-powered logic, combinational logic blocks begin to switch as soon as clock-powered nodes are charged to  $V_{th}$ . For example, assume that a clock-powered signal drives a pulse-to-level converter. The converter starts operating as soon as the clock-powered signal voltage passes the threshold voltage  $V_{th}$ . Therefore, the switching time for charging the loads of clock-powered nodes to  $V_{\phi}$  is not as important as the delay for converting pulses to levels. With clock-powered logic, it is possible to overlap the time required for charge (and energy) recovery time with the computation time of the logic block. It is also possible, to a lesser degree, to overlap some of the charging time. The latter depends on many factors including clock and dc voltage levels, logic styles, and the CMOS technology.

In other E-R approaches (e.g., reversible logic [3,9], retractile cascade logic [27], and partially adiabatic logic families [10–16]), the signal switching time is important because the inputs of a logic block must be fully charged before the block starts operating. Furthermore, as in conventional CMOS circuits, voltage scaling is possible for clock-powered nodes at the expense of increased circuit latencies.

To investigate the effectiveness and the scalability of clock-powered logic, a simulation experiment was conducted to compare the driver stage of the E-R latch, i.e., the clocked buffer to a conventional driver. The two circuits were evaluated for energy versus delay and energy-delay product (EDP) versus voltage scaling.

### Experimental Setup

The goal of the experiment was to compare the clock-powered approach for driving high-capacitance nodes with a conventional, low-power approach. Because it is impractical to compare clock-powered logic against all low-power conventional techniques, a dual-supply-voltage approach in which high-capacitance nodes are charged to a lower voltage  $V_{ddL}$  than the rest of the nodes was chosen. The dual-supply-voltage approach is similar to the clock-powered approach in that it attempts to reduce power dissipation in the high-capacitance nodes. Furthermore, like the clock-powered approach, the dual-supply-voltage approach requires that low-supply-voltage signals be converted to high-supply-voltage signals before they are fed to high-supply-voltage gates. Otherwise, these gates would suffer from short-circuit current, or may not work at all, depending on the two supply voltage levels, the logic style, and the technology process.

The dual-rail-input, static pulse-to-level converter (DS P2LC—Fig. 21.11(b)) is a converter circuit that operates simply with both approaches (Fig. 21.16). Two 150 fF capacitive loads were added to the converter

**FIGURE 21.16** Clocked buffer (a) and conventional drivers (b) connected to 150 fF capacitance loads and a DD P2LC.

inputs  $x_p$  and  $\bar{x}_p$  to model the capacitance of the interconnect. Two inverters were added to the converter outputs  $x_l$  and  $\bar{x}_l$  to model the driving load of the converter.

A single-rail-input, dual-rail-output clocked buffer (Fig. 21.17(a)) was used for the clock-powered approach. This clocked buffer was derived from the single-rail-output buffer by duplicating the bootstrap, the isolation, and the clamp transistors. The two inverters of the clocked buffer, as well as the converter and its output inverters, were powered from the same supply voltage  $V_{dd}$ . The clock phase  $\phi_D$  swung to a voltage  $V_\phi$  (Fig. 21.17(a)). The input  $D_{in}$  of the clocked buffer swung from 0 to  $V_{dd}$ .

For the dual-supply-voltage approach, two drivers, powered from the low-supply-voltage  $V_{ddL}$ , drove the converter (Fig. 21.16(b)). The converter and its output inverters were powered from the same supply voltage  $V_{dd}$ . The inputs  $D_{in}$  and  $\bar{D}_{in}$  of the two drivers swung from 0 to  $V_{dd}$ . Two different driver designs were used in the experiment. One was a regular inverter (Fig. 21.17(b)). The nFET of the inverter had the same width with the bootstrap transistors of the CB (Fig. 21.17(a)) and the pFET was set by the mobility ratio in the CMOS technology. The regular inverter becomes very slow as  $V_{ddL}$  is scaled down. This is because the gate-to-source voltage of the pull-up transistor is equal to  $V_{ddL}$  when the input is at 0 V. The operation of the pull-down nFET is not affected by  $V_{ddL}$  scaling because when it is on, its gate-to-source voltage is equal to  $V_{dd}$ , i.e., the voltage that  $D_{in}$  swings to. To mitigate this effect, a second driver design with both an nFET and a pFET as pull-ups was used (Fig. 21.17(c)). As  $V_{ddL}$  decreases, the nFET pull-up can fully charge the output, given the significant voltage difference between  $V_{ddL}$  and  $V_{dd}$ .

