The hardware architecture of an embedded SoC is generally tuned to the requirements of the application. Different domains, such as automotive, image processing, and networking all have very different characteristics. In order to make best use of the available silicon area, the system architecture is chosen to match the computational and communication requirements of the application. As a result, a much wider range of hardware architectures is found for embedded systems as compared with traditional computer systems.

Figure 22.2 shows one common configuration, a bus-based uniprocessor architecture for an embedded system. This architecture has one CPU, which greatly simplifies the software architecture. In addition to I/O devices, the architecture may include several devices known as accelerators designed to speed up

FIGURE 22.2 A bus-based, single-CPU embedded system.

computations. (Though some authors refer to these units as co-processors, we prefer to reserve that term for units that are dispatched by the CPU's execution unit.) For example, a video operation's inner loops may be implemented in an application-specific IC (ASIC) so that the operation can be performed more quickly than would be possible on the CPU. An accelerator can achieve performance gains through several mechanisms: by implementing some functions in special hardware that takes fewer cycles than is required on the CPU, by reducing the time required for control operations that would require instructions on the CPU, and by using additional registers and custom data flow within the accelerator to more efficiently implement the available communication. The single-CPU/bus architecture is commonly used in applications that do not have extensive real-time characteristics and ones that need to run a wider variety of software. For example, many PDAs use this type of architecture. A single-CPU system simplifies software design and debugging since all the work is assumed to happen on one processing element. The single CPU system is also relatively inexpensive.

In general, however, a high-performance embedded system requires a heterogeneous multiprocessor—a multiprocessor that uses more than one type of processing element and/or a specialized communication topology. Scientific parallel processors generally use a regular architecture to simplify programming. Embedded systems use heterogeneous architectures for several reasons:

- *Cost*—A regular architecture may be much larger and more expensive than a heterogeneous architecture, which freed from the constraint of regularity, can remove resources from parts of the architecture where they are not needed and add them to parts where they are needed.
- *Real-time performance*—Scientific processors are designed for overall performance but not to meet deadlines. Embedded systems must often put processing power near the I/O that requires real-time responsiveness; this is particularly true if the processing must be performed at a high rate. Even if a high-rate, real-time operation requires relatively little computation on each iteration, the high interrupt rate may make it difficult to perform other processing tasks on the same processing element.

Many embedded systems use heterogeneous multiprocessors. One example comes from telephony. A telephone must perform both control- and data-intensive operations: both the network protocol and the user interface require control-oriented code; the signal processing operations require data-oriented code. The Texas Instruments OMAP architecture, shown in Fig. 22.3, is designed for telephony: the RISC processor handles general-purpose and control-oriented code while the DSP handles signal processing. Shared memory allows processes on the two CPUs to communicate, as does a bridge. Each CPU has its own RTOS that coordinates processes on the CPU and also mediates communication with the other CPU.

The C-Port network processor,<sup>11</sup> whose hardware architecture is shown in Fig. 22.4, provides an example of a heterogeneous multiprocessor in a different domain. The multiprocessor is a high-speed bus. The RISC executive processor is C programmable and provides overall control, initialization, etc. Each of the 16 HDLC processors is also C programmable. Other interfaces for higher-speed networks are not general-purpose computers and can be programmed only with register settings.

Another category of heterogeneous parallel embedded systems is the networked embedded system. Automobiles are a prime example of this type of system: the typical high-end car includes over a hundred microprocessors ranging from 4-bit microcontrollers to high-performance 32-bit processors. Networks help to distribute high-rate processing to specialized processing elements, as in the HP DesignJet, but

FIGURE 22.3 The TI OMAP architecture.<sup>10</sup>

FIGURE 22.4 Block diagram of the C-Port network processor.<sup>11</sup>

they are most useful when the processing elements must be physically distributed. When the processing elements are sufficiently far apart, busses designed for lumped microprocessor systems do not work well. The network is generally used for data transfer between the processing elements, with each processing element maintaining its own program memory as well as a local data memory. The processing elements communicate data and control information as required by the application. I<sup>2</sup>C and CAN are two widely-used networks for distributed systems.

## 22.5 Embedded SoC Design Methodologies

### Specifications

As described in section 22.2, embedded computers are typically used to build systems with complex functionality. Therefore, capturing a functional description of the system is an important part of the design process. A variety of specification languages have been developed. Many of these languages were developed for software systems, but several languages have been developed over the past decade with embedded systems in mind.

Specification languages are generally designed to capture particular styles of design. Many languages have been created to describe control-oriented systems. An early example was Statecharts,<sup>12</sup> which introduced hierarchical states that provided a structured description of state machines. The SDL language<sup>13</sup> is widely used to specify protocols in telecommunications systems. The Esterel language<sup>14</sup> describes a reactive system as a network of communicating state machines.

Data-oriented languages find their greatest use in signal processing systems. Dataflow process networks<sup>15</sup> are one example of a specification language for signal processing. Object-oriented specification and design have become very popular in software design. Object-oriented techniques mix control and data orientation. Objects tend to reflect natural assemblages of data; the data values of an object define its state and the states of the objects define the state of the system. Messages providing communication and control. The real-time object-oriented Methodology (ROOM)<sup>16</sup> is an example of an object-oriented methodology created for embedded system design.

In practice, many systems are specified in the C programming language. Many practical systems combine control and data operations, making it difficult to use one language that is specialized for any type of description. Algorithm designers generally want to prototype their algorithms and verify them through experimentation; as a result, an executable program generally exists as the golden standard with

**FIGURE 22.5** The waterfall model of software development.

which the implementation must conform. This is especially true when the product’s capabilities are defined by standards committees, which typically generate one or more reference implementations, usually in C. Once a working piece of code exists in C, there is little incentive to rewrite it in a different specification language; however, the C specification is generally a long way from an implementation. Algorithmic designs are usually written for uniprocessors and ignore many aspects of I/O, whereas embedded systems must perform real-time I/O and often distribute tasks among several processing elements. Algorithm designers often do not optimize their code for any particular platform, and their code is certainly not optimized for any particular embedded platform. As a result, a C language specification often requires substantial re-engineering before it can be used in an embedded system.

## Design Flows

In order to better understand modern design methodologies for embedded SoCs, we can start with traditional software engineering methodologies. The waterfall model, one of the first models of software design, is shown in Fig. 22.5. The waterfall model is a top-down model with only local feedback. Other software design models, such as the spiral model, try to capture more bottom-up feedback from implementation to system design; however, software design methodologies are designed primarily to implement functionality and to create a maintainable design. Embedded SoCs must, as mentioned in section 22.2, satisfy performance and power goals as well. As a result, embedded system design methodologies must be more complex.

The design of the architecture of an embedded SoC is particularly important because the architecture defines the capabilities that will limit both the hardware and software implementations. The architecture must of course be cost effective, but it must also provide the features necessary to do the job. Because the architecture is custom designed for the application, it is quite possible to miss architectural features that are necessary to efficiently implement the system. Retrofitting those features back into the architecture may be difficult or even impossible if the hardware and software design efforts do not keep in sync.

Important decisions about the hardware architecture include:

- How many processing elements are needed?
- What processing elements should be programmable and which ones should be hardwired?
- How much communication bandwidth is needed in the system and where is it needed?
- How much memory is needed and where should it go in the system?
- What types of components will be used for processors, communication, and memory?

The design of the software architecture is just as important and goes hand-in-hand with the hardware architecture design. Important decisions about the software architecture include:

- How should the functionality be split into processes?
- How are input and output performed?

- How should processes be allocated to the various processing elements in the hardware architecture?
- When should processes be scheduled?

In practice, information required to make these decisions comes from several sources. One important source is previous designs. Though technology and requirements both change over time, similar designs can provide valuable lessons on how to (and not to) design the next system. Another important source is implementation. Some implementation information can come from pre-designed hardware or software components, which is one reason why intellectual-property-based design is so important. Implementation can also come from early design efforts.

A variety of CAD algorithms have been developed to explore the embedded system design space and to help automate system architectures. Vulcan<sup>21</sup> and Cosyma<sup>22</sup> were early hardware/software partitioning systems that implemented a design using a CPU and one or more custom ASICs. Other algorithms target more general architectures.<sup>23,24</sup>

Once the system architecture has been defined, the hardware and software must be implemented. Hardware implementation challenges include:

- finding efficient protocols to connect together existing hardware blocks,
- memory design,
- clock rate optimization,
- power optimization.

Software implementation challenges include:

- meeting performance deadlines,
- minimizing power consumption,
- minimizing memory requirements.

The design must be verified throughout the design process. Once the design progresses to hardware and software implementation, simulation becomes challenging because the various components operate at very different levels of abstraction. Hardware units are modeled at the clock-cycle level. Software components must often be run at the instruction level or in some cases at even higher levels of abstraction. A hardware/software co-simulator<sup>19</sup> is designed to coordinate simulations that run at different time scales. The co-simulator coordinates multiple simulators—hardware simulators, instruction-level simulators, behavioral software processes—and keeps track of the time in each simulation. The co-simulator ensures that communications between the simulators happen at the right time for each simulator.

Design verification must include performance, power, and size as well as functionality. Although these sorts of checks are common in hardware design, they are relatively new to software design. Performance and power verification of software may require cache simulation. Some recent work has developed higher-level power models for CPUs.

## Platform-Based Design

One response to the conflicting demands of SoC design has been the development of platform-based design methodologies. On the one hand, SoCs are becoming very complex. On the other hand, they must be designed very quickly to meet the electronics industry's short product lifecycles.

Platform-based design tries to tackle this problem by dividing the design process into two phases. In the first phase, a platform is designed. The platform defines the hardware and software architectures for the system. The degree to which the architecture can be changed depends on the needs of the marketplace. In some cases, the system may be customizable only by reprogramming. In other cases, it may be possible to add or delete hardware components to provide specialized I/O, additional processing capabilities, etc. In the second phase, the platform is specialized into a product. Because much of the initial design work was done in the first phase, the product can be developed relatively quickly based on the platform.

Platform-based design is particularly well suited to products derived from standards. On the one hand, all products must meet the minimum requirements of the standard. On the other hand, standards committees generally leave room for different implementations to distinguish themselves: added features, lower power, etc. Designers will generally want to modify their design to add features that differentiate their product in the marketplace.

Platform-based design also allows designers to incorporate design experience into products. Each product derived from the platform will teach something: how to better design part of the system, unexpected needs of customers, etc. The platform can be updated as new products are developed from it so that successive designs will be easier.

Platforms are usually designed within a technology generation. A new VLSI technology generally changes enough design decisions that platforms must be rethought for each new generation of technology. Therefore, the platform itself must be designed quickly and each product based on the platform must be completed quickly in order to gain effective use of the platform design effort in the 18-month lifecycle of a manufacturing technology.

## **Software Performance Analysis and Optimization**

Although methods for hardware performance analysis and optimization are well-known, software techniques for optimizing performance have been developed only recently to meet the demands of embedded design methodologies.

The performance of an embedded system is influenced by several factors at different levels of abstraction. The first is the performance of the CPU pipeline itself. RISC design techniques tend to provide uniform execution times for instructions, but software performance is not always simple to predict. Register forwarding, which is used to enhance pipeline performance, also makes execution time less predictable. Branch prediction causes similar problems.

Superscalar processors, because they schedule instructions at execution time based upon execution data, provide much less predictable performance than do either RISC or VLIW processors. This is one reason why superscalar processors are not frequently used in real-time embedded systems.

The memory system is often an even greater source of uncertainty in embedded systems. CPUs use caches to improve average memory response time, but the effect of the cache on a particular piece of software requires complex analysis. In pathological cases, the cache can add uncertainty to execution times without actually improving the performance of critical software components. Cache simulation is often used to analyze the behavior of a program in a cache. Analysis must take into account both instructions and data. Unlike in workstation CPUs, in which the cache configuration is chosen by the CPU architect based on benchmarks, the designer of an embedded SoC can choose the configurations of caches to match the characteristics of the embedded software. Embedded system designers can choose between hardware and software optimizations to meet performance goals.

Analyzing the performance of a program requires determining both the execution path and the execution time of instructions along that path.<sup>18</sup> Both are challenging problems.<sup>20</sup> The execution path of a program clearly depends on input data values. To ensure that the program meets a deadline, the worst-case execution path must be determined. The execution time of instructions along the path depend on several factors: data values, interactions between instructions, and cache state.

## **Energy/Power Analysis and Optimization**

Many embedded systems must also meet energy and power goals as well as performance goals. The specification may impose several types of power requirements: peak power consumption, average power consumption, energy consumption for a given operation.

To a first-order, high-performance design is low-power design. Efficient implementations that run faster also tend to reduce power consumption, but trade-offs between performance and power in embedded system design. For example, the power consumption of a cache depends on both its size and the

memory system activity.<sup>25</sup> If the cache is too small, too many references require expensive main memory accesses. If the cache is too large, it burns too much static power. Many applications exhibit a sweet spot at which the cache is large enough to provide most of the available performance benefit while not burning too much static power. Techniques have been developed to estimate hardware/software power consumption.<sup>26</sup>

System-level approaches can also help reduce power consumption.<sup>27</sup> Components can be selectively turned off to save energy; however, because turning a component on again may consume both time and energy, the decision to turn it off must be made carefully. Statistical methods based on Markov models can be used to create effective system-level power management methodologies.

## 22.6 Summary

---

Embedded computers promise to solve a critical design bottleneck for SoCs. Because we can design CPUs relatively independently of the programs they run and reuse those CPUs design across many chips, embedded computers help to close the designer productivity gap. Embedded processors, on the other hand, require that many design techniques traditionally reserved for hardware—deadline-driven performance, power minimization, size—must now be applied to software as well. Design methodologies for embedded SoCs must carefully design system architectures that will allow hardware and software components to work together to meet performance, power, and cost goals while implementing complex functionality.

### 23.1 Introduction

---

This chapter overviews the field of embedded processors and their applications. Some basic concepts will be introduced, and examples of embedded systems will be given. Each topic will include a problem statement, definitions of terminology, fundamental hardware and software, and interfacing specific devices to create the desired functionality. A systems-level approach to microcomputer applications is achieved by presenting a few case studies that illustrate the spectrum of applications that employ microcomputers.

As shown in [Fig. 23.1](#), the term embedded microcomputer system refers to a device that contains one or more microcomputers inside. To better understand the expression “embedded microcomputer system,” consider each word separately. In this context, the word embedded means “hidden inside so one cannot see it.” A computer is an electronic device with a processor, memory, and I/O ports. The processor executes software, which performs specific predefined operations. The processor includes registers (which are high-speed memory), an arithmetic logic unit or ALU (to execute math functions), a bus interface unit or BIU (which communicates with memory and I/O), and a control unit or CU (for making decisions.) Memory is a high-speed storage medium for software and data. Software consists of a sequence of commands that are usually executed in order. In an embedded system, we use read only memory (ROM) for storing the software and fixed constant data, and random access memory (RAM) for storing temporary information. The information in the ROM is nonvolatile, meaning the contents are not lost when power is removed. I/O ports allow information to enter via the input ports and exit via the output ports. The I/O devices (e.g., parallel ports, serial ports, timer, and ADC) are a crucial part of an embedded system because they

**FIGURE 23.1** An embedded system includes a microcomputer with electrical, mechanical, chemical, and optical devices. A microcomputer includes a processor with memory, input, and output devices.

provide necessary functionality. The software together with the I/O ports and associated interface circuits give an embedded computer system its distinctive characteristics.

The term “microcomputer” means a small computer. Small in this context describes its size not its computing power, so a microcomputer can refer to a very wide range of products from the very simple (e.g., the PIC12C08 is a 8-pin DIP microcomputer with 512 by 12 bit ROM, 25 bytes RAM, and five I/O pins) to the most powerful Pentium. One typically restricts the term “embedded” to refer to systems that do not look and behave like a typical computer. Most embedded systems do not have a keyboard, a graphics display, or secondary storage (disk). Embedded systems can be developed in two ways. The first technique uses the microcomputers that are available as single chips. These devices are suitable for low-cost, low-performance systems. On the other hand, one can develop a high-performance embedded system around the PC architecture. These systems are first developed on a standard PC, and then the software and hardware are migrated to a stand-alone embedded-PC platform.

One can appreciate the wide range of embedded computer applications by observing existing implementations. [Table 23.1](#) illustrates the breadth of applications that use an embedded microcomputer.

## 23.2 Embedded Processors

### Processor

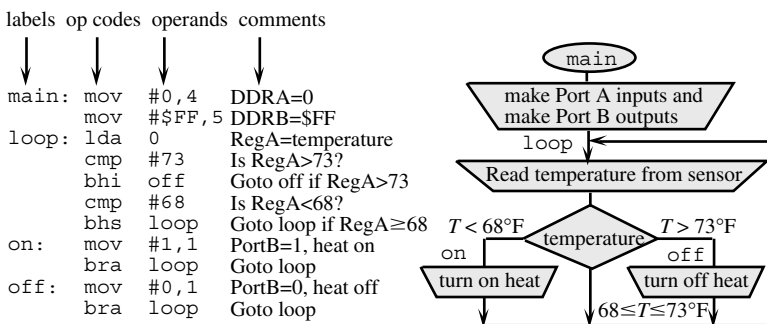

In the last 30 years, the microprocessor has made significant technological advances. The term microprocessor refers to products ranging from the oldest Intel 8080 to the newest Pentium. The processor or CPU controls the system by executing instructions. It contains a BIU, which provides the address, direction (read data from memory into the processor or write data from processor to memory), and timing signals for the computer bus. The registers are very high-speed storage devices for the computer. The program counter (PC) is a register that contains the address of the current instruction that the computer is executing. The stack is a very important data structure used by computers to store temporary information. It is very easy to allocate temporary storage on the stack and deallocate it when done. The stack pointer (SP) is a register that points into RAM specifying the top entry of the stack. The condition code (CC) is a register that contains status flags describing the result of the previous operation and operating mode of the computer. Most computers have data registers that contain information and address registers that contain pointers. The ALU performs arithmetic (add, subtract, multiply, divide) and logical (and, or, not, exclusive or, shift) operations. The inputs to the ALU come from registers and/or memory, and the outputs go to registers or memory. The CC register contains status information from the previous ALU operation.

Software is a sequence of commands stored in memory. The control unit (CU) manipulates the hardware modules according to the software that it is executing. The CU contains an instruction register (IR) which holds the current instruction. The BIU contains an effective address register (EAR) which holds the effective address of the current instruction. The computer must fetch both instructions (op codes) and information (data). The BIU controls both types of access.

When an instruction is executed, the microprocessor often must refer to memory to read and/or write information. Often the I/O ports are implemented as memory locations. For example, on the Motorola

**TABLE 23.1** Examples of Embedded Systems

Category	Examples	What the Microcomputer Does
Consumer	Washing machines	Controls the water and spin cycles
	Exercise bikes	Monitors the workout
	TV remotes	Accepts key touches and sends IR pulses
	Clocks and watches	Maintains the time, alarm, and display
	Games and toys	Entertains the child
	Audio/video	Enhances performance
Communication	Answering machines	Saves and organizes messages
	Phones and pagers	Communication and security
	ATM machines	Security and convenience
Automotive	Automatic braking	Stopping on slippery surfaces
	Noise cancellation	Improves sound quality
	Theft deterrent devices	Security
	Electronic ignition	Controls sparks and fuel injectors
	Windows and seats	Remember preferred settings
Military	Instrumentation	Collects and provides information
	Smart weapons	Does not fire at friendly targets
	Missile guidance	Directs ordnance at the target
Industrial	Global positioning	Where one is on the planet
	Set-back thermostats	Controls temperature and save energy
	Traffic control systems	Optimizes traffic
	Robot systems	Performs complex tasks
	Bar codes	Inventory control
Medical	Sprinklers	Optimizes farming
	Monitors	Measures and alarms
	Apnea	Alarms if the baby stops breathing
	Cardiac	Monitors heart functions
	Renal	Studies kidney functions
	Drugs	Automatic delivery
	Cancer treatments	Controls radiation, drugs, heat
	Pacemakers	Helps the heart beat regularly
Prosthetic devices	Increases mobility	
	Dialysis machines	Provides kidney functions

**FIGURE 23.2** A bang-bang temperature controller with hysteresis implemented using a Motorola 6808.

6808, I/O ports A and B exist as locations 0 and 1. Similar to most microcomputers, the I/O ports can be configured as inputs or outputs. The 6808 ports A and B have direction registers at locations 4 (DDRA) and 5 (DDR B), respectively. The software writes 0's to the direction register to specify the pins as inputs, and 1's to specify them as outputs. When the 6808 software reads from location 0 it gets information from Port A (lda 0). When the software writes to location 1, it sends information out Port B (sta 1). For example, the Motorola 6808 assembly language program, shown in Fig. 23.2, reads from a sensor

that is connected to Port A, if the temperature is above 73°F, it turns off the heat (by writing 0 to Port B). If the temperature is below 68°F, it turns on the heat by writing 1 to Port B.