## Simulation Results

All circuits were laid out in Magic using the 0.5- $\mu\text{m}$  Hewlett-Packard CMOS14B process parameters. The netlists extracted from the layout were simulated with HSPICE using the level-39 MOSFET models. The 150 fF load capacitances were added in the netlist as shown in Fig. 21.16. The delay to switch the DS P2LC output  $x_l$  from zero to one and the required energy for switching the DS P2LC inputs (i.e., nodes  $x_p$  and  $\bar{x}_p$ ) were simulated for the clock-powered and dual-supply-voltage cases. For the clock-powered case, it was assumed that all return energy was recovered.

The supply voltage  $V_{dd}$  was held constant at 3.3 V for all the simulations. The isolation voltage  $V_{iso}$  of the clocked buffer was set to 4.5 V. This was found to be a near-optimum point through HSPICE simulations. If the isolation voltage is too low, the boot node will not charge to the maximum possible voltage. If the isolation voltage is too high, then during bootstrapping, the boot node voltage will reach a point at which the isolation transistor turns on and charge flows backward from the boot node, thus diminishing the bootstrapping effect.

FIGURE 21.18 HSPICE waveforms for clock-powered approach when  $V_\phi$  is 2.4 V.

FIGURE 21.19 Energy vs. delay for the driver experiment. For comparison purposes, it should be noted that the delay of a minimum size inverter (nFET width  $0.7\ \mu\text{m}$ , pFET width  $2.2\ \mu\text{m}$ ) was recorded at 150 ps by simulating a 15-stage ring oscillator in HSPICE (supply voltage 3.3 V).

The clock voltage swing,  $V_\phi$ , of the clock-powered logic, was varied from 1.1 to 3.3 V. Specifically, simulations were performed for the following clock voltage swings: 1.1, 1.2, 1.5, 1.8, 2.1, 2.4, 2.7, 3.0, and 3.3 V. Switching time  $T_s$  was varied from nearly 0 to 1 ns (0.001, 0.25, 0.50, and 1.0 ns). For all simulations the phase width  $T_w$  was set to 2.5 ns, whereas the phase high time  $T_h$  was equal to  $T_w - 2T_s$  (see Fig. 21.16(a)). The delay was recorded from the point where the phase started switching until the output  $x_l$  reached the 50% point (e.g., 1.65 V in Fig. 21.18). If the delays were evaluated from when the phase reached its 50% point, the clock-powered approach would be allowed a longer start time than the conventional case. To eliminate this advantage, the delay was evaluated as described previously (see Fig. 21.18).  $V_{\text{ddl}}$  was varied identically to  $V_\phi$  for the conventional case. The switching time of the inputs  $D_{\text{in}}$  and  $\bar{D}_{\text{in}}$  was 1 ps. Delay was measured from the  $D_{\text{in}}$  50% point to the  $x_l$  50% point (i.e., 1.65 V).

The energy versus delay results (Fig. 21.19) show that the delay of the inverter increases significantly as  $V_{\text{ddl}}$  is reduced. At 3.3 V, the delay is approximately 0.7 ns, whereas at 1.1 V, the delay is nearly 3.6 ns (not shown in Fig. 21.19). The conventional driver with the two pull-ups (Fig. 21.17(c)) has a performance

FIGURE 21.20 Energy-delay product (EDP) vs. driver operating voltage for the driver experiment.

similar to that of the clocked buffer when the clock transition time  $T_s$  is 1 ps. The nearly zero transition time is equivalent to nonadiabatically switching nodes  $x_p$  and  $\bar{x}_p$ . The performance of the clocked buffer indicates better scalability than conventional drivers. For a given transition time, delay can be traded efficiently for energy by reducing the clock voltage swing. When the point is reached where voltage scaling is no longer efficient, i.e., delay increases faster than energy decreases, then it is better to increase the transition time. For instance, when  $T_s$  is 0.25 ns and  $V_\phi$  is 1.2 V, the energy dissipated is 91 fJ and the delay is 1.08 ns. If energy dissipation were to be reduced, it would be more energy efficient to increase the switching time to 0.50 ns rather than to scale the clock voltage swing to 1.1 V. The former would result in 54 fJ dissipation and 1.28 ns delay, whereas the latter would result in 76 fJ dissipation and 1.26 ns delay.

The pulse-to-level converter reaches its limits as the voltage swing of its inputs  $x_p$  and  $\bar{x}_p$  approaches  $V_{th}$ . For all cases, the converter would not switch during the allotted 5 ns cycle time when the driver operating voltage ( $V_\phi$  for the CB and  $V_{ddl}$  for the conventional drivers) was 1.0 V. This is a limiting factor for conventional approaches. Energy cannot be reduced any further because the circuit would not work at lower voltages; however, energy can be reduced for the clocked-power approach simply by stretching out the switching time. The better scalability is a result of its energy dependency on both clock voltage swing and clock switching time.