## Embedded Microcomputer

During the development phases of a project, we often would like the flexibility of accessing components inside the single-chip computer. In addition, during development, we are often unsure of the memory size and I/O capabilities that will be required to complete the design. Both of these factors point to the need for a single-board computer. This board has all of the features of the single-chip computer but laid out in an accessible and expandable manner. For some microcomputer systems, the final product is delivered using a single-board computer. For example, if the production volume is small and the project does not have severe space constraints, then a single-board solution may be cost-effective. Another example of final product delivered with a single-board occurs when the computer requirements (memory size, number of ports, etc.) exceed the capabilities of any single-chip computer.

## Choosing a Microcomputer

The computer engineer is often faced with the task of selecting a microcomputer for the project. In 1997 Motorola had 17.4% of the 4/8/16+ bit microcontroller market, Hitachi had 15.6%, and NEC had 13.2%. [Table 23.2](#) breaks the 8-bit market share down by architecture, showing the 8051 architecture to be most popular. As of 1997, Motorola has shipped over 2 billion 68HC05 8-bit microcontrollers. This cumulative number on a unit level is more than all microprocessors from all other chip vendors. [Table 23.3](#) lists major manufacturers and their web sites

Often, only those devices for which the engineers have hardware and software experience are considered. Fortunately, this blind approach often still yields an effective and efficient product, because many of the computers overlap in their cost and performance. In other words, if a microcomputer that you are familiar with can implement the desired functions for the project, then it is often efficient to bypass that perfect piece of hardware in favor of a faster development time. On the other hand, sometimes one wishes to evaluate all potential candidates. Sometimes, it may be cost-effective to hire or train the engineering

**TABLE 23.2** 1997 Market Share in Dollars of 8-bit Microcontrollers [1]

$\mu$ C	Company	Revenue (millions)
8051	Intel, Philips, Siemens, Dallas Semiconductor	1027
HC05	Motorola	864
HC11	Motorola	643
H8	Hitachi	505
78K	NEC	497

personnel so that they are proficient in a wide spectrum of potential computer devices. Many factors must be considered when selecting an embedded microcomputer. The labor costs include training, development, and testing. The material costs include parts and supplies. The manufacturing costs depend on the number and complexity of the components. The maintenance costs involve revisions to fix bugs and perform upgrades. The ROM size must be big enough to hold instructions and fixed data for the software. The RAM size must be big enough to hold locals, parameters, and global variables. The EEPROM size must be big enough to hold nonvolatile fixed constants that are field configurable. The speed must be fast enough to execute the software in real time. The I/O bandwidth affects how fast can the computer input/output data. The data size (8, 16, or 32 bit) should match most of the data to be processed. Numerical operations like multiply, divide, signed, and floating point may be needed. Special functions like multiply/accumulate, fuzzy logic, complex numbers are sometimes required. There must be enough parallel ports for all the I/O digital signals. The microcomputer needs enough serial ports to interface with other computers or I/O devices. The timer functions can be used to generate signals, measure frequency, and measure period. Pulse width modulation is convenient for the output signals in many control applications. An ADC is used to convert analog inputs to digital numbers. The package size and environmental issues affect many embedded systems. In order to meet manufacturing deadlines, the availability of a second source is advantageous. The availability of high-level language cross-compilers, simulators, emulators will facilitate software development. The power requirements will be important if the systems will be battery operated.

When considering speed, it is best to compare time to execute a benchmark program similar to your specific application, rather than just comparing bus frequency. One of the difficulties is that the microcomputer selection depends on the speed and size of the software, but the software can not be written without the computer. Given this uncertainty, it is best to select a family of devices with a range of execution speeds and memory configurations. In this way, a prototype system with large amounts of memory and peripherals can be purchased for software and hardware development, and once the design is in its final stages, the specific version of the computer can be selected now knowing the memory and speed requirements for the project.

## 23.3 Software Systems

---

### Assembly Language

An assembly language program, like the one shown in [Fig. 23.2](#), has a 1-to-1 mapping with the machine code of the computer. In other words, one line of assembly code maps into a single machine instruction. The label field associates the absolute memory address with a symbolic label. The op code represents the machine instruction to be executed. The operand field identifies the data itself or the memory location for the data needed by the instruction. The comment field is added by the programmer to explain what, how, and why. The comments are not used by the computer during execution, but rather provide a means for one programmer to communicate with another, including oneself at a later time. This style of programming offers the best static efficiency (smallest program size), and best dynamic efficiency (fastest program execution). Another advantage of assembly language programming is the complete freedom to implement any arbitrary decision function or data structure. One is not limited to a finite list of predefined structures as is the case with higher level languages. For example, one can write assembly code with multiple entry points (places to begin the function).

### High-Level Languages

Although assembly language enforces no restrictions on the programmer, many software developers argue that the limits placed on the programmer by a structured language, in fact, are a good idea. Building program and data structures by combining predefined components makes it easy to implement modular software that is easier to debug, verify correctness, and modify in the future. Software maintenance is

the debug, verify and modify cycle, and it represents a significant fraction of the effort required to develop products using embedded computers. Therefore, if the use of a high level language sacrifices some speed and memory performance, but gains in the maintenance costs, most computer engineers will choose reliability and ease of modification over speed and memory efficiency. Cross-compilers for C, C++, FORTH, and BASIC are available for many single-chip microcomputers with C being the most popular.

One of the best approaches to this assembly versus high-level language choice is to implement the prototype in a high level language, and see if the solution meets the product specifications. If it does, then leave the software in the high level language because it will be easier to upgrade in the future. If the software is not quite fast enough (or small enough to fit into the available memory), then one might try a better compiler. Another approach is to profile the software execution, which involves collecting timing information on the percentage of time the computer takes executing each module. The profile allows you to identify a small number of modules that, if rewritten in assembly language, will have a big impact on the system performance.

## Software Development

Recent software and hardware technological developments have made significant impacts on the software development for embedded microcomputers. The simplest approach is to use a cross-assembler or cross-compiler to convert source code into the machine code for the target system. The machine code can then be loaded into the target machine. Debugging embedded systems with this simple approach is very difficult for two reasons. First, the embedded system lacks the usual keyboard and display that assist us when we debug regular software. Second, the nature of embedded systems involves the complex and real time interaction between the hardware and software. These real-time interactions make it impossible to test software with the usual single-stepping and print statements.

A logic analyzer is a multiple channel digital oscilloscope. For the single-board computer that has external memory, the logic analyzer can be placed on the address and data bus to observe program behavior. The logic analyzer records a cycle-by-cycle dump of the address and data bus. With the appropriate personality module, the logic analyzer can convert the address and data information into the corresponding stream of executed assembly language instructions. Unfortunately, the address and data bus singles are not available on most single-chip microcomputers. For these computers, the logic analyzer can still be used to record the digital signals at the microcomputer I/O ports. The advantages of the logic analyzer are very high bandwidth recording (100 MHz to 1 GHz), many channels (16–132 inputs), flexible triggering and clocking mechanisms, and personality modules that assist in interpreting the data.

The next technological advancement that has greatly affected the manner in which embedded systems are developed is simulation. Because of the high cost and long times required to create hardware prototypes, many preliminary feasibility designs are now performed using hardware/software simulations. A simulator is a software application that models the behavior of the hardware/software system. If both the external hardware and software program are simulated together, even although the simulated time is slower than the actual time, the real time hardware/software interactions can be studied.

Once the design is committed to hardware, the debugging tasks become more difficult. One simple approach, mentioned earlier, is to use a single-board computer that behaves similarly to the single-chip. Another approach is to use an in-circuit emulator. An in-circuit emulator (ICE) is a complex digital hardware device, which emulates (behaves in a similar manner) the I/O pins of the microcomputer in real time. The emulator is usually connected to a personal computer, so that emulated memory, I/O ports, and registers can be loaded and observed. To use an emulator we first remove the microcomputer chip from the circuit then attach the emulator pod into the socket where the microcomputer chip used to be.

The only disadvantage of the in-circuit emulator is its cost. To provide some of the benefits of this high-priced debugging equipment, some microcomputers have a background debug module (BDM). The BDM hardware exists on the microcomputer chip itself and communicates with the debugging personal computer via a dedicated 2 or 3 wire serial interface. Although not as flexible as an ICE, the

BDM can provide the ability to observe software execution in real time, the ability to set breakpoints, the ability to stop the computer, and the ability to read and write registers, I/O ports, and memory.

## Memory Allocation

Embedded systems group together in physical memory information that has similar logical properties. Because the embedded system does not load programs off disk when started, allocation is an extremely important issue for these systems. Typical software segments include global variables, local variables, fixed constants, and machine instructions. For single chip implementations, different types of information are stored into the three types of memory. RAM is volatile and has random and fast access. EEPROM is nonvolatile and can be easily erased and reprogrammed. ROM is nonvolatile but can be programmed only once.

In an embedded application, structures that must be changed during execution are usually put in RAM. Examples include recorded data, parameters passed to subroutines, and global and local variables. We place fixed constants in EEPROM because the information remains when the power is removed, but can be reprogrammed at a later time. Examples of fixed constants include translation tables, security codes, calibration data, and configuration parameters. We place machine instructions, interrupt vectors, and the reset vector in ROM because this information is stored once and will not need to be reprogrammed in the future.

## 23.4 Interfacing

---

### Digital Logic

Many logic families are available to design digital circuits. Each family provides the basic logic functions (and or not), but differ in the technology used to implement these functions. This results in a wide range of parameter specifications. Basic parameters of digital devices can be found in references [1] and [2]. Because many microcomputers are high-speed CMOS, typical values for this family are given. In general, it is desirable to design digital systems using all components from the same family. There are three basic considerations when using digital logic: speed and signal loading.

One of the pressures that exists in the microcomputer embedded systems field is the need to implement higher and higher levels of functionality into smaller and smaller amounts of space using less and less power. Many examples of technology were developed according to these principles. Examples include portable computers, satellite communications, aviation devices, military hardware, and cellular phones. Simply using a microcomputer provides significant advantages in this faster-smaller race. The embedded system is not just a computer, so there must also be mechanical and electrical devices external to the computer. To shrink the size and power required of these external electronics, they can be integrated into a custom integrated circuit (IC) called an application specific integrated circuit (ASIC). An ASIC provides a high level of functionality squeezed into a small package. Advances in IC design allow more and more of these custom circuits (both analog and digital) to be manufactured in the same IC chip as the computer itself. In this way, single-chip solutions are possible.

The microcomputer typically responds to external events with an appropriate software action. The time between the external event and the software action is defined as the latency. If an upper bound on the latency can be guaranteed, the system is characterized as real-time, or hard real-time. If the system allows one software task to have priority over the others, then it is described as soft real-time. Because most real-time systems utilize interrupts to handle critical events, we can calculate the upper bound on the latency as the sum of three components (1) maximum time the software executes with interrupts disabled (e.g., other interrupt handlers, critical code); (2) the time for the processor to service the interrupt (saving registers on stack, fetching the interrupt vector); and (3) software delays in the interrupt handler before the appropriate software action is performed. Examples of events that sometimes require real-time processing include input, output, and alarms. When new input data is ready, the software must respond by reading the new input.

When the output device is idle, the software must respond by giving it more data to output. When an alarm condition occurs, the software must process the data until the time the alarm is processed.

Sometimes the software must respond to internal events. Many real time systems involve performing software tasks on a fixed and regular rate. For these systems, a periodic interrupt is employed to generate requests at fixed intervals. The microcomputer clock guarantees that the interrupt request is made exactly on time, but the software response (latency) may occur later. Examples of real-time systems that utilize periodic interrupts include: data acquisition systems where the software executes at the sampling rate, control systems where the software executes at the controller rate, and time of day clocks where the software maintains the date and time.

### Keyboard Interfacing

Individual buttons and switches can be interfaced to a microcomputer input port simply by converting the on/off resistance to a digital logic signal with a pull-up resistor. When many keys are to be interfaced, it is efficient to combine them in a matrix configuration.  $n^2$  keys can be constructed as an  $n$  by  $n$  matrix. To interface the keyboard with  $n^2$  keys,  $2n$  I/O ports are needed, the rows to open collector (or open drain) microcomputer outputs and the columns to microcomputer inputs are connected. Open collector means the output will be low if the software writes a zero to the output port, but will float (high impedance) if the software writes a one. Pull-up resistors on the inputs will guarantee the column signals will be high if no key is touched in the selected row. The software scans the key matrix by driving one row at a time to zero, while the other rows are floating. If there is a key touched in the selected row, then the corresponding column signal will be zero. Many switches will bounce on/off for about 10 ms when touched or released. The software must read the switch position multiple times over a 20-ms time period to guarantee a reliable reading. One simple software method uses a periodic interrupt (with a rate slower than the bounce time) to scan the keyboard. In this way, the software will properly detect single key touches. One disadvantage of the matrix-scanned keyboard is the fact that three keys simultaneously pressed sometimes “looks” like four keys are pressed.

### Finite State Machine Controller

To illustrate the concepts of programmable logic and memory allocation consider the simple traffic light controller illustrated in Fig. 23.3. The finite state machine (FSM) has two inputs from sensors that identify the presence of cars. There are six outputs, red/yellow/green for the North road and red/yellow/ green for the East road. In this FSM, each state has a 6-bit output value, a time to wait in that state, and four next states depending on if the input is 00 (no cars), 01 (car on the North road), 10 (car on the East road) or 11 (cars on both roads). The software will output the pattern for the current state, wait the specified amount of time, input from the sensors, and jump to the next state depending on the input. The finite state machine data structure (linked list or table) will be defined in EEPROM, and the program will be stored in ROM. The software for this system exhibits the three classic segments. Since the variables have values that change during execution, they must be defined in RAM. One should be able to make

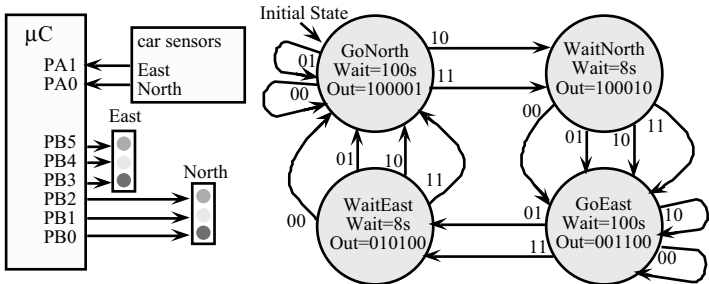

FIGURE 23.3 A simple traffic controller implemented using a finite-state machine.

minor modifications to the finite state machine (e.g., add/delete states, change input/output values) by changing the linked list data structure in EEPROM without modifying the assembly language controller in ROM. A C-level program written for a Motorola 6812 follows:

```

const struct State{          // const means put in EEPROM
    unsigned char Out;       // 6-bit Output
    unsigned char Time;     // Time to wait in seconds
    unsigned char Next[4];  // Next state if input=00,01,10,11
typedef const struct State StateType;
#define GoN    0    // Green on North, Red on East
#define WaitN  1    // Yellow on North, Red on East
#define GoE    2    // Red on North, Green on East
#define WaitE  3    // Red on North, Yellow on East
StateType fsm[4]={          // EEPROM
    {0x21, 100, {GoN, GoN, WaitN, WaitN}}, // GoN EEPROM
    {0x22, 8, {GoE, GoE, GoE, GoE}}, // WaitN EEPROM
    {0x0C, 100, {GoE, WaitE, GoE, WaitE}}, // GoE EEPROM
    {0x14, 8, {GoN, GoN, GoN, GoN}}}; // WaitE EEPROM
void main(void){           // ROM
    unsigned char Input;   // RAM
    unsigned int St;       // Current State RAM
    St=GoN;                // Initial State ROM
    DDRA=0, DDRB=0xFF;    // Set direction registers ROM
    while(1){              // ROM
        PORTB=fsm[St].Out; // output for this state ROM
        Wait(fsm[St].Time); // wait in this state ROM
        Input=PORTA&0x03; // Input=00 01 10 or 11 ROM
        St=fsm[St].Next[Input]; // ROM
    }

```

## Current-Activated Output Devices

Many external devices used in embedded systems activate with a current, and deactivate when no current is supplied. The control element can be either a diode or a coil (resistor and inductor combination). The microcomputer controls the device by passing current or no-current through the control element. Coil devices include electromagnetic relays, solenoids, DC motors, and stepper motors. Diode-based devices include LEDs, optosensors, optical isolation, solid state relays. Diode-based devices require a current limiting resistor. The value of the resistor determines the voltage ( $V_d$ ), current ( $I_d$ ) operating point. The coil-based devices require a snubber diode to eliminate the large back EMF (over 200 V) that develops when the current is turned off. The back EMF is generated when the large  $di/dt$  occurs across the inductance of the coil. The microcomputer output pins do not usually have a large enough  $I_{OL}$  to drive these devices directly, so an open collector gate (such as the 7405, 7406, 75492, 75451, or NPN transistors) can be used to sink current to ground or use an open emitter gate (like the 75491 or PNP transistors) to source current from the power supply. Darlington switches such as the ULN-2061 through ULN-2077 can be configured as either current sinks (open collector) or sources (open emitter). A device with an output current larger than the current required by the control element needs to be selected.

## Stepper Motors

A bipolar stepper motor has only two coils and four wires, as shown in [Fig. 23.4](#). Using the full-step algorithm, current always passes through both coils. The computer controls a bipolar stepper by reversing the direction of the currents. If the computer generates the sequence (positive, positive) (negative, positive) (negative, negative) (positive, negative), the motor will spin. A unipolar stepper motor is controlled by

**FIGURE 23.4** A hardware interface of a bipolar stepper motor and the linked-list data structure used by the software to spin the motor.

passing current through four coils, exactly two at a time. There are five or six wires on a unipolar stepper motor. For both types of stepper motors, the software outputs the sequence 1010, 1001, 0101, 0110 to spin the motor. The software makes one change (e.g., change from 1001 to 0101) to affect one step. The software repeats the entire sequence over and over at regular time intervals between changes to make the motor spin at a constant rate. Some stepper motors will move on half-steps by outputting the sequence 1010, 1000, 1001, 0001, 0101, 0100, 0110, 0010. Assuming the motor torque is large enough to overcome the mechanical resistance (load on the shaft), each output change causes the motor to step a predefined angle. One of the key parameters that determine whether the motor will slip (a computer change without the shaft moving) is the jerk, which is the derivative of the acceleration (i.e., third derivative of the shaft position). Software algorithms that minimize jerk are less likely to cause a motor slip. If the computer outputs the sequence in the opposite order, the motor spins in the other direction. A circular linked list data structure, as shown in Fig. 23.4, is a convenient software implementation that guarantees the proper motor sequence is maintained.