The energy-delay product (EDP) versus driver operating voltage graph (Fig. 21.20) also indicates the scalability of the clock-powered approach. Moreover, the clocked buffer exhibits better EDP than the conventional drivers for all switching times. The point where energy is not efficiently traded for performance is clearly shown for the inverter to be around 1.5 V.

Some other important issues related to the nature of the two approaches should be pointed out. First, for the clock-powered approach, both  $x_p$  and  $\bar{x}_p$  are at 0 V before the CB passes a clock pulse to one of them. On the other hand, for the conventional approach, both  $x_p$  and  $\bar{x}_p$  switch simultaneously. This could potentially slow down the converter, since for a short time both pull-down devices would be on.

Second, in the clock-powered approach, the dual-rail-output CB used for this experiment has a switching activity of 1, meaning that one of its outputs is pulsed every cycle even if its input remains the same. CB designs with reduced output switching activity can be designed at the expense of increasing their complexity [22]. Nevertheless, conventional driver outputs switch only if their inputs change. Therefore, at a system level, energy dissipation would depend on the input switching activity factor. For instance, if inputs switch every other cycle, the conventional driver's average energy dissipation would be halved.

Third, although the internal dissipation of the clocked buffer and the conventional drivers was not presented, the conventional drivers have higher internal dissipation due to the wide pFETs [22]. Furthermore, the short switching time of the conventional driver inputs excluded short-circuit current. Typically, the conventional drivers would have some dissipation due to short-circuit current [25] for supply voltage  $V_{ddl}$  higher than  $2V_{th}$  (assuming that nFETs and pFETs have the same threshold voltage  $V_{th}$ ).

# 21.7 Clock-Powered Microprocessor Design

General-purpose microprocessors represent a good application target for clock-powered logic for two reasons: First, they contain a mixture of different circuit types (i.e., function units, random logic, and register file). Second, high-capacitance nodes are a small percentage of the total node count and are easily identifiable (e.g., control signals, register file address, word, and bit lines, buses between function units, etc.). An example of a simple processor microarchitecture that shows potential clock-powered nodes is shown in Fig. 21.21. After identifying the high-capacitance nodes, it is decided on a case-by-case basis, which ones could be clock-powered. Factors to consider for this decision are system-level and timing implications, and associated overhead [22].

Two clock-powered microprocessors were successfully implemented: AC-1 [28] and MD1 [29]. In this section, first both these microprocessors are described followed by a presentation of their lab results. Finally, their performance is compared with an equivalent conventional implementation of the same processor architecture through circuit simulations.

## AC-1 Versus MD1

AC-1 and MD1 are extensively described in [28] and [29], respectively. The purpose of this section is to provide a brief description of each one and a summary of their comparison. As we see next, although both processors are based on similar instruction set architectures (ISAs), their implementations are radically different in terms of circuit style and physical design.

Both processors implement a RISC-type, 16-bit, 2-operand, 40-instruction architecture [30]. These instructions include arithmetic and logic operations that require an adder, a shifter, a logic unit, and a compare unit. In addition to the general-purpose instructions, MD1 supports another 20 microdisplay extension (MDX) instructions. These latter instructions operate on bytes that are packed in 16-bit words. The available function units were modified to support them along with general-purpose instructions. AC-1 and MD1 have similar five-stage pipelines.

Despite the fact that both AC-1 and MD1 are clock-powered CMOS microprocessors, they are based on two different design approaches. AC-1 is implemented with dynamic logic, i.e., precharged (Fig. 21.9) and pass-transistor logic (Fig. 21.10). As a result, clock phases were running a threshold voltage above the core supply voltage  $V_{dd}$ . Logic blocks were arranged in pipeline stages as shown in Fig. 21.13. Consequently, the available computation time was shortened by all four slow edges within a cycle. AC-1 was a full-custom layout implemented in the Hewlett-Packard CMOS14B process, which is a 0.5- $\mu\text{m}$ , 3-metal-layer,

3.3-V, *n*-well CMOS process. The core size is 2.63 mm by 2.63 mm. It contains 12.7 k transistors. The chip was packaged in a 108-pin PGA package.