## 23.5 Data Acquisition Systems

Before designing a data acquisition system (DAS) the system goals must be clearly understood. The system can be classified as a quantitative DAS, if the specifications can be defined explicitly in terms of desired range, resolution, precision, and frequencies of interest. If the specifications are more loosely defined, we classify it as a qualitative DAS. Examples of qualitative DASs include systems that mimic the human senses where the specifications are defined using terms like “sounds good,” “looks pretty,” and “feels right.” Other qualitative DASs involve the detection of events. In these types of systems, the specifications are expressed in terms of specificity and sensitivity. For example, some premature infants stop breathing during sleep. If we can detect this event and “wake up the baby,” it will start breathing again. An apnea monitor is attached to the baby as it sleeps to alert the parents to this life-threatening event. Other binary detection systems include the presence/absence of a burglar or the presence/absence of cancer. A true positive (TP) is defined when the condition exists (the baby stops breathing) and the system properly detects it (the alarm rings). A false positive (FP) is defined when the condition does not exist (the baby is breathing normally) but the system thinks it exists (the alarm rings). A false negative (FN) occurs when the condition exists (the baby stops breathing) but the system does not think it exists (the alarm is silent, and baby dies). Sensitivity,  $TP/(TP + FN)$ , is the fraction of properly detected events (the baby stops breathing and the alarm rings) over the total number of events (the baby stops breathing). It is a measure of how well our system can detect an event. A sensitivity of 1 means the baby will not die. Specificity,  $TP/(TP + FP)$ , is the fraction of properly detected events (the baby stops breathing and the alarm rings) over the total number of detections (number of alarms). It is a measure of how much we believe the system is correct when it says it has detected an event. A specificity of 1 means when the alarm rings, the parents will rush to the baby’s crib and resuscitate the baby.

Many components are included in a data acquisition system. The transducer converts the physical signal into an electrical signal. The amplifier converts the weak transducer electrical signal into the range of the ADC (e.g., 0–5 V). The analog filter removes unwanted frequency components within the signal. The analog filter is required to remove aliasing error caused by the ADC sampling. A periodic interrupt is used to control the sampling process. The interrupt service routine will sample the ADC and store the data in a first-in-first-out queue. The data will be processed in the foreground by the main program. Examples of digital processing include digital filters, calibration calculations, event detection, and data display. Inherent in digital signal processing is the requirement that the ADC be sampled on a fixed time basis. Sampling at a known and fixed rate is particularly important when a digital filter is used.

The first decision to make is the ADC precision. Whether we have a qualitative or quantitative DAS, we choose the number of bits in the ADC so as to achieve the desired system specification. For a quantitative DAS, this is a simple task because the relationship between the ADC precision and the system measurement precision is obvious. For a qualitative DAS, experimental trials are often employed to evaluate the relationship between ADC bits and system performance.

The next decision is the sampling rate,  $f_s$ . The Nyquist theorem states we can reliably represent in digital form a band-limited analog signal if we sample faster than twice the largest frequency that exists in the analog signal. For example, if an analog signal only has frequency components in the 0–100 Hz range, then if sample are taken at a rate above 200 Hz, the entire signal can be reconstructed from the digital samples. One of the reasons for using an analog filter is to guarantee that the signal at the ADC input is band-limited. Violation of the Nyquist theorem results in aliasing. Aliasing is the distortion of the digital signal that occurs when frequency components above  $0.5 f_s$  exist at the ADC input. These high-frequency components are frequency shifted or folded into the 0– $0.5 f_s$  range.

## 23.6 Control Systems

---

### Digital Control Equations

A control system is a collection of mechanical and electrical devices connected for the purpose of commanding, directing, or regulating a physical plant. The real-state variables are the actual properties of the physical plant that are to be controlled. The goal of the sensor and data acquisition system is to estimate the state variables. Any differences between the estimated state variables and the real state variables will translate directly into controller errors. A closed loop control system uses the output of the state estimator in a feedback loop to drive the errors to zero. The control system compares these estimated state variables,  $x(n)$ , to the desired state variables,  $x^*$ , in order to decide appropriate action,  $u(n)$ . The terminology ( $n$ ) refers to the fact that these parameters are digital values sampled at finite-time intervals, where  $n$  is the sample number. The actuator is a transducer, which converts the control system commands,  $u(n)$ , into driving forces, which are applied to the physical plant. The goal of the control system is to drive  $x(n)$  to equal  $x^*$ . If the error is defined as the difference between the desired and estimated state variable:

$$e(n) = x^* - x(n) \quad (23.1)$$

then the control system will attempt to drive  $e(n)$  to zero. We usually evaluate the effectiveness of a control system by determining three properties: steady-state controller error, transient response, and stability. The steady state controller error is the average value of  $e(n)$ . The transient response is how long does the system take to reach 99% of the final output after  $x^*$  is changed. A system is stable if steady state (smooth constant output) is achieved. An unstable system may oscillate.

### Pulse Width Modulation

Many embedded systems must generate output pulses with specific pulse widths. The internal micro-computer clock is used to guarantee the timing accuracy of these outputs. Many microcomputers have built-in hardware that facilitates the generation of pulses. One classic example is the pulse-width modulated motor controller. The motor is turned on and off at a fixed frequency (see the *Out* signal in Fig. 23.5).

**FIGURE 23.5** An interface to a DC motor that uses PWM to control the delivered power and period measurement to determine the rotation speed.

The value of this frequency is chosen to be too fast for the motor to respond to the individual on/off signals. Rather, the motor responds to the average. The computer controls the power to the motor by varying the pulse width or duty cycle of the wave. The IRF540 MOSFET can sink up to 28 A. To implement pulse width modulation (PWM) the computer (either with the built-in hardware or the software) uses a clock. The clock is a simple integer counter that is incremented at a regular rate. The *Out* signal is set high for time  $T_h$  then set low for time  $T_l$ . Since the frequency of *Out* is to be fixed,  $(T_h + T_l)$  remains constant, but the duty cycle  $T_h/(T_h + T_l)$  is varied. The precision of this PWM system is defined to be the number of distinguishable duty cycles that can be generated. Let  $h$  and  $l$  be integer numbers representing the number of clock counts the *Out* signal is high and low, respectively. We can express the duty cycle as  $h/(h + l)$ . Theoretically, the precision should be  $h + l$ , but practically the value may be limited by the speed of the interface electronics.

## Period Measurement

In order to sense the motor speed, a tachometer can be used. The AC amplitude and frequency of the tachometer output both depend on the shaft speed. It is usually more convenient to convert the AC signal into a digital signal (*In* shown in the Fig. 23.5) and measure the period. Again, many microcomputers have built-in hardware that facilitates the period measurement. To implement period measurement the computer (again either with the built-in hardware or the software) uses a clock. Period measurement simply records the time (value of the clock) of two successive rising edges on the input and calculates the time difference. The period measurement resolution is defined to be the smallest difference in period that can be reliably measured. Theoretically, the period measurement resolution should be the clock period, but practically the value may be limited by noise in the interface electronics. The software can calculate shaft speed, because the frequency is one over the period.

## Control Algorithms

There are many common approaches to designing the software for the control system. The simplest approach to the closed-loop control system uses incremental control. In this motor control example, the actuator command,  $u$ , is the duty cycle of the pulse-width-modulated system. An incremental control algorithm simply adds or subtracts a constant from  $u$  depending on the sign of the error. To add hysteresis to the incremental controller, we define two thresholds,  $x_H$ ,  $x_L$ , at values just above and below the desired speed,  $x^*$ . In other words, if  $x < x_L$  (the motor is spinning too slow) then  $u$  is incremented, and if  $x > x_H$  (the motor is spinning too fast) then  $u$  is decremented. It is important to choose the proper rate at which the incremental control software is executed. If it is executed too many times per second, then the actuator

will saturate resulting in a bang-bang system like Fig. 23.2. If it is not executed often enough, then the system will not respond quickly to changes in the physical plant or changes in  $x^*$ .

A second approach, called proportional integral derivative (PID), uses linear differential equations. To simplify the PID controller, we break the controller equation into separate proportion, integral and derivative terms, where  $p(n)$ ,  $i(n)$ , and  $d(n)$  are the proportional, integral, and derivative components, respectively. In order to implement the control system with the microcomputer, it is imperative that the digital equations be executed on a regular and periodic rate (every  $\Delta t$ ). The relationship between the real time,  $t$ , and the discrete time,  $n$ , is simply  $t = n\Delta t$ . If the sampling rate varies, then controller errors will occur. The proportional term makes the actuator output linearly related to the error. Using a proportional term creates a control system that applies more energy to the plant when the error is large.

$$p(n) = k_p e(n) \quad (23.2)$$

The integral term makes the actuator output related to the integral of the error. Using an integral term often will improve the steady state error of the control system. If a small error accumulates for a long time, this term can get large. Some control systems put upper and lower bounds on this term, called anti-reset-windup, to prevent it from dominating the other terms. The implementation of the integral term requires the use of a discrete integral or sum. If  $i(n)$  is the present control output, and  $i(n-1)$  is the previous calculation, the integral term is simply

$$i(n) = i(n-1) + k_i e(n) \quad \text{where} \quad i_{\min} \leq i(n) \leq i_{\max} \quad (23.3)$$

The derivative term makes the actuator output related to the derivative of the error. This term is usually combined with either the proportional and/or integral term to improve the transient of the control system. The proper value of  $k_d$  will provide for a quick response to changes in either the set point or loads on the physical plant. An incorrect value may create an overdamped (very slow response) or an underdamped (unstable oscillations) response. There are a couple of ways to implement the discrete time derivative. A simple approach is

$$d(n) = k_d (x(n) - x(n-1)) \quad (23.4)$$

In practice, this first order equation is quite susceptible to noise. More sophisticated calculations can be found in reference [1]. The PID controller software is also implemented with a periodic interrupt every  $\Delta t$ . The interrupt handler first estimates the state variable,  $x(n)$ , and then calculates  $e(n)$ . The next actuator output is calculated by combining the three terms.

$$u(n) = p(n) + i(n) + d(n) \quad (23.5)$$

A third approach uses fuzzy logic to control the physical plant. Fuzzy logic can be much simpler than PID. It will require less memory and execute faster. When complete knowledge about the physical plant is known, then a good PID controller can be developed, i.e., the physical plant can be described with a linear system of differential equations, an optimal PID control system can be developed. Because the fuzzy logic control is more robust (still works even if the parameter constants are not optimal), then the fuzzy logic approach can be used when complete knowledge about the plant is not known or can change dynamically. Choosing the proper PID parameters requires knowledge about the plant. The fuzzy logic approach is more intuitive, following more closely to the way a "human" would control the system. If there is no set of differential equations that describe the physical plant, but there exists expert knowledge (human intuition) on how it works, then a good fuzzy logic system can be developed. It is easy to modify an existing fuzzy control system into a new problem. So if the framework exists, rapid prototyping is possible. Examples of fuzzy logic implementations can be found in reference [1].

# 23.7 Remote or Distributed Systems

Many embedded systems require the communication of command or data information to other modules at either a near or a remote location. We will begin our discussion with communication with devices within the same room as presented in Fig. 23.6. A full-duplex channel allows data to transfer in both directions at the same time. In a half-duplex system, data can transfer in both directions but only in one direction at a time. Half-duplex is popular because it is less expensive (two wires) and allows the addition of more devices on the channel without change to the existing nodes. If the distances are short, half-duplex can be implemented with simple open collector TTL-level logic. Many microcomputers have open collector modes on their serial ports that allow a half-duplex network to be created without any external logic (although pull-up resistors are often used). Three factors will limit the implementation of this simple half-duplex network: (1) the number of nodes on the network, (2) the distance between nodes, and (3) presence of corrupting noise. In these situations a half-duplex RS485 driver chip, such as the SP483 made by Sipex or Maxim, can be used. The master-slave system connects the master transmit output to all slave receive inputs. This provides for broadcast of commands from the master. All slave transmit outputs are connected together using wire or open collector logic, allowing for the slaves to respond one at a time. The ring network is a simple distributed approach, because it can be constructed using standard serial ports, by chaining the transmit and receive lines together in a circuit, as shown in Fig. 23.6.

A very common approach to distributed embedded systems is called multi-drop. To transmit a byte to the other computers, the software activates the SP483 driver and outputs the frame. Since it is half-duplex, the frame is also sent to the receiver of the computer that sent it. This echo can be checked to see if a collision occurred (two devices simultaneously outputting.) If more than two computers exist on the network, address information is usually sent first, so that the proper device receives the data.

Within the same room, IR light pulses can be used to send and receive information. This is the technology used in the TV remote control. In order to eliminate background EM radiation from triggering a false communication, the signals are encoded as a series of long and short pulses that resemble bar codes.

A number of techniques are available for communicating across longer distances. Within the same building the X-10 protocol can be used. The basic idea is to encode the binary stream of data as 120 kHz pulses and mix them onto the standard 120 V 60 Hz AC power line. For each binary one, a 120 kHz pulse is added at the zero crossing of the 60 Hz wave. A zero is encoded as the absence of the 120 kHz pulse. Because there are three phases within the AC power system, each pulse is repeated also 2.778 ms, and 5.556 ms after the zero crossing. It is decoded on the receiver end. X-10 has the flexibility of adding or expanding communication capabilities in a building without rewiring. The disadvantage of X-10 is that the bandwidth is fairly low (about 120 bits/s) when compared to other techniques. A typical X-10 message includes a 2-bit start code, a 4-bit house code, and a 5-bit number code requiring 11 power line cycles to transmit. A second technique for longer distances is RF modulation. The information is modulated on the transmitted RF and demodulated at the receiver. Standard telephone modems and the Internet can also be used to establish long distance networks.

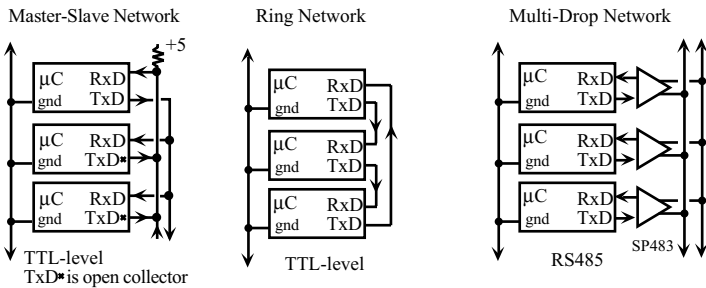

FIGURE 23.6 Three simple configurations for distributed embedded systems.

Two approaches are used to synchronize the multiple computers. In a master/slave system, one device is the master, which controls all the other slaves. The master defines the overall parameters that govern the functions of each slave and arbitrates requests for data and resources. This is the simplest approach but may require a high-bandwidth channel and a fast computer for the master. Collisions are unlikely in a master/slave system if the master can control access to the network.

The other approach is distributed communication. In this approach each computer is given certain local responsibilities and certain local resources. Communication across the network is required when data collected in one node must be shared with other nodes. A distributed approach will be successful on large problems that can be divided into multiple tasks that can run almost independently. As the interdependence of the tasks increase so will the traffic on the network. Collision detection and recovery are required due to the asynchronous nature of the individual nodes.

### 24.1 Introduction

---

Signals are traditionally classified as being analog (continuous-time), discrete-time (sample-data), or digital. A continuous-time signal has infinite precision in both the time- and amplitude-domain. Discrete-time signals have infinite amplitude precision, but are discretely resolved in time (sampled). Digital signals are of finite precision in both the time (sampled) and amplitude (quantized). Digital signals are either synthesized by a digital system (e.g., computer), or digitized by quantizing the sample values of an analog signal using an analog-to-digital converter (ADC). A digital-to-analog converter (DAC) maps a digital signal into an analog signal. Signal processing refers to the science of analyzing, synthesizing, and manipulating audio, acoustic, speech, video, image, geophysical, radar, radio signals, plus a host of other signals, using mathematical and experimental methods. Signal may be scalars, of one, two, or  $M$  dimensions, of finite or infinite duration. Digital signal processing (DSP) refers to the processing of digital or digitized signals using digital technologies. DSP system elements can be linear or nonlinear and perform in the time (e.g., filter) or transform domain (e.g., frequency). The processing agents range from mathematical and statistical abstractions or processes, to tangible software and hardware systems. DSP systems must often be designed to meet restrictive real-time speed, precision, dynamic range requirements in multisignal, multisystem environments. The design of a DSP solution, therefore, requires a concurrent knowledge of signal processing methods and technology.

DSP is currently a major market force, consisting of semiconductor, hardware, software, methodology, application, and training sectors. The origins of DSP are open to debate, but a seminal moment surely occurred when Claude Shannon developed an understanding of sample-data signal processing in the middle of the 20th century. Shannon's sampling theorem states that if an analog signal, having a highest frequency bounded by  $B$  Hz, is sampled at a rate in excess of  $f_s > B$  Hz, then it can be perfectly reconstructed (exactly) from its sample values. The critical parameter  $f_N = f_s/2$  is called the *Nyquist frequency* and represents a strict upper frequency bound on the highest baseband frequency allowed in the sampled signal (i.e.,  $B$ ). Most DSP solutions are over-sampled, operating at a sample frequency far in excess of its minimally required value. If a signal is under-sampled at a rate below the minimum rate of  $2B$  Hz, *aliasing* errors can occur. An aliased signal is a baseband signal whose sample values impersonate those of a signal having

frequency components in excess  $B$  Hz. Another early enabler of the DSP revolution was the Cooley–Tukey fast Fourier transform (FFT) algorithm. The FFT made many signal-processing tasks practical for the first time using, in many instances, only software. Another defining DSP moment occurred when the first DSP microprocessors (DSP  $\mu$ p) made a marketplace appearance beginning in the late 1970s. These devices provided an affordable and tangible means of developing hardware and embedded solutions with a minimum risk and effort. Regardless of the origins, today’s DSP objects and systems have become part of a pervasive technology, appearing in a myriad of applications, and supported with a rich and deep technological infrastructure. DSP is now a discipline unto itself, with its own professional societies, academic programs, trained practitioners, and industrial infrastructure.

## 24.2 Digital Signals and Systems

Digital systems process digital signals in the time or frequency-domain. Systems can be analyzed and characterized by the system’s response to a pure impulse (i.e.,  $\delta[k]$ ), called the *impulse response* denoted  $h[k] = \{h[0], h[1], h[2], \dots\}$ . The sequence of sample values  $h[k]$ , called a *time-series*, can also be mathematically represented using a *z-transform*. The *z-transform* of an arbitrary time-series  $x[k]$ , consisting of sample values  $x[k] = \{x[0], x[1], x[2], \dots\}$ , is given by  $X(z) = \sum_{k=0}^{\infty} x[k]z^{-k}$ . The  $z$  operator is defined in terms of the Laplace transform delay operator, namely  $z = e^{-sT_s}$ , where  $T_s$  is the sample period. The *z-transforms* of common signals are reported in standard table of *z-transforms*, such as those shown in Table 24.1. The common signals shown in Table 24.1 can be manipulated and combined, using the property list shown in Table 24.2, to synthesize higher-order and more complex signals. In addition to the properties listed in Table 24.2, the initial value theorem  $x[0] = \lim_{z \rightarrow \infty} X(z)$  and the final value theorem  $x[\infty] = \lim_{z \rightarrow \infty} (z - 1)X(z)$  provide a convenient means of evaluating two end points of a time-series. The mapping of a *z-transformed* signal  $X(z)$  back into the time-domain is performed in a piecemeal manner. Specifically, the inverse *z-transform*  $X(z)$  is normally expressed in partial fraction, or Heaviside expansion having the form  $X(z) = \sum_{i=1}^M A_i X_i(z)$ , where  $X_i(z)$  is an element of Table 24.1 corresponding to a discrete-time signal  $x_i[k]$ , with  $A_i$  is a Heaviside coefficient associated with the term  $X_i(z)$ . The inverse *z-transform* of  $X(z)$  is given by  $x[k] = \sum_{i=1}^M A_i x_i[k]$ .