Significant design effort was dedicated to implementing the clock driver and clock distribution network. AC-1 contains two clock drivers integrated together—a resonant clock driver like the one described previously (Fig. 21.4) and a conventional NOR-based, two-phase generator. The AC-1 clock circuitry (Fig. 21.22) was mostly integrated on-chip. Only the inductors for the resonant driver were externally attached. It is possible to enable either clock driver with an external control input. The conventional clock driver is powered from a separate dc supply ( $V_{clk}$ ) for measurement purposes. Also, the voltage swing of the clock phases must be higher than the core dc supply. The clock phases are distributed inside the chip through a clock grid. The calculated resistance of the clock grid is less than  $4\Omega$ . Each of the two large transistors of the resonant clock driver was partitioned in 306 small transistors that were connected in parallel throughout the clock grid. To minimize clock skew, the conventional clock driver was placed in the center of the grid. The extracted clock capacitance is 61 pF evenly distributed between the two phases. Approximately 20% of the clock capacitance is attributed to the clock grid.

The power measurements are plotted in Figs. 21.23 and 21.24. In resonant mode, the frequency was varied from 35.5 to 58.8 MHz by connecting external inductors that ranged from 290 nH down to 99 nH. The voltages for increasing frequencies ranged from 1.8 to 2.5 V for  $V_{dd}$  (the core supply) and 1.0 to 1.4 V for  $V_{dc}$  (the resonant clock driver supply), which corresponded to a resonant-clock voltage swing ( $V_{\phi}$ ) from 2.9 to 4.0 V. The combined power dissipation ranged from 5.7 to 26.2 mW. Under conventional drive, the external clock frequency was adjusted from 35 to 54 MHz and the power measurement

**FIGURE 21.24** Lab measurements of AC-1 clock and core energy dissipation (mW/MHz) per clock cycle as function of frequency.

procedure was repeated. The voltages for increasing frequencies ranged from 2.5 to 3.3 V for the supply voltage of the conventional clock driver ( $V_{\text{clk}}$ ) and from 1.9 to 2.6 V for  $V_{\text{dd}}$ . The combined power dissipation ranged from 26.7 to 85.3 mW. The results show that in resonant mode, the dissipation is a factor of four to five less than in conventional mode. The clock power is approximately 90% of the total power under conventional drive and 60–70% under resonant drive. The core supply ( $V_{\text{dd}}$ ) dissipation is about the same for both resonant and conventional modes.

The AC-1 results indicated two drawbacks on the dynamic-logic approach that was employed. First, the clock voltage swing was dependent on the core dc supply. Specifically, the clock voltage swing was a threshold voltage higher than the supply voltage  $V_{\text{dd}}$ . This made AC-1 a low-energy processor only when operated on energy-recovery mode, i.e., the energy savings were attributed mostly to the high-efficiency resonant clock driver. Second, the computation time was penalized for all slow clock edges within a cycle. These issues were addressed with MD1, the second generation clock-powered microprocessor. The key difference compared to AC-1 is that static logic was used instead of dynamic. As was discussed previously, with static logic and explicit pulse-to-level conversion, the clock voltage swing and core dc supply are independent from each other. Furthermore, it is possible to build pipeline stages that are slowed down by the slow clock edges twice per cycle instead of four times. Two options were available: (i) to use dual-rail pulse-to-level converters and arrange pipeline stages as shown in Fig. 21.14, or (ii) to use single-rail pulse-to-level converters and arrange pipeline stages as shown in Fig. 21.15a. The latter was preferred because it considerably reduces bus wiring and switching activity of clock-powered nodes. In dual-rail signaling of clock-powered nodes, one node is pulsed every cycle regardless if the datum is a zero or a one. To further reduce the switching activity of clock-powered nodes, two other versions of clock buffers with a conditional enable signal were also used (Fig. 21.25). The output can either be clamped to ground or left floating.

The physical design approach for MD1 was different than AC-1. Individual cells were custom-made layouts. For larger blocks, a place-and-route CAD tool was used. The control unit was synthesized with standard cells from a Verilog description. MD1 was implemented in the same 0.5- $\mu\text{m}$ , 3-metal-layer, 3.3-V,  $n$ -well CMOS process, but only two metal layers were available for routing. The top-level metal was reserved to be used as a ground shield to improve noise immunity. This was imposed by the MD1 application as a graphic processor closely placed to a microdisplay. The core size is 2.4 mm by 2.3 mm. It contains 28 k transistors. The chip was packaged in a 108-pin PGA package.

MD1 was tested with an external resonant clock driver for 8.5 and 15.8 MHz. The core dc supply voltage was set to 1.5 V. At 8.5 MHz, the dissipation of the core dc supply was 480  $\mu\text{W}$  and the dissipation of the resonance clock driver was 300  $\mu\text{W}$ . At 15.8 MHz, the dissipation of the core dc supply was 900  $\mu\text{W}$  and the dissipation of the resonant clock driver was 2.0 mW. PowerMill simulations indicated that the

clock-powered nodes accounted for 80% of the total dissipation when energy-recovery was disabled. Table 21.2 summarizes the characteristics for both AC-1 and MD1.