**TABLE 24.1** *z*-Transforms of Primitive Time Functions

Discrete-time signal $x[k]$	<i>z</i> -transform $X(z)$
$\delta[k]$ (impulse)	1
$u[k]$ (unit step)	$z/(z - 1)$
$a^k u[k]$ (exponential)	$z/(z - a)$
$\sin[bkT_s]u[kT_s]$ (sine wave)	$\sin(bT_s)z/(z^2 - 2z \cos(bT_s) + 1)$
$\cos[bkT_s]u[kT_s]$ (cosine wave)	$(z - \cos(bT_s))z/(z^2 - 2z \cos(bT_s) + 1)$
$a^k \sin(bkT_s)u[kT_s]$ (damped sine)	$a \sin(bT_s)z/(z^2 - 2az \cos(bT_s) + a^2)$
$a^k \cos(bkT_s)u[kT_s]$ (damped cosine)	$(z - a \cos(bT_s))z/(z^2 - 2az \cos(bT_s) + a^2)$

**TABLE 24.2** Properties of *z*-Transforms

Property	Time-Series	<i>z</i> -Transform
Linearity	$x_1[k] + x_2[k]$	$X_1(z) + X_2(z)$
Real scaling	$ax[k]$	$aX(z)$
Complex scaling	$w^k x[k]$	$X(z/w)$
Time reversal	$x[-k]$	$X(1/z)$
Modulation	$e^{-ak} x[k]$	$X(e^d z)$
Summation	$\sum_{n=-\infty}^k x[n]$	$zX(z)/(z - 1)$
Shift delay	$x[k - 1]$	$z^{-1}X(z) - zx[0]$

The output of a linear system having an impulse response  $h[k]$  to an input  $x[k]$  is denoted  $y[k]=h[k] \times x[k]$ , where  $y[k]$  is defined by the discrete-time *linear convolution* sum

$$y[k] = - \sum_{m=1}^N a_m y[k - m] + \sum_{m=0}^M b_m x[k - m].$$

Computing the convolution sum is rare. Instead, a linear system is generally analyzed using simulation, emulation, or the  $z$ -transform. The *convolution theorem* states that the linear convolution  $y[k] = h[k] \times x[k]$  of a  $z$ -transformable impulse response  $h[k]$  (i.e.,  $H(z) = \sum_{k=-\infty}^{\infty} h[k]z^{-k}$ ) and input  $x[k]$  (i.e.,  $X(z) = \sum_{k=-\infty}^{\infty} x[k]z^{-k}$ ), is given by the inverse  $z$ -transform of the product  $Y(z)=H(z)X(z)$ . This method is only viable in instances where the  $z$ -transform of  $h[k]$  and  $x[k]$  have been precomputed or tabled, and the inverse  $z$ -transform of  $Y[z]$  can be computed. While  $H(z)$  is generally known, most real signals are arbitrary and possibly noise contaminated, making the general availability of  $X(z)$  questionable. Nevertheless, the importance of this equation has resulted in the elements being given specific titles and meaning. The  $z$ -transform of the impulse response  $h[k]$ , namely  $H(z)$ , is called the system's *transfer function* and has the general form

$$H(z) = Y(z)/X(z) = \sum_{m=0}^M b_m z^{-m} / \sum_{m=0}^N a_m z^{-m} = N(z)/D(z).$$

The filter's *poles* ( $p_m$ ) and *zeros* ( $z_m$ ) are the roots of  $D(z)=0$  and  $N(z)=0$ , respectively. The system's steady-state frequency response can be determined by evaluating the transfer function  $H(z)$  along the trajectory  $z = e^{j\omega}$ , where  $\omega \in [-\pi, \pi]$  which represents a normalized baseband frequency range  $[-f_s/2, f_s/2]$  ( $\pm$ Nyquist frequency). Specifically, the frequency response of a system in magnitude-phase form is  $H(e^{j\omega}) = |H(e^{j\omega})| \angle \phi(e^{j\omega})$ .

## 24.3 Digital Filters

Transfer functions, when implemented in the time-domain, result in digital filters. The attributes of a digital filter can be specified in the time- or frequency-domain, or both. Digital filters can be grouped into three broad classes called finite impulse response (FIR), infinite impulse response (IIR), and multirate filters.

### Finite Impulse Response (FIR) Filters

An FIR filter possesses an impulse response that persists only for a finite number of sample values. The impulse response of an  $N$ th order FIR is given by  $h[k] = \{h[0], \dots, h_{N-1}[k]\}$ , and in the  $z$ -transform domain by  $H(z) = \sum h_i z^{-i}$ ,  $i \in [0, N - 1]$ . One of the attributes of an FIR is its simplicity, consisting of a string of multiply-accumulations (MACs), and shifts registers. The steady-state frequency response of an FIR  $H(z)$  is given by  $H(e^{j\omega}) = |H(e^{j\omega})| \angle \phi(e^{j\omega})$ . A system is said to possess a *linear phase response* if  $\phi(e^{j\omega}) = \alpha\omega + \beta$  (i.e., linear in frequency). Linear phase filters are important in a number of applications including (1) synchronizing phase modulated data streams, (2) anti-aliasing filters placed in front of signal phase sensitive analysis subsystems (e.g., FFT), and (3) use in phase sensitive applications (e.g., image processing). Linear phase filtering can be guaranteed whenever the coefficients of an  $N$ th order FIR are symmetrically distributed about the filter's mid-point  $L = (N-1)/2$  (i.e.,  $h_i = \pm h_{N-i}$ ,  $i = 0, \dots, L$ ). The resulting phase response satisfies the linear phase equation  $\angle \phi(\omega) = -L\omega + \{0, \pm\pi\}$ . Another important phase response measure is called the group delay, given by  $\tau_g = -d\phi(e^{j\omega})/d\omega$ . For a linear phase FIR,  $\tau_g = L$ , which indicates that the filter propagation delay is always  $L$  clock cycles regardless of the input signal frequency.

**TABLE 24.3** Effects of Data Windows

Window	Transition Width $f_s/N$	Highest Sidelobe in dB
Rectangular	0.9	-13
Hann	2.07	-31
Hamming	2.46	-41
Blackman	3.13	-58
Kaiser ( $\beta = 2.0$ )	1.21	-19

**FIGURE 24.1** Comparison of direct and equiripple FIR designs.

FIR design methods are well known and well developed. The simplest design technique is called the direct, or window method. The design process begins with a specification of the desired filter frequency response  $H(e^{j\omega})$ . An  $M$ -harmonic ( $M \gg 1$ ) inverse Fourier transform (IFFT) of  $H(e^{j\omega})$  is computed, which defines an  $M$ -sample time-series  $h'[k]$  that is an approximation to the desired FIR impulse response. Normally, the long  $M$ -sample symmetric time-series is symmetrically reduced to an  $N$ -sample impulse response  $h[k]$ , defined by the  $N$  central values of  $h'[k]$ . The major weakness of the direct design paradigm is that the approximation errors in the frequency domain can be locally large about points of discontinuity of  $H(e^{j\omega})$ , as shown in Fig. 24.1. A commonly used design criteria that overcomes this weakness is based on a minimax error criterion. The minimax criterion requires that the maximum value of the approximation error be minimized. A minimax FIR is characterized by the frequency domain errors having an equiripple (equal ripple) envelope. Thus, this class of FIR is logically referred to as an equiripple filter and has a typical magnitude frequency response shown in Fig. 24.1.

Windows are tools that are sometimes used to improve the shape of an FIR's frequency domain envelope. An  $N$ -sample data window is applied to an  $N$ th-order FIR on a sample-by-sample basis according to the rule  $h_w[k] = h[k]w[k]$ , where  $h[k]$  is an FIR's impulse response,  $w[k]$  is a window function, and  $h_w[k]$  is the windowed FIR impulse response. In the frequency domain, the effect of a window is defined by the convolution operation  $H_w(\omega) = H(\omega) * W(\omega)$ , which results in a tendency to smooth the envelope of the parent FIR's frequency response. The attributes of a window are defined by the width of the center (main) lobe and sideband suppression in the frequency domain (see Table 24.3). Common window functions are rectangular, Hann, Hamming, Blackman, Kaiser, and Flat Top. The effect of a window on the direct FIR frequency response shown in Fig. 24.1 is also displayed in Fig. 24.2.

## Infinite Impulse Response (IIR) Filters

Filters containing feedback are called IIR filters. With feedback, an IIR's impulse response can be infinitely long. The presence of feedback allows an IIR to achieve very high frequency selectivity and near resonance behavior. An  $N$ th-order constant coefficient IIR filter can be modeled by the transfer function

$$H(z) = N(z)/D(z) = \sum_{i=0}^M b_i z^{-i} / \sum_{i=0}^N a_i z^{-i} = K(z^{N-M}) \prod_{i=0}^{M-1} (z - z_i) / \prod_{i=0}^{N-1} (z - p_i)$$

where the filter's zeros  $\{z_i\}$  are the roots of  $N(z) = 0$ , and the filter's poles  $\{p_i\}$  are the roots of  $D(z) = 0$ .

**FIGURE 24.2** Effects of windowing an FIR. Note that the windowed spectrum is smoothed and has an increased transition bandwidth.

The frequency response of an  $N^{\text{th}}$ -order IIR is given by

$$H(e^{j\omega}) = \sum_{i=0}^M b_i e^{-j\omega i} / \sum_{i=0}^N a_i e^{-j\omega i} = (K e^{j\omega(N-M)}) \prod_{i=0}^{M-1} (e^{j\omega} - z_i) / \prod_{i=0}^{N-1} (e^{j\omega} - p_i)$$

evaluated over the normalized frequency range  $\omega \in [-\pi \leq \omega \leq \pi]$ , which defines the baseband frequency range bounded by  $\pm f_{\text{Nyquist}}$ .

The traditional IIR design strategy is based on converting classic analog filter models into their digital filter equivalents. Throughout the first half of the 20th century, analog radio filter engineers created classic Bessel, Butterworth, Chebyshev, and Elliptic (Cauer) filter instantiations whose magnitude frequency response emulates that of an ideal filter. To standardize the analog filter design procedures, a set of normalized  $-1$  dB or  $-3$  dB lowpass filter models, having a  $1.0$  rad/s passband were created. These models were reduced to tables, charts, and graphs and are called *analog prototype* filters. The prototype lowpass filters can be the frequency scaled to define an analog lowpass, highpass, bandpass, and bandstop filters  $H(s)$ , having desired frequency-domain attributes. The classic analog filter  $H(s)$  can then be converted into a digital filter model  $H(z)$  to define a classic digital filter (See [Table 24.4](#)). The basic domain conversion techniques (i.e.,  $H(s) \rightarrow H(z)$ ) are (1) the impulse-invariant and (2) bilinear  $z$ -transform methods.

The impulse invariance filter design method results in a digital filter having an impulse response  $h[k]$  that agrees with that of the parent analog filter's impulse response  $h_a(t)$ , up to a scale factor ( $h[k] = T_s h_a(kT_s)$ ). An impulse invariant design can be of significant value in applications, such as automatic control, where design objectives are defined in the time-domain (e.g., rise-time, overshoot, settling time). If the parent analog filter's impulse response  $h_a(t)$ , or transfer function  $H_a(s)$  are known, then the impulse invariant digital filter is defined by

$$h_a(t) \Leftrightarrow H_a(s) = \sum_{i=1}^N \frac{a_i}{(s + p_i)} \Leftrightarrow \left(\frac{1}{T_s}\right) \sum_{i=1}^N \frac{a_i}{(1 + e^{-p_i T_s} z^{-1})} = \left(\frac{1}{T_s}\right) H(z) \Leftrightarrow \left(\frac{1}{T_s}\right) h[k]$$

and in the frequency-domain by

$$H(e^{j\Omega}) = \left(\frac{1}{T_s}\right) \sum_{k=-\infty}^{\infty} H_a\left(j\left(\frac{\Omega}{T_s} - \frac{2\pi k}{T}\right)\right)$$

**TABLE 24.4** Comparisons of  $N$ th-Order Classic IIR Lowpass Filters Having  $f_s = 50$  kHz, a  $-3$  dB 15 kHz Passband, 5 kHz Transition Band, and  $-50$  dB Stopband

Type	Order	Passband	Stopband	Magnitude Frequency Response
Butterworth	High ( $N = 8$ )	Smooth	Smooth	<div style="display: flex; align-items: flex-start;"> <div style="margin-right: 10px;">                     Generated — Desired - - - 1.000                 </div> <div style="text-align: center;"> </div> </div>
Chebyshev I	Medium ( $N = 5$ )	Ripple	Smooth	<div style="display: flex; align-items: flex-start;"> <div style="margin-right: 10px;">                     Generated — Desired - - - 1.000                 </div> <div style="text-align: center;"> </div> </div>
Chebyshev II	Medium ( $N = 5$ )	Smooth	Ripple	<div style="display: flex; align-items: flex-start;"> <div style="margin-right: 10px;">                     Generated — Desired - - - 1.000                 </div> <div style="text-align: center;"> </div> </div>
Elliptic	Low ( $N = 4$ )	Ripple	Ripple	<div style="display: flex; align-items: flex-start;"> <div style="margin-right: 10px;">                     Generated — Desired - - - 1.000                 </div> <div style="text-align: center;"> </div> </div>

This equation exhibits a weakness of the impulse invariant design method. For any physically meaningful sampling rate  $f_s = 1/T_s$ , aliasing errors can occur whenever the analog filter passes components at frequencies greater than  $2f_s$ . Typically, analog filters have a gain that is finite for all frequencies. The aliased filter energy can be mapped back into the baseband and can distort (sometimes significantly) the frequency response of an impulse invariant filter. As a result, the impulse invariant method is generally only used to design frequency selective filters that are decidedly lowpass.

When meeting frequency domain specifications is the design objective, the *bilinear z-transform* method is normally used. The bilinear  $z$ -transform maps a classic analog filter  $H_a(s)$  into a digital filter  $H(z)$  without introducing aliasing errors. The bilinear  $z$ -transform establishes a relationship between the  $s$ - and  $z$ -domain, given by  $s = (2/T_s)(z + 1)/(z - 1)$ . The bilinear  $z$ -transform also defines an algebraic connection between the analog and digital frequency axis given by  $\omega = (2/T_s)\tan(\varpi/2)$ , where  $\omega$  is the analog frequency,  $|\omega| < \infty$ , and  $\varpi$  is the normalized digital frequency range  $-\pi/2 \leq \varpi < \pi$ , corresponding to the

frequency range  $\pm f_{\text{Nyquist}} = \pm f_s/2$ . The mapping from analog frequencies  $\omega$  to digital frequencies  $\varpi$  is called *warping*, and *pre-warping* in the opposite direction. The bilinear  $z$ -transform design paradigm is a multistep process consisting of the following steps:

1. Define the digital filter's frequency-domain attributes (gains at critical frequencies).
2. Prewarp the critical digital frequencies  $\varpi$  into analog frequencies  $\omega$ .
3. Design a prewarped classic analog filter  $H_a(s)$  that meets specified passband and stopband gain requirements.
4. Apply the bilinear  $z$ -transform to convert  $H_a(s)$  into a digital filter  $H(z)$ . In the process, the prewarped analog filter frequencies  $\omega$  will be warped back to their original locations  $\varpi$ .

## Multirate Systems

DSP systems that contain multiple sample rates are called *multirate* systems. A signal  $x[k]$ , sampled at a rate  $f_{\text{in}}$ , is said to be *decimated* by  $M$  if it is exported at a rate  $f_{\text{out}} = f_{\text{in}}/M$ , where  $M > 1$ . Mathematically, the decimated signal  $x_d[k]$  can be expressed as  $x_d[k] = x[Mk]$ , indicating that only every  $M$ th sample of the fast sampled time-series  $x[k]$  is retained in the decimated signal  $x_d[k]$ . Decimation can also be modeled in the  $z$ -transform domain as  $X_d(z) = X(z^M)$  and  $X_d(e^{j\varpi}) = X_d(e^{jM\varphi})$  in the frequency domain, as suggested in Fig. 24.3. In order to insure that a signal  $x[k]$  can be reconstructed from its decimated samples of  $x_d[k]$ , Shannon's sampling theorem must be obeyed. Specifically, if the minimum sampling frequency is bounded by  $f_s > 2B$  Hz, the maximum decimation rate must be bounded by  $M \leq f_s/2B$ . Decimation is routinely found in audio signal and video data transmission and signal compression applications, and interfacing equipment with dissimilar fixed sample rates. By reducing the system's sample rate by a factor  $M$ , arithmetic bandwidth requirements can often be reduced by a similar amount.

*Interpolation* is the antithesis of decimation. While decimation is used to reduce the sampling rate, interpolation is used to increase the sample rate. A signal  $x[k]$ , sampled at a rate  $f_{\text{in}}$ , is said to be interpolated by  $N$  if  $x_i[k] = x[k]$  whenever  $k \equiv 0$  modulo  $(N)$ , and zero elsewhere. The interpolated signal  $x_i[k]$  is a time-series consisting of  $N - 1$  zeros separated by the sample values  $x[k]$  and  $x[k + N]$  and is clocked at a rate  $f_{\text{out}} = Nf_{\text{in}}$   $N > 1$ . In the  $z$ -transform domain,  $X_i(z) = X(z^N)$ , and  $X_i(e^{j\varphi}) = X(e^{jN\varphi})$  in the frequency-domain, as shown in Fig. 24.3. It can be noted that the interpolated spectrum contains multiple copies of the baseband spectrum  $X(e^{j\varphi})$ , where the unwanted copies can be removed using a lowpass filter.

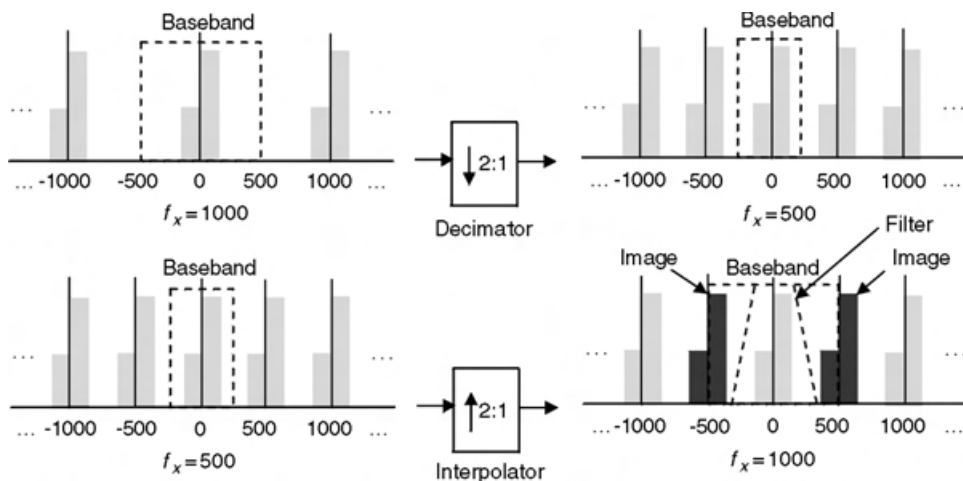

FIGURE 24.3 Multirate system elements showing decimation (top) and interpolation (bottom).

### Special Filter Cases

Besides baseline FIR, IIR, and multirate filters (which are based on FIR or IIR elements), other classes of digital filters are found in common use. One of the most important of these is the adaptive filter. An adaptive filter modifies the filter coefficients during run-time in order to respond to measurable changes in the signal and system environment. The adaptation rules and procedures, generally based on a squared error criteria, range from simple to sophisticated, establishing trade-offs between implementation simplicity and accuracy. Adaptive filters that contain nonlinear elements are called neural networks. Some filters classes are defined in terms of special features of their defining mathematical framework. Wavelets, for example, are basis functions that satisfy a formal set of scaling and dilatation rules. They often appear as a multirate solution consisting of collections of sub-filters defined by wavelet basis functions that have been selected to match signal-specific signal attributes or features.