## Comparison Study

To compare the effectiveness of clock-powered logic against conventional CMOS, an equivalent fully dissipative microprocessor, DC1, was implemented. DC1 shares the same instruction set with AC-1, i.e., it does not include the MDX instructions. DC1 was implemented following the MD1 design flow for the same  $0.5\ \mu\text{m}$  CMOS process. All the three metal layers were available for routing. DC1 uses the same pipeline timing with MD1. Circuit-wise, DC1 is based on static CMOS as is MD1. The main difference compared to MD1 is that clocked buffers were replaced with regular drivers and latches were replaced with sense-amp, edge-triggered flip-flops [31]. DC1 uses a single-phase clock, which was distributed automatically by the place and route CAD tool following an H-tree. Clock is gated away from unused blocks. The DC1 core size is  $1.8\ \text{mm} \times 1.9\ \text{mm}$ . The core contains 21 k transistors.

The three processor cores were compared through PowerMill simulations since DC1 was not fabricated. All three SPICE netlists were extracted from physical layout using the same CAD tool and extraction rules. It was not possible to simulate the clock-powered processors operating in energy-recovery (i.e., resonant) mode due to limitations of the simulation software. Instead both of them were simulated operating in conventional mode. For AC-1, the conventional clock driver was used to generate the two

**FIGURE 21.26** Energy per cycle vs. frequency simulation results for all three processors (data combined from [28] © 1997 IEEE and [29] © 2000 IEEE).

clock phases. For MD1, conventional buffers were used to drive the two clock phases. These buffers were powered from a separate dc supply, so that clock power was recorded separately than the core power. For both AC-1 and MD1, the operating power under resonant mode was projected by dividing the clock power under conventional mode by 6.5. This factor indicates the efficiency of the all-resonant clock driver and was derived from laboratory measurements.

The simulation results are shown in Fig. 21.26. For DC1, the operating frequency ranged from 20 MHz at 1.5 V to 143 MHz at 3.3 V. Power dissipation ranged from 2.7 mW (at 20 MHz) to 100 mW (at 143 MHz). For AC-1, the top operating frequency was 74 MHz. For increasing frequency, clock voltage ranged from 2.4 to 3.3 V and core voltage ranged from 1.8 to 2.6 V. As discussed earlier, the AC-1 logic style requires that the clock voltage swing be a threshold voltage higher than the core voltage. Power dissipation under conventional mode was 22.3 mW at 33.3 MHz and 95.1 mW at 74 MHz. The projected power dissipation under resonant mode is 4.7 and 21.5 mW, respectively. For MD1, the top frequency was 110 MHz. For all operating points, clock and core voltages were maintained at the same level ranging from 1.4 V at 10 MHz to 2.7 V at 110 MHz. Power dissipation was 2.1 mW at 10 MHz and 108 mW at 110 MHz. The power dissipation in resonant mode would be 850  $\mu$ W and 34 mW, respectively.

Simulation results show that MD1 is a more efficient design than AC-1 in terms of power dissipation and operating frequency especially under conventional mode. The significantly higher power dissipation of AC-1 under conventional mode is attributed to the higher clock voltage swing. Therefore, applying energy recovery has a greater effect on AC-1 than on MD1 since clock power is a larger portion of the total power for AC-1 when both processors operate in conventional mode. For MD1 under conventional mode, the clock-powered nodes (including the two clock phases) account for 80% of the total power dissipation. Clock-powered nodes are about 5% of the total nodes. Both AC-1 and MD1 would dissipate less power than DC1 when they operate under resonant mode. Specifically, the projected MD1 dissipation under resonant mode would be about 40% less than the dissipation of DC1.

## 21.8 Conclusions

In this chapter, clock-powered logic was discussed as a low-overhead, node-selective adiabatic style for low-power CMOS computing. The merit of clock-powered logic is that it combines the low-overhead of standard CMOS for driving low-capacitance nodes and the superior energy versus delay scalability of adiabatic charging for high-capacitance nodes. All the components of a clock-powered microsystem were presented in detail. Clock-powered logic is more effective for applications in which a small percentage of nodes accounts for most of the dynamic power dissipation (e.g., processors, memory structures [32], etc.).

Two generations of clock-powered microprocessors were presented in this article and compared against an equivalent standard CMOS design. For both processors, the results indicated that a small percentage of nodes (i.e., 5–10%) contributed most of the dynamic power dissipation (i.e., 80–90%) when operated in conventional mode. Compared to the standard CMOS design, the improved second-generation clock-powered microprocessor would dissipate approximately 40% less energy per cycle, assuming 85% efficiency of the clock driver.