### Digital Filter Architecture

The physical implementation of a particular FIR or IIR filter is called an *architecture*. Architectures specify how a digital filter is assembled using a collection of DSP primitive objects, such as shift-registers, multipliers, and adders. The choice of architecture has a direct influence on the performance, cost, power consumption, and precision of the design outcome. Common FIR architectures are the direct, transpose, and lattice implementations. Common IIR architectures include (1) direct I and II, (2) normal (optimized second-order section), (3) cascade ( $H(z) = \prod H_i(z)$ ,  $H_i(z)$  a first or second order direct II or normal subsystem), (4) parallel ( $H(z) = \sum H_i(z)$ ,  $H_i(z)$  a first- or second-order direct II or normal subsystem), (5) ladder-lattice, and (6) wave. Architectures are often instantiated in terms of a *state variable* model. The state variable model for a single-input single-output,  $n$ th order IIR, having an arbitrary architecture is given in terms of a state equation  $\mathbf{x}[k + 1] = \mathbf{A}\mathbf{x}[k] + \mathbf{b}u[k]$ , and output equation  $y[k] = \mathbf{c}^T \mathbf{x}[k] + du[k]$ , where  $\mathbf{x}[k]$  is an  $n$ -vector,  $y[k]$  and  $u[k]$  are scalars,  $\mathbf{A}$  is an  $n \times n$  matrix, and  $\mathbf{b}$  and  $\mathbf{c}$  are  $n$ -vectors, and  $d$  is a scalar. The  $i$ th state of the digital filter,  $x_i[k]$  resides in the system's  $i$ th shift register. The coefficient  $A_{ij}$  denotes the filter gain existing between the  $i$ th and  $j$ th shift register,  $\mathbf{b}_i$  represents the gain between input and  $i$ th shift register,  $\mathbf{c}_i$  the gain between  $i$ th shift register and output, and  $d$  is the direct path gain between input and output. The state variable model is interpreted in Fig. 24.4, where the  $n$  states of the system are stored in  $n$  shift registers. The filter complexity and run-time dynamic range requirements of a system in state variable form can be mathematically computed or predicted. The dynamic range requirements are generally expressed in terms of the  $l_p$  norm of the states, namely  $\|\mathbf{x}_i[k]\|_p$ , for  $p = 1, 2$ , and  $\infty$ , where  $\|\mathbf{x}_i[k]\|_p = (\sum |x_i[k]|^p)^{1/p}$ . These norms are used to scale a filter in order to protect it against run-time register overflow, a serious error condition. Errors of less severity, which can nevertheless adversely influence system performance, are coefficient and arithmetic roundoff errors. Another minor error source is called limit cycling, a phenomenon that relates to the least significant bits of the output being “toggling” (producing a dynamically changing output) while the input is zero. Of the common architectural choices, cascade is the most popular and generally provides a good balance between

FIGURE 24.4 State variable system model where  $x[k]$  is the state vector,  $u[k]$  the input, and  $y[k]$  the output.

performance, complexity, and precision. Direct II filters are known to be low-complexity, but often suffer from low precision. Parallel filters exhibit certain fault tolerance attributes, ladder-lattice have good coefficient roundoff error immunity, but are comparatively complex.

## 24.4 Fourier and Spectral Analysis

The frequency-domain analysis and representation techniques can provide invaluable information about a signal and a system’s environment. The mapping between the time- and frequency-domain are traditionally defined by a Fourier transform. The historic difficulty in computing a Fourier transform of an arbitrary signal radically changed in 1965 when Cooley and Tukey introduced the now celebrated FFT algorithm. For over three decades, the FFT established that a time-series  $x[k]$  can be efficiently mapped into a frequency-domain using a general purpose digital computer. The FFT is a special manifestation of a more general class of transform called the discrete Fourier transform (DFT). The DFT defines a mapping of an  $N$ -sample time-series  $x_N[k]$  (possibly complex) into an  $N$ -harmonic complex frequency domain distribution  $X[n]$ , where  $X[n]$  is called the  $n$ th harmonic. The DFT of the  $N$ -sample time-series  $x_N[k]$  is given by the *analysis equation*

$$X[n] = \sum_{k=0}^{N-1} x_N[k] W_N^{nk}, \quad n \in [0, N - 1]$$

where  $W_N = e^{-j2\pi/N}$ . The DFT is also known to be periodic with period  $N$  (i.e.,  $X[n] = X[n \pm kN]$ ). The inverse transform is given by *synthesis equation*

$$x_N[k] = \frac{1}{N} \sum_{n=0}^{N-1} X[n] W_N^{-nk}, \quad n \in [0, N - 1]$$

The DFT is parameterized in a manner shown in Table 24.5, and computes an  $N$ -harmonic spectrum using  $N^2$  complex-multiply accumulates. The FFT algorithm significantly reduced the computational complexity of performing a DFT to  $N \log_2(N)$ . In general, a long FFT can be constructed from a collection of small DFTs. Using the Cooley–Tukey FFT ordering algorithm, a DFT of length  $N = \prod N_i$  can be created. Using the Good–Thomas ordering algorithm, a length  $N = \prod N_i$  ( $N_i$  and  $N_j$  relatively prime) transform result. For example, using a  $N_1 = 15$ ,  $N_2 = 16$ , and  $N_3 = 17$ -point DFTs, an  $N = 4080$ -point DFT can be computed.

In addition to the classic FFT, there are other spectral analysis techniques found in common use. One is called the chirp-z DFT that implements a DFT using linear convolution. The convolution filter has an

**TABLE 24.5** DFT Parameters

DFT Parameter	Notation or Units
Sample size	$N$ samples
Sample period	$T_s$ seconds
Record length	$T = NT_s$ seconds
Number of harmonics	$N$ harmonics
Number of positive (negative) harmonics	$N/2$ harmonics
Frequency spacing between harmonics	$\Delta f = 1/T = 1/NT_s = f_s/N$ Hz
DFT frequency (one-sided baseband range)	$f \in [0, f_s/2]$ Hz
DFT frequency (two-sided baseband range)	$f \in [-f_s/2, f_s/2]$ Hz
Frequency of the $k$ th harmonic	$f_k = kf_s/N$ Hz

impulse response that is equivalent to a linearly swept FM signal. Other DFT forms include filter banks and number theoretic transforms (NTT) that can compete with the FFT only in narrowly defined applications. While not technically qualifying as a DFT, the discrete Cosine transform (DCT) has significance in image compression applications and, like the FFT, has been reduced to both software and hardware instantiations.

The DFT and its derivatives are an important signal analysis tool. They are sometimes used for off-line signal processing, while in other applications they must operate at real-time speeds using dedicated hardware, firmware, or software. An  $N$ -sample time-series is often windowed (e.g., Hann) prior to being transformed in order to improve the interpretability of the resulting DFT. DFTs can also be used to convolve two time-series if the DFTs are suitably modified. The DFT assumes that the signals being transformed are periodic, with period  $N$ . As a result, the convolution theorem for DFT is expressed as the periodic outcome  $y[k] = x[k] \otimes h[k] = \text{IDFT}(\text{DFT}(x[k]) \times \text{DFT}(h[k]))$ , where  $\otimes$  denotes *circular* (periodic) *convolution*, and IDFT denotes an inverse DFT. A circular convolution can be functionally converted to behave like a linear convolution by adding a string of  $N$  zeros to the time-series  $x[k]$  and  $h[k]$  prior to performing the DFTs. This process, called *zero padding*, allows an efficient FFT replace an inefficient linear convolution sum. This advantage is exploited in high-order application, such as convolving two large, two-dimensional images.

One of the principle uses of a DFT or FFT is in performing *spectral analysis*. Spectral analysis pertains to the study of signals and systems based on their frequency-domain signatures and attributes. The frequency domain image of a signal or system is often interpreted in terms of a power spectrum that is a display of the power in a process on a per-harmonic basis. Spectral analysis methods generally fall into two classes, called parametric and nonparametric. Nonparametric spectral analysis methods are based on the DFT of one or more noise contaminated time-series records. The individual spectra can be averaged or combined in various ways to create a more interpretable frequency-domain image of the signal or system under study. Parametric methods attempt to build a mathematical model of a process that approximates the measured power spectrum of a signal or system. The moving-average (MA) method is a parametric spectral estimation method that constructs an FIR (all zero) model of a signal process or system. Another parametric method is called auto-regressive (AR) and produces an all-pole IIR model of a signal or system, combining the two results in the parametric auto-regressive moving-average (ARMA) method. Other parametric methods are based on an eigenvalue analysis and result in a highly frequency-selective signal or system model.

## 24.5 DSP System Implementation

---

The implementation of a digital filter is an iterative process requiring design trade-off choices be made in the statement of filter specifications, filter type, architecture, and technology to achieve a design that meets performance, precision, and complexity (cost/power) requirements. Numerous software packages are commercially available to automatically design a baseline FIR or IIR filter of DFTs. Fewer software packages automatically support architectural or design optimization activities that can quantify run-time errors and register overflow saturation events. Furthermore, the majority of hardware-enabled DSP filters and transforms are implemented in *fixed-point*, a point often ignored by existing design software tools. The range of an unsigned fixed-point number is given by  $R = X_{\max} - X_{\min}$ , and has a resolution given by  $Q = R/2^N$ , where  $Q$  is called the quantization step-size and is the weighted value of the least significant bit (LSB). The quantization error is defined to be the difference between a number's real and fixed-point representation, specifically  $e = X - X_Q$  (rounded). Statistically, the error is uniformly distributed over  $[-Q/2, Q/2]$ , with mean and variance is given as  $E(e) = 0$  and  $\sigma^2 = Q^2/12$ , respectively. Of all the known fixed-point numbering systems, two's complement (2C) is by far the most popular and important. A 2C attribute, that makes it particularly attractive for DSP applications, is called the modulo ( $2^N$ ) wrap-around property. This property states that if a string of valid 2C numbers  $\{X_i\}$  are added to form  $S = \sum X_i$ , and  $S$  is a valid 2C number, then the final outcome will be correct regardless of possible

overflows of intermediate sums. That is, as the final result is correct even though intermediate sums may be flawed.

For cases where higher dynamic ranges are needed, *floating point* solutions are employed. The floating point representation of a real number  $X$  is given by  $X \sim (-1)^S M r^E$ , where  $M$  is the mantissa,  $r$  the radix,  $E$  is the signed exponent, and  $S$  is the sign bit. The mantissa is usually normalized to a value  $1/r \leq M < 1$ , and the format is defined by published standards (e.g., IEEE). A variation on the floating-point theme is called *block floating point*, a format used by a number of DSP chips, especially FFTs. A block floating point representation of an array of numbers  $\{x[k]\}$  is defined in terms of a maximum exponent  $E$ , where  $|x[k]|_{\max} = r^E$ . A block floating point representation of the number  $x[k]$  is given by  $x[k] = \pm M[k] r^E$ , where  $E$  is the fixed maximum exponent and  $M[k]$  is a fractional mantissa ( $M[k] \leq 1$ ). Since the scale factor  $r^E$  is known *a priori*, it need not be explicitly carried in number system representation.

The primary DSP arithmetic operation is the signed multiply accumulation (MAC). Fixed-point multipliers cover a wide range of speed, precision, and complexity tradeoffs. Compact low-complexity MACs can be designed using ripple adders. When adder area and power dissipation are not an issue, carry-lookahead adders can be used to accelerate wide wordlength adders and, therefore improve MAC speed. Carry-save adders (modified full adders) can also be an important element in implementing fast multipliers. Another fast multiplier architecture is based on Booth's algorithm and interprets strings of consecutive of "ones" as multiplicative NO-OP operations. Fast multipliers can also be constructed using arrays of small wordlength multipliers. These architectures are referred to as cellular array multipliers, or simply array multipliers.

General-purpose programmable DSP  $\mu$ ps make use of multipliers that map  $X*Y \rightarrow P$ , where  $X$  and  $Y$  are variables. Most DSP applications, however, are SAXPY ( $S = A*X + Y$ ) intensive, which refers to multiplying a variable  $X$  by a constant  $A$  (e.g., filter coefficients), followed by an accumulation. Implementing SAXPY algorithms technically does not require general multiplication but rather an operation called scaling. Several techniques have been developed to exploit scaling in the implementation of DSP algorithms. They are particularly useful in implementing fixed-coefficient DSP algorithms with application specific integrated circuits (ASIC), application specific standard parts (ASSP), and field-programmable gate-arrays (FPGA) devices. One scaling technique is called the reduced adder graph (RAG) method. RAG arithmetic is based on the theory of the ternary-valued ( $\{0, \pm 1\}$ ) canonical sign-digit numbers (CSD). For example, the 4-bit binary unsigned representation of the number 15 is  $15_{10} \leftrightarrow 1111_2$ , while the RAG representation is given by  $15_{10} = 16_{10} - 1_{10} \leftrightarrow 100 \bar{1}_{\text{RAG}}$ , which can be implemented using one adder and a shift register. The cost of an RAG multiplier is measured in terms of the number of adders needed to complete a design. Another scaling method is called distribute arithmetic (DA) and is applicable only to the implementation of constant DSP coefficient algorithms. As a point of reference, an  $N$ th order FIR digital filter, having known coefficients  $h_r, r \in [0, N]$ , requires  $N$  MAC operations be performed per cycle. The data is assumed to be coded as an  $M$ -bit 2C word, where

$$x[k] = -x[k:0] + x[k:1]2^{-1} + \dots + x[k:N-1]2^{-(N-1)}$$

where  $x[k:i]$  is the  $i$ th-bit of sample  $x[k]$ . The output  $y[k]$  is given by

$$\begin{aligned} y[k] &= -\sum_{r=0}^{N-1} h_r x[k-r:0] + \sum_{i=1}^{M-1} 2^{-i} \sum_{r=0}^{N-1} h_r x[k-r:i] \\ &= \theta[\underline{x}[k]:0] + \sum_{i=1}^{M-1} 2^{-i} \theta[\underline{x}[k]:i] \end{aligned}$$

where the mappings  $\theta[\underline{x}[k]:i]$  are implemented using  $2^N$ -word memory lookups. The lookup table  $\theta$  maps an array of binary valued digits  $\underline{x}[k:i] = \{x[k:i], x[k-1:i], \dots, x[k-M+1:i]\}$ , taken from the  $i$ th

common-bit location from  $x[s]$ ,  $s \in [0, \dots, N-1]$ , under the rule

$$\theta[\underline{x}[k]:i] = \sum_{r=0}^{N-1} h_r x[k-r:i]; x[s:i] \in [0,1]$$

Weighting the lookup value  $\theta[\underline{x}[k]:i]$  by a factor  $2^{-i}$  is implemented using a shift register. The result is generally a high-speed compact design.

## 24.6 DSP Technology

---

The semiconductor revolution, which began in the 20th century, began to shape the field of DSP beginning in the late 1970s. Since then, DSP has been both a facilitating technology (replacing existing solutions) as well as an enabling technology (creating new solutions). The hallmark of the DSP technology revolution was the general purpose DSP microprocessor (DSP  $\mu$ p). The first generation DSP chips included on-chip ADC and DAC and large capable multiplier. The second generation DSP  $\mu$ ps overcame many of the first generation device memory and precision limitations, and also removed the noisy ADCs and DACs. Since then, third generation floating-point and fourth generation multiprocessors have been added to the list of general-purpose DSP products. Along with the DSP  $\mu$ p technology explosion came attendant improvements in software for both uni- and multiprocessor systems. High- and low-level software environments have been created to rapidly develop and test DSP solutions. Since DSP problems tend to be algorithmic, stressing real-time bandwidth, optimized solutions continue to be dominated by assembly language code solutions. Throughout these generational changes, DSP  $\mu$ ps have maintained their dependence on capable MACs, tightly coupled memory, and a modified Harvard architecture. These trends continue to differentiate DSP  $\mu$ ps from general-purpose microprocessors. Microprocessors emphasize (1) multiple data types, (2) multilevel cache memories, (3) paged virtual memory management in hardware, (4) support for hardware context management including supervisor and user modes, (5) large general-purpose register files, (6) orthogonal instruction sets, and (7) simple or complex memory addressing, depending upon whether the processor is RISC or CISC. DSP  $\mu$ ps, however, typically (1) have only one or two data types supported by the processor hardware, (2) limited data cache memory, (3) no memory management hardware, (4) no support for hardware context management, (5) exposed pipelines, (6) predictable instruction execution timing, (7) limited register files with special purpose registers, (8) nonorthogonal instruction sets, (9) enhanced memory addressing modes, (10) onboard fast RAM, ROM, and DMA, and (11) nonsequential access to data addressing modes (e.g., bit-reversed addressing). Techniques have also been developed to exploit opportunities for instruction level parallelism, superpipelining, and superscalar architectures. These innovations have led to very long instruction word (VLIW) architectures. Due to the upward spiral of software development costs a significant amount of the academic and commercial activities have been directed to automatic compiler-based optimization of high-level language code.

In parallel with the explosion of general-purpose DSP  $\mu$ p products, there has been a growing presence of DSP-centric ASICs, ASSPs, and FPGAs. Although DSP  $\mu$ ps enabled the DSP revolution, DSP technology innovations have become increasingly driven by intellectual property (IP) supplied by semiconductor houses, fabless semiconductor technology suppliers, and third-party IP providers. Their use and justification is based on performance, power dissipation, cost, and time-to-market considerations. At the beginning of the new millennium, the market value of ASICs and ASSPs exceeded that of general-purpose DSP  $\mu$ ps. The trend toward ASICs and ASSPs, over DSP  $\mu$ ps, is motivated by the need to achieve rapid system-on-a-chip (SOC) designs by integrating predefined DSP IP cores together using high-end electronic design automation (EDA) software. FPGAs are becoming an increasingly important DSP technology but continue to remain primarily prototype tools and useful in some low-volume applications.

## 24.7 Applications

---

“DSP” has become a well-known acronym, often appearing explicitly in the marketing vernacular of commercial electronic products. The sphere of influence and relevance of DSP continues to expand, often enabling solutions that could only be speculated a decade earlier. Modern DSP applications areas include general purpose DSP (filtering, signal detection/classification, spectral analysis, adaptive filtering), instrumentation (waveform analysis, transient analysis), information/communication systems (speech, audio, voice over Internet, facsimile, modems, cellular telephones, wireless LANS), control systems (servos, disks, printers, automotive, guidance, vibration, power systems, robots), entertainment (sound, video, music), defense (radar, sonar, object recognition, ordinance) plus other areas such as biomedical, transportation, and geophysical signal processing.

### 25.1 Introduction

---

The story goes like this. In 1982, when Texas Instruments’ (TI) engineers came up with their first general-purpose chip for DSP applications, they did not know how to call it. Terms like analog microprocessor or signal microprocessor sounded cumbersome for the user. Therefore, an engineer said, “why don’t we confuse the chip and its application? In other words why don’t we use the term DSP (digital signal processing) to describe our chip?” Hence, the DSP (digital signal processor) was born. Unfortunately, this still brings confusion 20 years later.

## DSP (Digital Signal Processor) or DSP (Digital Signal Processing)?

What do we mean by DSP applications?

- Applying the science of digital signal processing to the real world?
- An application that uses a digital signal processor?

Although the two areas largely overlap, they are not identical. For instance, a typical digital signal processing application such as V90 modem is performed by a general purpose DSP but also by a custom chip or a Pentium.

### A DSP Can Do More Than DSP Applications

A general purpose DSP can be efficient at many other tasks than pure processing of signals (Fig. 25.1). The reason is that a DSP is low cost and very efficient at processing in general. It is also good at processing math, bits, events, state-machines, etc. In addition, a DSP has a very deterministic behavior. Hence, it can precisely control hardware and multiple external events. It is the main reason that hard disk drives use a DSP as their main CPU. Disk drives and motor control represent one of the biggest applications for a DSP. They are classified under DSP applications, in reality they are more control-like; however, the “spread” of a general purpose DSPs into non-DSP applications is much less interesting than the discovery of new DSP applications.