DC1 is powered from a single supply voltage. Typically, microprocessors contain a few circuit critical paths. If such a system is powered from a single supply voltage, voltage scaling cannot provide a near-optimum dissipation versus speed trade-off, because the voltage level is determined by the few critical paths. The noncritical paths would switch faster than they absolutely need to. If a second dc supply voltage was used to power the high-capacitance nodes in conjunction with low-voltage-swing drivers [33], the DC1 dissipation would be decreased at the expense of reducing its clock frequency; however, clock-powered logic is inherently a multiple-supply-voltage system. As the driver experiment showed in section 21.6, energy dissipation for clock-powered nodes scales better than a dual-supply-voltage approach, since both the clock voltage swing and the switching time can be scaled. Another low-power approach is to dynamically adjust the system dc supply voltage and clock frequency based on performance demands [34]. Such a system resembles clock-powered logic. Voltage is dynamically varied to different constant dc levels, whereas in clock-powered logic, the supply voltage itself is statically time-varying, i.e., every cycle, it switches between 0 and  $V_{\phi}$ .

Clock-powered logic is a low-power approach that does not rely solely on low-voltage operation. Therefore, it can be applied in CMOS processes without the need of low-threshold transistors that result in excessive leakage dissipation. Furthermore, the availability of high-energy signaling in clock-powered logic offers better noise immunity compared to low-voltage approaches.

To summarize, three conditions must be satisfied for applying clock-powered logic to a low-power system. First, the system should contain a small percentage of high-capacitance nodes with moderate to high switching activity. Second, the system should contain a few critical and many time-relaxed circuit paths. Third, the switching time of clock-powered nodes should be longer than the minimum obtainable switching time from the technology process. Controlling the speed of the energy transport to clock-powered nodes results in less energy dissipation. If the longer switching time of clock-powered nodes is made to be an explicit system-design consideration, conventional switching techniques can be used for nodes in critical paths while the other high-capacitance nodes are clock-powered.

### 22.1 Introduction

---

Advances in VLSI technology now allow us to build systems-on-chips (SoCs), also known as systems-on-silicon (SoS). SoCs are complex at all levels of abstraction; they contain hundreds of millions of transistors; they also provide sophisticated functionality, unlike earlier generations of commodity memory parts. As a result, SoCs present a major productivity challenge.

One solution to the SoC productivity problem is to use embedded computers.<sup>1</sup> An embedded computer is a programmable processor that is a component in a larger system that is not a general-purpose computer. Embedded computers help tame design complexity by separating (at least to some degree) hardware and software design concerns. A processor can be used as a pre-designed component—known as intellectual property (IP)—that operates at a known speed and power consumption. The software required to implement the desired functionality can be designed somewhat separately.

In exchange for separating hardware and software design, some elements traditionally found in hardware design must be transferred to software design. Software designers have traditionally concentrated on functionality while hardware designers have worried about critical delay paths, power consumption, and area. Embedded software designers must worry about real-time deadlines, power consumption, and program and data size. As a result, embedded SoC design disciplines require a blending of hardware and software skills.

This chapter considers the characteristics of SoCs built from embedded processors. The next section surveys the types of requirements that are generally demanded from embedded SoCs. Section 22.3 surveys the characteristics of components used to build embedded systems. Section 22.4 introduces the types of architectures used in embedded systems. Section 22.5 reviews design methodologies for embedded SoCs.

## 22.2 Requirements on Embedded SoCs

---

A digital system typically uses embedded processors to meet a combination of performance, complexity, and possibly design time goals. If the system's behavior is very regular and easy to specify as hardware, it may not be necessary to use embedded software. An embedded processor becomes more attractive when the behavior is too complex to be easily captured in hardwired logic.

Using embedded processors may reduce design time by allowing the design to be separated into distinct software and hardware units. In many cases, the CPU will be predesigned; even if the CPU and associated hardware is being designed for the project, many aspects of the hardware design can be performed separately from the software design. (Experience with embedded system designs does show, however, that the hardware and software designs are intertwined and that embedded software is prone to some of the same scheduling problems as mainframe software projects.)

But even if embedded processors seem attractive by reducing much of the design to “just programming,” it must be remembered that embedded software design is much more challenging than typical applications programming for workstations or PCs. Embedded software must be designed to meet not just functional requirements—the software's input and output behavior—but also stringent nonfunctional requirements. Those nonfunctional requirements include:

- *Performance*—Although all programmers are interested in speed of execution, performance is measured much more precisely in the typical embedded system. Many embedded systems must meet real-time deadlines. The deadline is measured between two points in the software: if the program completely executes from the starting point to the end point by the deadline, the system malfunctions.
- *Energy/power*—Traditional programmers don't worry about power or energy consumption. However, energy and power are important to most embedded systems. Energy consumption is of course important in battery-operated systems, but the heat generated as a result of power consumption is increasingly important to wall-powered systems.
- *Size*—The amount of memory required by the embedded software determines the amount of memory required by the embedded system. Memory is often one of the major cost components of an embedded system.

Embedded software design resembles hardware design in its emphasis on nonfunctional requirements such as performance and power. The challenge in embedded SoC design is to take advantage of the best aspects of both hardware and software components to quickly build a cost-effective system.

### CPUs

As shown in Fig. 22.1, a CPU is a programmable instruction set processor. Instructions are kept in a separate memory—a program counter (PC) that points to the current instruction. This definition does not consider reconfigurable logic to be a programmable computer, because it does not have a separate instruction memory and a PC. Reconfigurable logic can be used to implement sequential machines, and

FIGURE 22.1 A CPU and memory.

so a CPU could be built in reconfigurable logic. But the separation of CPU logic and memory is an important abstraction for program design.

An embedded processor is judged by several characteristics:

- *Performance*—The overall speed of execution may be important in some systems, but in many cases we particularly care about the CPU's performance on critical sections of code.
- *Energy and power*—Processors provide different mechanisms to manage power consumption.
- *Area*—The area of the processor contributes to the total implementation cost of the SoC. The area of the memory required to store the program also contributes to implementation cost.

These characteristics are judged relative to the embedded software they are expected to run. A processor may exhibit very different performance or energy consumption on different applications.

RISC processors are commonly used in embedded computing. ARM<sup>2</sup> and MIPS<sup>3</sup> processors are examples of RISC processors that are widely used in embedded systems. A RISC CPU uses a pipeline to increase CPU performance. Many RISC instructions take the same amount of time to execute, simplifying performance analysis. However, many RISC architectures do have exceptions to this rule. An example is the multiple-register feature of the ARM processor: an instruction can load or store a set of registers, for which the instruction takes one cycle per instruction.

Most CPUs used in PCs and workstations today are superscalar processors. A superscalar processor builds on RISC techniques by adding logic that examines the instruction stream and determines, based on what CPU resources are needed, when several instructions can be executed in parallel. Superscalar scheduling logic adds quite a bit of area to the CPU in order to check all the possible conflicts between combinations of instructions; the size of a superscalar scheduler grows as  $n^2$ , where  $n$  is the number of instructions that are under consideration for scheduling. Many embedded systems, and in particular SoCs, do not use superscalar processors and instead stick with RISC processors. Embedded system designers tend to use other techniques, such as instruction-set optimization caches, to improve performance. Because SoC designers are concerned with overall system performance, not just CPU performance, and because they have a better idea of the types of software run on their hardware, they can tackle performance problems in a variety of ways that may use the available silicon area more cost-effectively.

Some embedded processors are known as digital signal processors (DSPs). The term DSP was originally used to mean one of two things: either a CPU with a Harvard architecture that provided separate memories for programs and data; or a CPU with a multiply-accumulate unit to efficiently implement digital filtering operations. Today, the meaning of the term has blurred somewhat. For instance, version 9 of the ARM architecture is a Harvard architecture to better support digital signal processing. Modern usage applies the term DSP to almost any processor that can be used to efficiently implement signal processing algorithms.

The application-specific integrated processor (ASIP)<sup>4</sup> is one approach to improving the performance of RISC processors for embedded application. An ASIP's instruction set is designed to match the requirements of the application software it will run. On the one hand, special-purpose function units and instructions to control them may be added to speed up certain operations. On the other hand, function units, registers, and busses may be eliminated to reduce the CPU's cost if they do not provide enough benefit for the application at hand. The ASIP may be designed manually or automatically based on profiling information. One advantage of generating the ASIP automatically is that the same information can be used to generate the processor's programming environment: a compiler, assembler, and debugger are necessary to make the ASIP useful building blocks.

Another increasingly popular architecture for embedded computing is very long instruction word (VLIW). A VLIW machine can execute several instructions simultaneously but, unlike a superscalar processor, relies on the compiler to schedule parallel instructions at compilation time. A pure VLIW machine uses slots in the long, fixed-length instruction word to control the CPU's function units, with NOPs used to indicate slots that cannot be used for useful work by the compiler. Modern VLIW machines, such as the TI C6000<sup>5</sup> and the Motorola/Agere StarCore,<sup>6</sup> group single-operation instructions into

execution packets; the packet's length can vary depending on the number of instructions that the compiler was able to schedule for simultaneous operation. VLIW machines provide instruction-level parallelism with a much smaller CPU than is possible in a superscalar system; however, the compiler must be able to extract parallelism at compilation time to be able to use the CPU's resources. Signal processing applications often have parallel operations that can be exploited at compilation time. For example, a parallel set of filter banks runs the same code on different data; the operations for each channel can be scheduled together in the VLIW instruction group.