In the following paragraph, we will concentrate on describing applications, which recently opened new markets thanks to some DSP techniques.

### The Importance of DSP Applications

Over the last 20 years, the different market segments have made a different use of DSP applications (Fig. 25.2). The next 10 years will also bring its changes. For instance, the consumer market is likely to occupy more and more space in the life of DSP engineers.

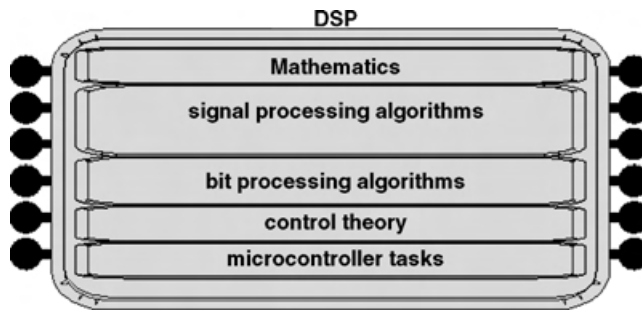

FIGURE 25.1 A general purpose DSP can do more than DSP.

FIGURE 25.2 Relative importance of market segments for DSP applications.

# Classifying DSP Applications

It is usually to classify DSP applications following the market segments. For the purpose of this chapter, we conveniently classify the seven main areas of DSP applications without necessarily following the market segments of Fig. 25.1:

1. Military
2. Telecommunication terminals
3. Consumer products
4. Telecommunication infrastructure (including networking)
5. Computers, peripherals, and office automation
6. Automotive, industrial
7. Others, such as biometrics, biomedical, etc.

## 25.2 Military Applications

---

The first DSP applications were born in the 70s and were mainly military (radar, sonar). Today, the same applications exist with a much higher performance target. In addition, many military applications (vocoder) are taking advantage of “civilian” work. An interesting development for the military is the detection and disposal of mines [1]. It must be noted that, since the military community was the first DSP customer, strong links were created between DSP manufacturers and these pioneers. Despite its small size, the military community continues today to have a strong influence on the evolution of DSP architecture (floating-point, multiprocessing).

## 25.3 Telecommunication Terminals

---

By 1995, DSP has left its original circles (military, universities) and became a household name. The most popular DSP applications were telecommunications terminals such as cellular telephone, PC (modem), fax, and digital-answering machine (Table 25.1). Today, the quantity of telecom terminals that is produced per year reaches 450 M units for cell phones alone.

### Phones and Answering Machines

The plain old residential telephone has very little DSP inside it (maybe calling ID). This is the exception among voice communication devices. For instance, second generation cordless phones (DECT) use digital techniques. Also all “packet telephones” such as Internet (IP) phones, LAN phones, are using voice compression, echo cancellation, and modem techniques to receive/transmit voice. An extreme telephone application can cater for up to 12 voice conference channels. This requires 12 decompression channels and mixing. Voice compression is not new, since they allowed the development of cheap “solid-state” DAM (digital answering machines). All put together, a combo device including a multi-channel cordless + a DAM + a connection to IP is a very demanding DSP application.

**TABLE 25.1** List of Telecom Terminals Using DSP Techniques

Communication Function	List of Terminals
Voice (telephony)	Feature phone, DAM, cordless phone, Internet phone, business phone, LAN phone, DECT phone, combo products (LAN/POTS)
PC modem	(Voiceband) modem, DSL modem, cable modem
Fax	Color fax, fax/phone, fax/printer, fax/printer/scanner/copier
Web access	Web station, Web phone, Web pad
Videophony	Videophone
Cellular phone	Standard, voice + data cellular phone, smart phone, pager

## **PC as a Terminal (Modem)**

The PC is the second most successful telecom terminal of all times. For that it requires a modem (most advanced voiceband modem is V90). The modem was the application that created a mass market for DSP devices (1982–1992). Today, all DSP devices are trying to implement broadband modems. Roughly five classes of broadband modems are available, which all use massive amount of DSP power:

- DSL, which is made of three classes in order of difficulty (SDSL, ADSL, VDSL)
- Cable modem, which is classified as a set-top box peripheral
- Broadband wireless modem (LMDS, MMDS), which is also called the “wireless DSL”
- Broadband satellite modems
- Gigabit Ethernet (and above), which positions itself as the cheapest technology

## **Fax**

A fax can be seen as medium range modem, plus a scanner writing bits into a graphics compression engine, and a decompression engine driving a printer. The three functions are all DSP-based. There is no reason why fax manufacturer will not develop DSL fax. Modern networks will allow a DSL fax to speak to a LAN fax. In fact, modern networks will allow “anything over everything” such as fax-over-IP and voice-over-DSL. You can bet that DSP will be in the middle of all that.

## **Web Access Terminals**

Not to be confused with an IP phone (which is limited to voice communication), a Web access device is targeted at Web browsing and e-mail. Today (2001), all these types of devices and the so-called “Internet appliances” are struggling to find a mass-market acceptance. Despite this, three classes exist: Web station, Web phone, and Web pad.

### **Web Station**

It is a \$99–299 consumer device in the form factor of a small laptop. It allows web browsing, send/receive e-mail, and (maybe) JPEG decode. Web browsing requires a modem (more likely V90 than DSL), which means DSP. Since V90 is less than 30 DSP MIPS and today’s DSPs give anything from 100 to 1500 DSP MIPS, the use of a full-blown DSP might not be required. On the other hand, the unused performance can be put to good use: multimedia decode.

### **Web Phone**

This is the same as the Web station with the addition of telephony. Note that in the IP world, phoning requires more DSP MIPS than Web browsing.

### **Web Pad**

This is a cordless web station with a form factor identical to the pentop of 1992–1994. The DSP functions are fifty/fifty shared between the base and the tablet. The big advantage of a Web pad is to be network independent or modem independent. The big disadvantage is the price of the display.

## **Videophone**

Videophone shares with speech recognition the honor of being the most promising 1971 DSP application. Thirty years later, many progresses have been made. The next 10 years will surely bring their annual series of breakthroughs.

## **Cell Phones**

The modem put DSP on the radar screen in the 80s. By comparison, cell phones put DSP in the stratosphere in the 90s. By the end 1999, the cell phone was the star of the electronics world with more than 300 million handsets a year, some containing multiple DSPs. Multiple DSPs are needed because a cell phone DSP function is traditionally divided into two parts: the speech coding and the channel coding.

**TABLE 25.2** A List of Possible Wireless Devices

	Cellular	Proximity (Bluetooth)	Home RF (Residential)	DECT (Cordless)	Wireless LAN	Broadband	Satellite
Phone							
Modem							
Fax							
Web access							
Videophone							
Digital camera							
Palm-top							
DVD player							
DVR							
Set-top							
Digital TV							
Games							
MP3 player							
Home theater							
DAB							
MP3 Juke-box							
E-book							
PC							
Printer							
Car							

*Speech coding* is a traditional speech codec (compression/decompression) algorithm varying from 5 to 12 kbit/s depending on standards, economic forces, and target quality. Above that, several speech-quality enhancement features are added. This includes echo cancellation and noise suppression. A promising trend is the use of wideband codec. All together, the sum of all speech functions put in a modern cell phone can require up to 100 DSP MIPS.

*Channel coding* is working on bits in transmission and (supposedly) in reception. As such, it does not qualify as a pure DSP application; however, in the first place, the reception is mainly done on samples and secondly equalization and other heavy DSP techniques (Viterbi algorithm) are classified under channel coding. Finally, the channel coding problems represent DSP research at its best today.

## Wireless Terminals

The cell phone is the first of many types of wireless terminals that will come up over the next decade. In fact, wireless terminals are in a class of their own. Their rapid evolution differentiates them strongly from their wired cousins. Wireless is the technology with the most development potential over the next 10 years. It is easy to explain this statement by taking any existing equipment (from telephones to automobile) and turn it into a wireless device (Table 25.2). It is left to the reader to complete the table based on his or her own wishes.

## 25.4 Consumer Products

Section 25.3 proves that wireless will revolutionize many types of equipment. This is especially true for consumer devices. For instance, Bluetooth and GPS (both based on DSP) will be standard features on most consumer products described in the following subsections. In addition, consumer products have been traditionally nonconnected devices (camera, CD player) or passive devices (television). This is changing, in the form of access to the Web. This itself gives a big push to DSP applications.

### Digital Cameras (and Digital Pictures)

One of the most promising consumer DSP applications is the field of digital pictures. Its most common incarnation is the digital camera. This very large field can be segmented in many ways, following these

characteristics:

- Fixed pictures versus moving pictures (example: digital camera versus digital camcorder)
- Picture production (camera) versus picture consumption (digital frame)
- Portable versus semi-fixed/fixed equipment (example: digital camcorder versus webcam)
- Equipment versus module (example: digital camera versus add-on to a palm-type device)

### **Digital Camera**

A digital camera is made of several functions: an image sensor, a processing part, and a storage element. The processing includes three main algorithms, front-end processing, image compression (DCT is mainly used here), and coding (Huffman coding).

In theory, a digital camera requires 10 DSP MIPS. Nevertheless, higher resolution, advanced algorithms (pixel by pixel) and sophisticated features such as the paparazzi effect turned the digital camera into a big DSP MIPS consumer. The paparazzi effect is when a series of pictures are taken at high speed (for example, 10 pictures in 1 s). In effect, we are not far from the performance of a video camera.

### **Digital Video Camera (Camcorder)**

Big brother to the still camera, the video camera follows the same principle. It approximates the behavior of a digital camera except it has a better resolution and a continuous automatic stream of pictures. Another key difference is that it is a slave to the television set. Hence, decompression of pictures is as important as compression.

### **Web Camera**

Not all video cameras need the sophistication of a camcorder. Common examples are surveillance cameras (slow speed, black and white) and Web cameras. The Webcam's block diagram is very similar to a digital (still) camera except the storage function has been replaced by a modem. Because the speed of the network is the bottleneck, there is no need to take more than one or two pictures every 5 s. Note also that a Web camera does not need any decompression algorithms.

### **PC Camera**

The PC is a \$10 digital video camera put on top of PC and used for video telephony or college room broadcasting. Its consists of a very low sensor quality and a sub-dollar micro-controller. The PC has taken the role of a DSP.

### **Modules and Toy Cameras**

In the same spirit, any host can take the DSP role. For instance, there is the case of digital camera modules (host independent), add-on to a PDA (palm OS is the host), and toy cameras (PC is host).

### **Digital Picture Frame**

Not the most fascinating killer application of all times (sending baby pictures to grandparents), the digital picture frame is exactly the opposite of the Web camera. The image first goes through a modem function, then through decompression, and ends up its life on a picture frame display; however; contrary to a Web camera there are large problems due to the human interface and the way we (the grandparents) interact with this kind of device.

### **PDAs (Handheld Devices, Palmtops)**

PDA is not (yet) a big DSP platform. Still serious inroads are made. Two common ones are the use of a PDA as a common platform for digital camera and MP3 player. Also Web access (necessitating a modem) and wireless access (obviously necessitating a wireless link) are the two good classical DSP applications, which are being pushed into these devices.

## **DVD Player (and Digital Storage Devices)**

Storage devices such as hard disk and CD-ROM players are basic sub-elements of the PC. The CD audio is also a well-known element of our life. The equipment, which really puts DSP into the consumer storage field, is the DVD player.

### **DVD Player**

A digital versatile disk (DVD) uses MPEG2 compression to store its video and audio tracks. A DVD player requires in the order of 200 DSP MIPS to decode the signal. Still, compared to some recent consumer platforms the function seems relatively straightforward, but this is only one-third of the DSP functions. The other two functions are the control of the disk (servo) and the reading and decoding of the stored data bits (channel coding).

### **Universal Player/Recorder**

Moreover, the DVD player is fast becoming a recorder device. MPEG2 coding algorithm necessitates many more DSP MIPS than decoding. Finally, the number of standards (in other words the number of DSP algorithms), which are currently supported by a DVD player, is mind-boggling. Effectively, the DVD player is the de facto universal home player/recorder. It can do nearly everything from recording MP3 audio to reading karaoke Chinese videodisk.

### **DVR (Digital Video Recorder)**

Further pushing this recording trend is the emergence of the DVR. Here there is no disk to read or to record. Or, more specifically, there is no BOUGHT disk; however, this is still a storage device (hard disk) on which television program can be stored (recorded) and read in nearly real-time. The DSP algorithm is the same as DVD (omnipresent MPEG2) but with the added complexity of simultaneous coding/decoding. In fact, there are two coding channels and one decoding channel requiring more than 700 DSP MIPS of DSP power.

## **Digital Set-Top Box (and Digital Television Peripheral Devices)**

The DVR function just described can also be integrated in a set-top device. We will call set-top devices any consumer devices, which sits at home between the TV operator(s) and the television set (hence the name set top). A Web TV fits neatly into this definition.

### **Digital Set Tops**

Two types of digital set-top boxes are currently used, the wired and the wireless. The wired is the well-known connection to a cable, the wireless is the satellite type. Both require a massive amount of DSP in the demodulation/error correction schemes, followed by the good old MPEG2 decode. It must be noted that the DSP functions have a relatively minor role to play in the whole software. Set-top boxes are considered more of an open platform similar to a PC, than a closed device such as a DVD player. This comment was to introduce the current evolution of set-top boxes from one-way device to two-way devices (up-link is added to down-link).

### **Two-Way Set Tops—Cable Modems and Web TVs**

But what about the amount of DSP functions? Intuitively both devices would require twice the number of DSP workload since they now receive and transmit information. This is not so. The up-link is only for data, consequently the need for compression is null and the modem speed relatively low. To summarize, DSP did not drive the recent evolution of set-top boxes; however, this might change if they evolve into multimedia home gateways.

## **HDTV (and Digital Television)**

If there is a domain in which DSP is bringing a lot, this is high definition TV (HDTV). This is not due to the high definition but to the use of digital techniques. Contrary to the current digital television, the digital functions (read MPEG2) are not put into a peripheral device but in the TV set. Even if there is still a lot of uncertainties in this market, there is no doubt about its massive use of DSP power.

## **GAMES (and Toys)**

Although it is not the obvious place where DSP can be found, games and toys have more and more needs of DSP because of the need for communication.

### **Games Consoles (3D)**

Games have massive amount of CPU and hardware power devoted to the manipulation of 3D graphics. It is interesting to know the three reasons why this cannot be classified as DSP. The first one is that 3D graphics is executed in floating point (whereas DSP is 95% fixed point). Reason number two is that graphics is a synthesized object whereas DSP manipulates real signals. Finally, DSP is software whereas graphics is a pipelined hardware. It is obvious that a lot of DSP applications can be found, which corresponds to the three above criteria. What about a 33-stage hardware floating point multi-channel polyphase audio synthesizer. Also, there are a lot of graphics algorithms, which are *not* floating point for instance. The bottom line is that the world of gaming, the world of video communications, and the world of image processing are now very close:

- Mixing of synthesized and real images found in modern games
- The adoption of MPEG4 as a telecom standard (MPEG4 principles rely on objects commonly found in PC graphics)

### **Game Consoles as an Universal Platform**

The same story as for set-top box or PDA applies here. Web browsing, modem, DVD player, MP3 player are all good examples of DSP applications. All are finding their way into game consoles.

### **Toys**

The first consumer device based on DSP was the Texas Instruments' speak and spell learning aid (1981). In fact, it was a toy disguised as a learning aid. Another TI DSP milestone was the famous "Julie doll" (1987). For the future, a lot of toys will be based on sophisticated electronics, adaptive behavior, and connected to the PC (possibly Bluetooth). All these functions have strong DSP contents.

## **MP3 Player (and Listening Musical Platforms)**

Traditionally, the music industry was relying on very crude DSP in the consumer product (CD player). The explosion of MP3 portable devices is opening the doors to sophisticated DSP in mass-market audio devices.

### **MP3 Player**

When drawing a block diagram of a MP3 player, one can use the block diagram of a portable digital picture frame and replace the display by the connection to the speaker. This represents the simplicity of a MP3 player. The DSP MIPS number is low and the DSP functions pretty basic. Nevertheless, as for DVD, the difficulty is in the number of audio format to support (each one means a different DSP algorithm) and the security features. Note that a large number of MP3 players are built with a single DSP (no micro-controller host), which means that its 80% of its program is used for NON DSP work.

### **Hi-Fi**

A large number of high-fidelity equipment rely on DSP techniques. The most common is the Dolby standard, which can be found in cinema and home (5.1 channel) theater. The most exotic could be the digital speaker. The most difficult and resource intensive DSP application is the so-called 3D sound (PC games).

**TABLE 25.3** Consumer Equipment—How Big Is the Market and How Much DSP Is Required?

Consumer Equipment	Units Sold per Year	DSP MIPS
Digital camera	10 M	10 → 1000
Palm top	10 M	50
DVD player	60 M	300
DVR	<1 M	700
Set top	50 M	300
Digital TV	<1 M	1000++
Games	100 M	100,000+ (graphics)
MP3 player	10 M	20
Home theater	<1 M	1000+
DAB	<1 M	80
MP3 juke box	<1 M	20
E-book	<1 M	5

Everyone knows about the difficulty of generating good 3D graphics. But one can appreciate the difficulty of generating 3D sounds when doing the comparison. An image is still displayed in a 2D world, whereas sound is really produced for a 3D world (by analogy: image will catch up with sound when it will be displayed as a hologram). In effect, we are speaking of thousands of DSP MIPS.

### **Musical Instruments**

In the professional musical world such as synthesizers, DSP first appeared as a label of quality. Music is a field where DSP can introduce massive improvements. For instance, adaptive techniques could make a good old country fiddle sound like a Stradivarius. It does not sound like a very good idea, though.

### **Home Networking and Multimedia**

MP3 player is the top of iceberg. The iceberg is the “connected” home. The infrastructure of this connected home is partially described later (refer to home gateway heading). Here, the new “gizmos” that this infrastructure allows are briefly described:

*MPEG4 player:* This is the same as MP3, except it also allows viewing video clips.

*Internet radio:* listening to radio on the Internet.

*MP3 juke box:* listening to MP3 clips; they had been previously stored on a hard disk drive (from the Internet Web sites). Similarly, we can add MPEG4 juke box.

*Home Storage or Multimedia Storage Box:* hard disk drive containing multimedia files.

*E-book:* Electronic book. Presently downloaded from the Web; in the future, this will be done in two passes: first to the home storage and then to the e-book.

Table 25.3 summarizes the DSP requirements of some consumer devices. Knowing that most of them are starting their commercial life, one is impressed by the amount of work remaining for DSP engineers.

## **25.5 The Telecom Infrastructure**

The telecom infrastructure could be divided into three spheres of influence (wired, wireless, networking). The convergence of all networks renders this distinction illusory. A very interesting trend is that infrastructure equipment such as servers, gateways, switches, radio relays are now finding their way into the home.

### **CTI (Computer Telephony Integration)**

Before the net, CTI was the biggest infrastructure user of DSP. CTI means voice server, voice mail, and the infamous IVR (interactive voice response) machines “please hold on, etc.” All these infrastructure equipment are built using standard software modules and boards. For years CTI was the lifeline of many DSP board manufacturers.

## **Modem Banks**

This is the first of the multi-channel DSP applications. Modem banks did not appear because of PC modems. They appeared because of the Internet (web servers) and remote workers (remote access servers). The number of required DSP MIPS is extremely high. For instance, a typical bank of 120 V90 modems requires 3600 DSP MIPS ( $120 \times \sim 30$ ).

## **DSL Modem Banks**

This is nothing compared to DSL, where (for instance) 30,000 DSP MIPS ( $120 \times \sim 250$ ) is required for a 120 channels S-HDSL modem bank.

## **Broadband Line Card (Voice-over-Broadband)**

The most likely example of broadband line card is a DSL line card, which fills the same function as modem banks plus the typical voiceband functions (echo cancellation, voice compression, DTMF detection, fax relay) found in gateways.

## **Gateway (Voice-over-Broadband)**

Under this heading are included all recent buzzword equipment such as voice-over-DSL, voice-over-IP, voice-over-Packet, etc. A gateway can be on the periphery of the network (access), in the center (core) or on customer premises (private). Its main use is to translate from a circuit network to a packet network and back. A state-of-the-art gateway SOC (System-on-Chip) targets 200 channels, which translates into 4000–10,000 DSP MIPS depending on the voice compression quality. The voice quality has been the subject of a lot of debate (and hard-learned lessons) in the IP community over the last four years.

## **Cellular Wireless Base Station**

In wireless, voice quality is not a problem (relatively speaking) since compression algorithms are standardized. They require as low as 3 DSP MIPS (GSM full rate) to 30 DSP MIPS (third generation such as AMR) per channel. Cellular wireless base stations are half gateway (access to network) and half radio relay (air interface). It is this air interfaces, which presently (2001) presents a lot of challenges to the DSP world. Many MIPS-hungry techniques have been introduced (CDMA, turbo coder) and many more will be coming (smart antenna, multiple reception, software radio, etc.) over the next 20 years. In essence this is 25,000 DSP MIPS per channel. In other words, each channel requires a 25 GHz general purpose DSP. One can see the interest of application specific DSP and custom instruction set in this market.

## **Home Gateways and “Personal Systems”**

A residential cordless base station is now the most common example of a “personal system.” A personal system is a device having both characteristics of telecom terminals and telecom infrastructure. It is a terminal because:

1. It is sold in retail stores.
2. It is targeted at a small entity (single person, family, SOHO).

It is a telecom infrastructure equipment because:

1. It has no human interface.
2. It very often acts as a point-to-multipoint access device.

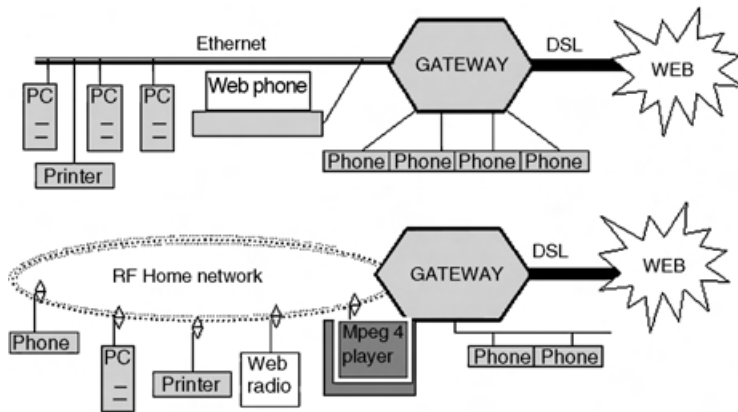

FIGURE 25.3 Two examples of residential gateways—SOHO and HOME.

### What is Residential Gateway?

This is the latest trend in “personal system.” Two examples are given in Fig. 25.3. The first one is a DSL (external) to Ethernet/twisted pair (internal) gateway. It could be a typical SOHO scenario where phones are organized in star topology. Note that the LAN supports additional phones.

The second one is a HOME gateway, which differs by being driven more by entertainment than by work. It also uses an external DSL link but the internal communications are mainly wireless. The wireless network is used to avoid rewiring the house. The phones are organized in bus topology, which also corresponds to a typical home.

If the architecture of the home network evolves into thin-client terminals, home gateways are going to be a gold mine for DSP applications. DSP is required on all access points, DSP is required for voice compression, DSP can be required to do MP3 decompression (Internet radio), MPEG4 decompression (Internet clips), etc. The limit is one’s wallet.

## 25.6 Computer, Peripherals, and Office Automation

### PC as a Home Gateway

Obviously, the home gateway market is not leaving the PC industry passive, especially after 10 years of multimedia hype. The more likely scenario will NOT see any major integration of “telecom personal systems” into PC; however, the home gateway is having several major impacts on PC: integration of wireless functions, still more performance for multimedia (such as the typical MPEG4 clip already mentioned).

### Printers

The benefit of a laser printer and color printer depends largely on the speed and quality of image processing. This is typical DSP task.

### Hard Disk Drive

In the last years, disk drives know-how has changed from complex control theory to sophisticated DSP coding techniques. The algorithms used have more to do with wireless telecommunications than servo control. In addition, the emergence of network attached storage requires communications, which in turn means DSP.

## 25.7 Automotive, Industrial

---

Although it is often forgotten when discussing advanced digital developments, the automotive industry could be the surprise of the decade for the DSP industry.

### Engine Control

Due to history and real-time constraints, the automotive industry uses the principle of table interpolation for engine control; however, the availability of faster CPUs and the development of sophisticated algorithms could change that in favor of more “classical” DSP techniques. In fact, automotive could become the first embedded mass-market where floating-point DSP is implemented.

### Navigation Platform

GPS/navigation: In automotive, GPS is part of the dashboard platform. How big will this market be?

### Industrial

A large application found in the industrial market segment is motor control. Quite a very different control from car engine control, the two applications are strongly related since they are the domain of microcontrollers. Identically to engine control above, motor control is fast becoming a big DSP application.

## 25.8 Others

---

To finish, small many promising applications using DSP as their bases for new or more advanced features include:

*White appliances:* Refrigerators, washing machines, or any equipment requiring closed control will eventually be heavy DSP users.

*Biomedical:* A good example is the processing of image in medical equipment such as scanner.

*Audio aids:* This is a much larger application than previously thought. Gene FRANTZ [2] made a parallel between visual aids (glasses) and audio aids. Let us imagine the size of the market if everybody was wearing a hearing aid to cancel noise and unwanted conversation.

*Biometrics:* All recognition methods (fingerprint, retina, voice, etc.) rely on DSP.

## 25.9 Conclusions: General Trends

---

The time when a single application was driving DSP is finished. The next DSP application goal is now several thousands of DSP MIPS, and many applications are driving it:

- Smart and multiple antennae techniques in wireless base stations
- Third generation cellular wireless phones, smart-phones, and terminals
- Broadband access devices (VDSL modem, wireless broadband, gigabit Ethernet)
- Multi-channel application of the telecommunication infrastructure (typically: voice-over-broadband gateway).
- Multimedia home gateways, integrated access device (IAD), wireless Home/LAN access devices
- Streaming media devices (could be a MPEG4 player connected by Bluetooth to a home gateway)
- HDTV, high resolution cameras, 3D audio

Finally, even if no “broadband” applications existed, people would use DSP for cost reasons. When a very good sensor is needed, an imperfect sensor is a worthless commodity. By using DSP techniques (interpolation, adaptive behavior, etc.) a worthless commodity can be turned into a production device.

The author is eager to see the day where a 30-inch 2000 × 4000 color LCD matrix with 80% defects will be turned into a \$100 HDTV screen. Only DSP can achieve that.

## References

Except for Will Strauss's unique (and expensive) monumental work, it is difficult to give a complete reference covering all those applications. Personal experience and key people from various conferences [3] were an invaluable tool. The author's recommendation is to go to the specialized electronics Web sites [4–12] and to type the keyword (e.g., e-book) in the search engine. Next, go to the Web sites of the principal DSP manufacturers [14–22] and look for products, white papers, and applications. The reader is encouraged to look into companies not so often associated with DSP, or smaller companies where the most innovative designs are found [23–45].

Finally, the author recommends the two INFINEON sites corresponding to the DSP chips on which he working or has recently worked: TriCore [46] and Carmel [47].

### 26.1 Introduction

---

For computer and information technology (IT) applications, signal processing is an important tool. Nowadays, it is much more efficient and accurate to work with sampled (or digitized) signals rather than with analog (or electrical) signals. Once a signal has been sampled, it can be treated as a sequence of numbers that is a function of a discrete-time variable. When the sampling rate is greater than the Nyquist rate, the digital signal will completely represent the analog signal, because the analog signal can be reconstructed from the digital signal. Digital signal processing (DSP) implements various kinds of mathematical operations, so that physical electrical devices are replaced by computer software or hardware. Unlike analog systems, DSP can handle very sophisticated jobs with as much accuracy as needed. The theory of DSP can be found in three excellent references [1–3].

One very basic DSP operation is digital filtering. It is common to use many filters inside a larger DSP application. Digital filters have widely been used in the following applications:

- *Audio*: spectral shaping
- *Speech*: filter banks
- *Image*: de-blurring, edge-enhancement/detection
- *Communications*: bandpass filters
- *Radar*: matched filters

## 26.2 Digital Filters

---

The theory of digital filters can be found in references [4–6]. A digital filter is defined as a linear, time invariant operator on a discrete-time input signal,  $x[n]$ , that generates an output signal,  $y[n]$ . The filtering operation can always be written as a convolution

$$a[n] * y[n] = b[n] * x[n] \quad (\text{convolution})$$

where  $b[n]$  and  $a[n]$  are the filter coefficients associated with the digital filter.

### Implementation

In order to implement the filter as a causal operation, the number of filter coefficients must be finite and the coefficients should be nonzero for only positive indices. Then the output signal can be computed via the difference equation:

$$y[n] = \sum_{k=0}^M b[k]x[n-k] - \sum_{k=1}^N a[k]y[n-k]$$

where  $N$  and  $M$  are the number of poles and the number of zeros, respectively, and  $N + M$  is the total order of the filter. If any one of the feedback coefficients  $a[k]$  is nonzero for  $k > 0$ , then the filter is called a recursive or infinite impulse response (IIR) filter. Otherwise, the filter is called a nonrecursive or finite impulse response (FIR) filter.

### Frequency Response

The filtering process for linear, time-invariant (LTI) systems can be characterized by the frequency response

$$H(\omega) = \sum_n h[n]e^{-j\omega n}$$

which shows how the filter processes sinusoidal inputs. The discrete-time Fourier transform (DTFT) decomposes a general input signal as a superposition of harmonic signals,

$$x[n] = \frac{1}{2\pi} \int_{-\pi}^{\pi} X(\omega)e^{j\omega n} d\omega,$$

where the complex amplitudes of those harmonic signals are computed by the DTFT sum:

$$X(\omega) = \sum_n x[n]e^{-j\omega n}.$$

Then the behavior of the system can be described as a multiplication in the frequency domain:

$$Y(\omega) = H(\omega)X(\omega)$$

where  $Y(\omega) = H(\omega)X(\omega)$  is the DTFT of the output. In terms of the filter coefficients we get

$$Y(\omega) = \frac{B(\omega)}{A(\omega)}X(\omega)$$

where  $A(\omega)$ ,  $B(\omega)$ ,  $X(\omega)$ , and  $Y(\omega)$  are the DTFT of  $a[n]$ ,  $b[n]$ ,  $x[n]$ , and  $y[n]$ , respectively. The difference between FIR and IIR filters can be summarized as follows:

**FIR filter:** An FIR filter has  $A(\omega) = 1$ , so its frequency response is formed as a linear combination of complex exponential functions that is equivalent to a polynomial. Hence, the design problem can be formulated on a linear vector space and very efficient mathematical optimization methods are available for approximating the desired frequency response. The design methods are simple, and often guarantee convergence to an optimal solution. Finally, since FIR filters do not have feedback they do not suffer stability and sensitivity problems.

**IIR filter:** In contrast to the FIR case, IIR filters are rational functions, so the design problem is inherently nonlinear. No elegant mathematical method can guarantee convergence to the global optimum. In addition to the difficulty of numerical design, IIR filters might exhibit instabilities where a finite input can generate infinite output and high sensitivity, and where roundoff noise can be amplified; however, IIR filter design has more design freedom, so IIR filters can have the same performance as FIR filters but with many fewer filter coefficients.

## FFT Implementation

It is possible to implement a digital filter in the frequency domain with the fast Fourier transform (FFT) algorithm [7]. The implementation requires one FFT of the input signal, one multiplication of vectors, and one inverse FFT. The length of the FFT determines a block length so the signal must be segmented into sections for both the input and output. The frequency domain implementation actually uses circular convolution, so some care is needed to get the correct outputs. The FFT-based method of convolution is used in special circumstances because it is only practical for real-time systems when the FIR filter length is rather long—the major drawback is that it requires a large amount of buffer memory for the block processing.

## Adaptive and Time-Varying Filters

Another important class of FIR filters is the class of adaptive filters [8], which find widespread application in areas such as equalizers for communication channels. The filter coefficients in an adaptive filter are continually changing as the input changes, so the filter design problem is quite different for these filters. The methods discussed in this chapter will not handle these cases where the coefficients are time varying.

## 26.3 Digital Filter Design Problem

---

### Design Specification

A digital filter is usually designed so that its output has a desired frequency content, i.e., the frequency response is frequency selective. The filter coefficients are then optimized so that the frequency response  $H(\omega)$  will best approximate an ideal frequency response  $I(\omega)$ . The ideal response varies for different applications.

**Frequency selective filter:** The ideal frequency response is either one or zero.

$$I(\omega) = \begin{cases} 1, & \omega \text{ in the pass band} \\ 0, & \omega \text{ in the stop bands} \\ \text{don't care,} & \omega \text{ in the transition bands} \end{cases}$$

The frequency selective filter is designed so that the actual frequency response  $H(\omega)$  is close to 1 in the passband and nearly 0 in the stopband. An example of a frequency selective filter is shown in Fig. 26.1.

**FIGURE 26.1** Frequency selective (bandpass) filter: (a) shows the ideal magnitude response (thick dashed line) and an example of an elliptic (with 6 poles, 6 zeros) bandpass filter (thin solid line.) The ideal filter has two cutoff frequencies,  $\omega_{c1}$  and  $\omega_{c2}$ , that separate the two stop bands from the pass band; (b) shows the ideal group delay response (thick dashed line) and the group delay of the elliptic bandpass filter. Note that elliptic filters usually have severe phase distortion (i.e., a highly nonlinear group delay) in the passband.

**FIGURE 26.2** The phase equalizer is designed to equalize the passband of the elliptic filter in Fig. 26.1 so that the group delay is flat in the pass band: (a) shows the ideal equalizer response (thick dashed line) and a FIR (order 25) equalizer; (b) shows the group delay,  $D_g\{\bullet\}$ , where  $D_g\{I_{Equal.}(\omega)\} = D_g\{I(\omega)\} - D_g\{H_{Elliptic}(\omega)\}$  is the ideal group delay (thick dashed line).

**FIGURE 26.3** Equalized filter. The figures show the magnitude and the group delay of the elliptic filter (with 6 poles, 6 zeros) after being equalized by the FIR (order 25) equalizer. The ideal filter for the example is a flat group delay frequency selective filter.

**Equalizer:** Equalizers are applied to existing systems in order to remove distortion, or to improve the overall filter characteristic. Therefore, if the desired response of the system is  $D(\omega)$ , the ideal frequency response of the equalizer depends on the distortion filter  $H_D(\omega)$ , such that

$$I_{Eq}(\omega) = \frac{D(\omega)}{H_D(\omega)}$$

One example is shown in Fig. 26.2 where the equalizer is used to reduce the phase distortion of the filter in Fig. 26.1. The phase equalized filter is shown in Fig. 26.3.

**Filter bank:** A filter bank is a set of filters that sum to 1, the identity system:

$$I_k(\omega), \text{ for } k = 1, \dots, P \quad \text{such that} \quad \sum_{k=1}^P I_k(\omega) = 1$$

With actual filters, the sum might be approximately one. This property lets us decompose signals with a filter bank and then reconstruct perfectly. Filter banks are now widely used as analysis, storage, and compression tools for DSP.

**Differentiator:** The derivative operation is a filter whose ideal frequency response is

$$I_{\text{Diff.}}(\omega) = j\omega$$

Operators such as the first difference make poor filters because they do not work well for high-frequency signals. Filter design, however, can create high-order numerical differentiators that have excellent wideband characteristics by approximating the ideal frequency response,  $I_{\text{Diff.}}(\omega) = j\omega$ .

## Error Measurement

In order to have a filter whose frequency response is very close to a given ideal response, a norm for error measurement must be introduced. Then the filter design problem becomes a mathematical optimization problem. Many possible error norms can be used. For example, the most popular norms are:

- Maximal magnitude error,  $\max ||I - H||$ , for a frequency-selective filter
- Maximal phase error,  $\max |\angle I - \angle H|$ , for an allpass filter
- Weighted complex error,  $||W(I - H)||$ , for general filters where the function  $W(\omega)$  is a positive weight function

The design problem is usually carried out by minimizing one of these norms, but it is also possible to add constraints on the error magnitude, on the pole locations, the transition band overshoot, the smoothness of the error, or the magnitude of the filter coefficients. These various criteria lead to many different filter design methods that offer trade-offs with respect to efficiency and flexibility.

## Filter Characteristics

Although many filter design papers and procedures have been published, only a few approaches have found widespread use in the 35-year history of DSP.

### Optimal Magnitude Response

IIR filters with optimal magnitude error are generally easy to design partially because they usually require low order; however, these IIR filters usually have severe phase distortion that, in turn, limits the filter's application to cases such as audio where phase does not seem to be important.

### Allpass Filters

The phase distortion of an optimal magnitude IIR filter is sometimes compensated by using an allpass equalizer, where the numerator and denominator of  $H(\omega)$  have the same order,  $M = N$ , and the filter coefficients satisfy  $a[k] = b^*[N - k]$ . The allpass equalizer, however, is usually not an efficient way to implement filtering, because the equalizer usually has very high order compared to the original filter. This not only causes the filtering to become inefficient, but also causes a long delay in the output signal. Allpass filters can also be used for frequency selective filter design if a pair of allpass filters are connected in parallel. Details of this clever allpass design method can be found in [9–13].

### Filters Designed by Optimizing a General Weighted Norm

In the most general case, filter design can be treated as the process of approximating a complex-valued function  $H(\omega)$ , where the filter coefficients are the approximating parameters. This treatment gives the filter design problem more degrees of freedom in choosing the ideal response because both magnitude and phase can be approximated. Figure 26.4 shows an example using the general weighted norm. The filter has a much better response than the filter in Fig. 26.3 with the same order as summarized in Table 26.1.

**TABLE 26.1** Filter Design Comparison

Filter	# Zeros	# Poles	Mag. Error	GD. Error	RMS GD. Error
Elliptic (Fig. 26.1)	6	6	0.082	13.90	3.57
Equalized elliptic (Fig. 26.3)	31	6	0.079	3.15	0.76
IIR (Fig. 26.4)	31	6	0.015	2.40	0.32

*Note:* The table shows three features: maximal magnitude error, maximal group delay error, and RMSs of the group delay error, of the optimal response of the filter in Figs. 26.3 and 26.4 designed under different approaches.

**FIGURE 26.4** Filter with optimal general weighted norm. The figures show the magnitude and the group delay of an IIR frequency selective filter (31 zeros, 6 poles) with flat delay passband. The ideal filter is the same as in Fig. 26.3, and the filter order is the same as the equalized elliptic filter.

Several optimization techniques are available to solve these general problems. In addition, the error can be controlled by the selection of an error constraint, an error weight, or a design norm; however, the optimization of general norms is often a difficult problem, especially in the complex domain. Most recent research has studied these general norm problems in order to improve the design when the goal is a simultaneous approximation of the magnitude and phase.