## Interconnect

Embedded SoCs may connect several CPUs, on-chip memories, and devices on a single chip. High-performance interconnect systems are required to meet the system's performance demands. The interconnection systems must also comply with standards so that existing components may be connected to them.

Busses are still the dominant interconnection scheme for embedded SoCs. Although richer interconnection schemes could be used on-chip, where they are not limited by pinout as in board-level systems, many existing architectures are still memory-limited and not interconnect-limited. However, future generations of embedded SoCs may need more sophisticated interconnection schemes.

A bus provides a protocol for communication between components. It also defines a memory space and the uses of various addresses in that memory space, for example, the address range assigned to a device connected to the bus. Busses for SoCs may be designed for high-performance or low-cost operation. A high-performance bus uses a combination of techniques—advanced circuits, additional bus lines, efficient protocols—to maximize transaction performance. One common protocol used for efficient transfers is the block transfer, in which a range of locations is transferred based on a single address, eliminating the need to transfer all the addresses on the bus. Some recent busses allow split transactions—the data request and data transfer are performed on separate bus cycles, allowing other bus operations to be performed while the original request is serviced. A low-cost bus design provides modest performance that may not be acceptable for instruction fetching or other time-critical operations. A low-cost bus is designed to require little hardware in the bus itself and to impose a small hardware and software overhead on the devices connecting to the bus. A system may contain more than one bus; a bridge can be used to connect one bus to another.

The ARM AMBA bus specification<sup>7</sup> is an example of a bus specification for SoCs. The AMBA spec actually includes two busses: the high-performance AMBA high-performance bus (AHB) and the low-cost AMBA peripherals bus (APB). The Virtual Sockets Interface committee has defined another standard for interconnecting components on SoCs.

## Memory

One of the great advantages of SoC technology is that memory can be placed on the same chip as the system components that use the memory. On-chip memory both increases performance and reduces power consumption because on-chip connections present less reactive load than do pins and traces between chips; however, an SoC may still need to use separate chips for off-chip memory.

Although on-chip embedded memory has many advantages, it still is not as good as commodity memory. A commodity SRAM or DRAM's manufacturing process has been carefully tuned to the requirements of that component. In contrast, an on-chip memory's manufacturing needs must be balanced against the requirements of the logic circuits on the chip. The transistors, interconnections, and storage nodes of on-chip memories all have somewhat different needs than logic transistors.

Embedded DRAMs suffer the most because they need quite different manufacturing processes than do logic circuits. The processing steps required to build the storage capacitors for the DRAM cell are not good for small-geometry transistors. As a result, embedded DRAM technologies often compromise both the memory cells and the logic transistors, with neither being as good as they would be in separate,

optimized processes. Although embedded DRAM has been the subject of research for many years, its limitations have kept it from becoming a widely used technology at the time of this writing.

SRAM circuits' characteristics are closer to those of logic circuits and so can be built on SoCs with less penalty. SRAM consumes more power and requires more chip area than does DRAM, but SRAM does not need refreshing, which noticeably simplifies the system architecture.

### Software Components

Software elements are also components of embedded systems. Just as pre-designed hardware components are used to both reduce design time and to provide predictions of the characteristics of parts of the system, software components can also be used to speed up software implementation time and to provide useful data on the characteristics of systems.

CPU vendors often supply software libraries for their processors. These libraries generally supply code for two types of operations. First, they provide drivers for input and output operations. Second, they provide efficient implementations of commonly-used algorithms. For example, libraries for DSPs generally include code for digital filtering, fast Fourier transforms, and other common signal processing algorithms. Code libraries are important because compilers are still not as adept as expert human programmers at creating code that is both fast and small.

The real-time operating system (RTOS) is the second major category of software component. Many applications perform several different types of operations, often with their own performance requirements. As a result, the software is split into processes that run independently under the control of an RTOS. The RTOS schedules the processes to meet performance goals and efficiently utilize the CPU and other hardware resources. The RTOS may also provide utilities, such as interprocess communication, networking, or debugging. An RTOS's scheduling policy is necessarily very different from that used in workstations and mainframes, because the RTOS must meet real-time deadlines. A priority-driven scheduling algorithm such as rate-monotonic scheduling (RMS)<sup>9</sup> is often used by the RTOS to schedule activity in the system.