## Filter Design as a Norm Problem

Filter design is usually done by minimizing either the worst-case error (Chebyshev norm), or the root mean squares (RMS) (least-squares norm) of the weighted error. Important norms from classical mathematics are listed below:

- Chebyshev norm:  $\|E\|_\infty = \max_{\omega} |E(\omega)|$
- Least-squares norm:  $\|E\|_2 = \left\{ \int_{-\pi}^{\pi} |E(\omega)|^2 d\omega \right\}^{1/2}$
- $p$ -norm:  $\|E\|_p = \left\{ \int_{-\pi}^{\pi} |E(\omega)|^p d\omega \right\}^{1/p}$  for  $p \in [1, \infty]$
- Combined norm:  $\|E\|_\alpha = \{ \alpha \|E\|_\infty^2 + (1 - \alpha) \|E\|_2^2 \}$  for  $\alpha \in [0, 1]$

where  $E = W(I - H)$  is the weighted complex error. When optimizing the Chebyshev norm, the resulting optimal filters have the smallest maximal error, while filters with minimal least-squares norm have the smallest RMS error. Preference for one norm over the other will generally depend on the application. In many cases, where both norms need to be small, filters should be designed under either the  $p$ -norm or the combined norm. Along with the norm, the numerical optimization can be done under design constraints, e.g., the most obvious one is a constraint on the magnitude of the error

$$\min \|E\| \quad \text{such that} \quad |E(\omega)| \leq \varepsilon(\omega)$$

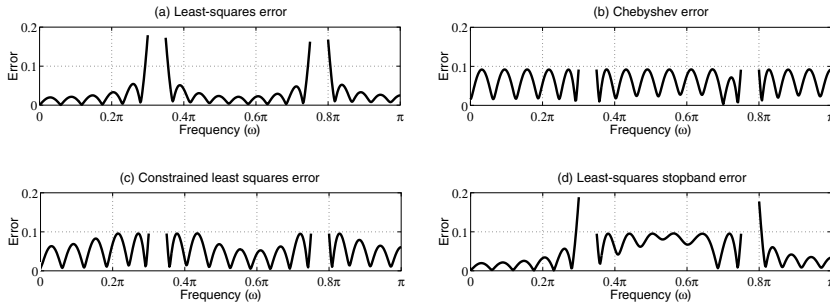

where  $\varepsilon(\omega)$  is the error constraint.

Figure 26.5 shows the error of the filter with the same specification designed under four different norms. The RMS and maximal errors are summarized in Table 26.2.

**TABLE 26.2** Error Measurements for Fig. 26.5

Filter	RMS Error	Maximal Error in Passband	RMS Error in Stopband
(a) Least-squares	0.0361	0.1793	0.0348
(b) Chebyshev	0.0657	0.0923	0.0660
(c) Constrained least-squares	0.0562	0.0959	0.0571
(d) Least-squares stopband	0.0584	0.0958	0.0374

Note: These are the passband and stopband errors in bandpass filters designed by a different norm problem.

**FIGURE 26.5** Different error norms. The four filters were designed to approximate the same bandpass filter of order 25 with four different norms. The filter in (c) was designed by minimizing the least-squares norm under the constraint that the maximal error be smaller than 0.0959. Note that the filter in (c) can also be designed by minimizing the unconstrained combined norm problem with the norm weighting  $\alpha = 0.4$ . The filter can also be designed so that both the distortion in the pass band and the power of the stopband error are small. The filter in (d) was designed by optimizing the combination of the Chebyshev error norm of the passband plus the least-squares norm of the stopband.

The norm optimization problem differs quite a bit for the FIR and IIR cases:

**FIR filter:** The problem is formed on a linear vector space and has been well studied. The optimal solution is unique by convexity. Many available design methods are not only elegant, but are also computationally efficient and have guaranteed convergence.

**IIR filter:** Although the IIR filter design problem does not have the same nice properties as the FIR filter design problem, optimizing the norm is relatively easy. One iterative approach to IIR filter design relies on a sub-procedure similar to the method for FIR filter design.

## 26.4 Conventional Design Methods

Although many filter design papers have been published in the 35 years of DSP, only a handful of filter design methods are widely used. Some of the older conventional methods can design filters with excellent magnitude response using a very simple procedure, but the variety of possible filter specifications and error norms are usually limited. More recent methods offer general design capabilities for both magnitude and phase approximation, but are based on numerical optimization.

### IIR Filters from Analog Filters

Originally digital filters were derived from analog filters [14] because analog filter design techniques had been studied for a long time and the design usually involved algebraic formulas that were simple to carry out. The two main design methods are impulse-invariance and the bilinear transformation.

#### Impulse Invariance

The design is carried out by starting with an already designed analog filter that is bandlimited. Let  $h_a(t)$  denote the impulse response of the analog filter. Then the impulse response of the digital filter is obtained by sampling, i.e., by setting  $h[n] = T_d h_a(nT_d)$ ; however, no analog filter is truly bandlimited, so the actual

frequency response involves some aliasing:

$$H(\omega) = \sum_{k=-\infty}^{\infty} H_a\left(j\frac{\omega}{T_d} + j\frac{2\pi}{T_d}k\right)$$

where  $H_a(s)$  is the Laplace transform system function of the analog filter. The aliasing effect usually causes only a slight perturbation of the digital filter with respect to the analog filter. The system function of the analog filter can be expressed in partial fraction form

$$H_a(s) = \sum_{k=1}^N \frac{A_k}{s - s_k}$$

After sampling the digital filter has a frequency response that is also a rational form:

$$\text{DTFT: } H(\omega) = \sum_{k=1}^N \frac{T_d A_k}{1 - e^{T_d s_k} e^{-j\omega}} = \frac{\sum_{k=0}^{N-1} b[n] e^{-j\omega n}}{1 + \sum_{k=1}^N a[n] e^{-j\omega n}}$$

where  $b[n]$  and  $a[n]$  are the coefficients of the designed filter. Impulse invariance is equivalent to a linear mapping of the analog frequency range  $[-\pi/T_d, \pi/T_d]$  into the digital frequency range  $[-\pi, \pi]$ .

### Bilinear Transform

On the other hand, the bilinear transformation performs a nonlinear mapping of the whole analog frequency range  $[-\infty, \infty]$  into the finite digital frequency range  $[-\pi, \pi]$ . The mapping of the  $s$ -plane to the  $z$ -plane is done by the bilinear transform:

$$s = \frac{2}{T_d} \left( \frac{1 - z^{-1}}{1 + z^{-1}} \right)$$

The resulting correspondence between the analog and digital frequency domains is a tangent function:

$$\omega_a = \frac{2}{T_d} \tan\left(\frac{\omega}{2}\right)$$

Despite the nonlinear nature of the mapping, it is relatively easy to turn the digital design specification into an analog design specification. The resulting filter is IIR and the filter coefficients can be computed with an algebraic form. The bilinear transform method is usually applied to four classical analog filter frequency selective filters: Butterworth, Chebyshev-I, Chebyshev-II, and elliptic filters. All these are well known for their frequency-selective behavior as lowpass, bandpass, or highpass filters. When using the bilinear mapping, elliptic IIR filters turn out to have the best magnitude response for given filter order, but elliptic filters have severe phase distortion, which can be a significant problem in advanced DSP applications such as telecommunications.

### Windowing

IIR filter designs have poor phase response, so interest in FIR filters has always been strong. If the coefficients of an FIR filter are real and symmetric  $b[k] = b^*[M - k]$  then the filter will have perfectly linear phase. The first attempt to design FIR filters in the 1960s was to truncate the inverse DTFT of the ideal frequency response (which is the impulse response  $h[n]$  of the ideal filter), so that the filter is symmetric and linear-phase. This requires the ideal filter to have linear-phase with slope  $-\frac{1}{2}M$ , where  $M$

is the FIR filter order. This method of filter design turns out to give the optimal least-squares filter. However, the least-squares filter is not an acceptable filter, especially when the application calls for a frequency selective filter. The reason is that the least-squares approximation exhibits an overshoot called the *Gibbs' phenomenon*, which means that the magnitude of the error is large at the cutoff frequency regardless of the filter order. To reduce the magnitude error near the cutoff frequency, the strict truncation (done by applying a rectangular window) can be replaced by other windowing. Windowing for filter design involves the multiplication of a finite-length window shape times the ideal impulse response. For example, the ideal lowpass filter with delay  $\mu = \frac{1}{2}M$  has an impulse response that is infinitely long:

$$h[n] = \frac{\sin(\omega_c(n - \mu))}{\pi(n - \mu)}, \quad -\infty < n < \infty$$

so the windowed filter coefficients are  $b[n] = w[n]h[n]$  for  $n = 0, 1, 2, \dots, M$ .

Different windows generate filter responses that allow a trade-off between the sharpness of transition region and the error magnitude. Popular windows are: Bartlett, Hamming, vonHann (or Hanning), and Kaiser, but for filter design the only important one is the Kaiser window, which is based on the modified Bessel function. The Kaiser window is defined as

$$w[n] = \frac{I_0(\beta\sqrt{1 - (n - \mu)^2/\mu^2})}{I_0(\beta)}, \quad n = 0, 1, 2, \dots, M$$

where  $I_0(x)$  is the modified Bessel function, and the parameter  $\beta$  is chosen to control the ripple height in the stopband with the relationship:

$$\beta = \begin{cases} 0, & \delta_{\text{dB}} < 21 \\ 0.5842(\delta_{\text{dB}} - 21)^{0.4} + 0.07886(\delta_{\text{dB}} - 21), & 21 \leq \delta_{\text{dB}} \leq 50 \\ 0.1102(\delta_{\text{dB}} - 8.7), & \delta_{\text{dB}} > 50 \end{cases}$$

where  $\delta_{\text{dB}} = -20 \log_{10}(\delta_{\text{stopband}})$  is the ripple height in dB. The design of the Kaiser window is illustrated in Fig. 26.6. Examples of digital filters designed via windowing are shown in Fig. 26.7.

**FIGURE 26.6** The Kaiser window: (a) shows the relationship between  $\beta$  and the ripple height in the stop band; (b) shows examples of length-51 Kaiser windows (i.e., filter order = 50) with different parameters  $\beta$ . Note that, with  $\beta = 0$ , the window is the rectangular window and, with  $\beta = 5$ , the window is very similar to the Hamming window.

**FIGURE 26.7** Digital filter design via Kaiser windowing: (a) shows the impulse response of an ideal lowpass filter (circles with dotted lines) and the filter designed by windowing (filled circles with solid lines). The windowed filter is the product of the ideal impulse response and the Kaiser window with  $\beta = 5$  (dashed line); (b) shows the log magnitude of four filters designed using the Kaiser window with different parameters  $\beta$ .

### Frequency Sampling

Another common, but naive, approach to FIR design is the method of frequency sampling. In this case, the ideal frequency response is sampled over the range  $-\pi < \omega \leq \pi$  at  $M + 1$  points and then the inverse FFT is computed to get the order- $M$  impulse response, which then contains the coefficients of the FIR filter. It is possible to let a few of the frequency samples be free parameters for a linear program that will optimize the resultant  $H(\omega)$ . This, in turn, improves the filter characteristics by making the error smaller near the cutoff frequency.

### Weighted Least-Squares

Although frequency sampling filters and windowing designs have pretty good responses, neither one is an optimal filter. In the general optimization approach, the transition band of the frequency response should be treated as a “don’t care” region. For common frequency selective filters, the optimal filter will have a smooth behavior in the transition band even though no optimization is done in that “don’t care” region. The FIR filter can be designed by minimizing any norm with a guaranteed unique solution. The design can be generalized further by using a weighting function on the error. For example, the weight can be used in clever ways to control the error. Here is the weight definition for an inverse filter (or equalizer).

$$I_{\text{Eq}}(\omega) = \frac{D(\omega)}{H_{\text{Sys}}(\omega)}, \quad W_{\text{Eq}}(\omega) = |H_{\text{Sys}}(\omega)|W(\omega)$$

The weighted design problem usually involves optimizing the norm of the error over the entire frequency domain, but that is done numerically by working on a dense frequency grid.

The easiest optimization problem is the least-squares norm minimization because the partial derivatives (which are the elements of the gradient) of the least-squares norm with respect to the filter coefficients are all linear combinations of the filter coefficients. This property implies that the optimal filter can be found by solving the set of linear equations obtained by setting all those partial derivatives to zero. The solution for the weighted least-squares FIR filter is

$$\frac{\partial}{\partial b[n]} \int_{\omega} |W(I-H)|^2 d\omega = 0, \quad \text{for } n = 0, 1, \dots, M$$

$$\int_{\omega} |W|^2 \left( I e^{j\omega n} - \sum_k b[k] e^{j\omega(n-k)} \right) d\omega = 0, \quad \text{for } n = 0, 1, \dots, M$$

For IIR filters, the problem is not nearly so easy because the denominator of the frequency response function makes the problem nonlinear. The solution can still be carried out by computing the partial derivatives and setting them equal to zero:

$$\int_{\omega} |W|^2 \left( \frac{e^{j\omega n}}{A^*} \left( I - \frac{B}{A} \right) \right) d\omega = 0, \quad \text{for } n = 0, 1, \dots, M$$

$$\int_{\omega} |W|^2 \left( \frac{e^{j\omega n} B^*}{A^* A^*} \left( I - \frac{B}{A} \right) \right) d\omega = 0, \quad \text{for } n = 0, 1, \dots, N$$

The solution may not exist, however, but even if it does, it is often not unique. Furthermore, it is likely that only a locally optimal solution of the nonlinear equations can be found. Another approach is to use an iteration to find a close-to-optimal solution using the Steiglitz–McBride method [15]:

$$\min \left| W \left( I - \frac{B}{A} \right) \right| \rightarrow \min \left| \frac{W}{|A|} (IA - B) \right|$$

The solution can be realized by iteratively updating the rational functions  $W/|A|$  and  $B/A$ .

## Remez Exchange

Least-squares filters are not desirable in many applications because they exhibit large worst-case error near the transition band. On the other hand, the worst-case error can be minimized by reformulating the design problem as a Chebyshev (or min-max) problem.

$$\min_{b[n], a[n]} \max_{\omega} |W(I - H)|$$

This min-max problem is usually difficult to solve unless the problem can be transformed into a real problem. To do this, the ideal filter needs to be a linear-phase filter with a group delay of  $\frac{1}{2}M$ . Then the problem becomes an approximation of a real function by a sum of sinusoidal functions. For the special case of an even-order FIR filter with symmetric coefficients, the real problem becomes:

$$\min_{c_k} \max_{\omega} \left| W(\omega) \left( I(\omega) e^{j\omega M/2} - \sum_{k=0}^{M/2} c_k \cos \omega k \right) \right|$$

where  $a = [1]$  and  $b = [\frac{1}{2} c_{N/2}, \dots, \frac{1}{2} c_1, c_0, \frac{1}{2} c_1, \dots, \frac{1}{2} c_{N/2}]$ . This min-max problem can be solved by the Remez algorithm [16–19]. The algorithm exploits the famous Alternation Theorem, which gives the necessary and sufficient condition for an optimal real Chebyshev solution as one that has at least  $M + 2$  alternating extremal points (i.e., points where the error is maximal). The operation of the algorithm involves an exchange that iteratively updates the extremal set and solves for the alternating error on that set. It turns out that the Remez Exchange algorithm is very efficient and always converges, so it has become a classical method for FIR filter design as the Parks–McClellan algorithm.

## Linear Programming

Filter design by optimizing the norm of the weighted error can be further improved by applying constraints. However, only the magnitude constrained problem seems to be easy to solve

$$\min \|W(I - H)\| \quad \text{or} \quad \min \|E\|$$

$$\text{subject to } |E(\omega)| < \varepsilon(\omega)$$

This constrained magnitude problem can be solved by Mathematical programming, which takes different forms depending on the norm. For the least-squares norm, the solution can be found by using quadratic programming.

Mathematical programming is also a tool for the nonlinear-phase Chebyshev problem [20], which can be rewritten as a constrained problem:

$$\begin{aligned} & \min \delta \\ & \text{subject to} \\ & \Re\{E(\omega)e^{j\theta}\} < \delta, \quad \text{for all } \omega \text{ and } \theta \end{aligned}$$

This problem is a semi-infinite linear minimization (SILM). Linear programming can then be applied to the problem by sampling the parameters  $\omega$  and  $\theta$ . The algorithm is not efficient for high-order filters because dense parameter sampling is needed to design filters with high precision. In order to improve efficiency, the SILM can be rewritten in a *dual form* [21–24].

## 26.5 Recent Design Methods

---

Because conventional design methods are available for only special types of digital filters, e.g., linear-phase, researchers have proposed various new methods that use complex approximation in filter design. Among those, only a few are discussed because they are elegant and useful in various applications.

### Complex Remez Algorithm

The complex Chebyshev design problem is one of the most important approaches for designing digital filters. Unfortunately, it might need a general algorithm such as SILM, which requires a large number of frequency samples (with resulting high computation and high memory) when high precision is desired. For high order filters, linear programming is very inefficient for Chebyshev filter design. Instead, modifications of the Remez Exchange algorithm would be more desirable. Therefore, the complex Remez algorithm (CRemez) [25,26] was proposed using an exchange method search that is similar to the Remez Exchange; however, the original CRemez is most efficient only for the special case where the extremal error alternates. In general, nonlinear-phase filters are not guaranteed to have this strict alternating property, so the exchange method does not converge to the optimum. In order to get the optimum filter in the case of nonalternating extremal errors, a second stage is needed for CRemez. This second stage has to be a general optimization method that ends up being as inefficient as the SILM method. As a result, some filters are designed very quickly by CRemez, but others take a long time when the general optimization step must be invoked.

### Constrained Least-Squares

Adams [27] suggested that Chebyshev digital filters do not always have the best overall characteristics. He found that by allowing the worst-case (Chebyshev) error to increase slightly, the least-squares error can be reduced significantly. To design this sort of filter, a constrained least-squares problem was introduced. The problem has been solved by [28–31] with an algorithm that is quite efficient for designing FIR filters.

### Generalized Remez Algorithm

The constrained least-squares methods have two design drawbacks: (1) error constraints are required to set up the problem, and (2) the existing methods only handle the FIR case. The first drawback is not severe, but it reduces the design efficiency because prior information such as a prior filter design procedure is needed to estimate the constraints; however, both drawbacks can be eliminated by using a different norm (called the combined norm) and by minimizing via the iterative reweighted least-squares (IRLS) technique.

## IRLS Technique

Lawson [32] proposed that the Chebyshev problem be turned into a weighted least-squares (WLS) problem. In fact, any general norm problem can also be turned into a WLS problem

$$\text{IRLS: } \|E\| \rightarrow \|VE\|_2$$

The trick is to find the correct weight,  $V$ , which is an unknown that must be found by running an iterative update [32–34]. For example, the following iterations converge to the appropriate weight for the Chebyshev norm and the  $p$ -norm, respectively.

- Chebyshev update:  $V^{(k+1)} = V^{(k)} \sqrt{|E|}$
- $p$ -norm update:  $V^{(k+1)} = \{V^{(k)} \sqrt{|E|}\}^{\frac{p-2}{p-1}}$

The convergence of the weight is dependent on the number of points in the frequency grid, so IRLS alone usually converges slowly.

## Combined Norm

It can be shown that the solution of the combined norm problem is equivalent to a constrained least-squares problem. The solution has multiple extremals of the error similar to the Chebyshev solution. To solve the combined norm problem, the IRLS technique can be used after the problem is turned into a weighted least-squares problem:

$$\|E\|_\alpha \rightarrow \{\alpha \|VE\|_2^2 + (1 - \alpha) \|E\|_2^2\}^{1/2}$$

By iterating on the weight,  $V$ , the solution generally converges quickly unless  $\alpha$  is large. The optimization procedure can be improved by exploiting the multiple extremal error property of the optimal combined norm solution.

## Generalized Remez Algorithm

The optimal filter design problem can be generalized further by considering the problem of minimizing the combined norm together with magnitude constraints. Using Lagrange multipliers, the problem can be turned into an unconstrained least-squares problem:

$$\min \{\alpha \|VE\|_2^2 + (1 - \alpha) \|E\|_2^2 + \|\Lambda E\|_2^2\}^{1/2}$$

where  $\Lambda$  is the Lagrange multiplier. This problem can be solved by the basic IRLS technique, but often converges slowly. On the other hand, it can be shown that the weight,  $V$ , and the multiplier,  $\Lambda$ , are nonzero for only a finite number of points and those points are extremal points and points where constraints are reached. So, the multiple exchange in the Remez algorithm can be used to find those points. After the points are found, the IRLS technique is applied to compute the filter coefficients. The solution will converge much more quickly than the classical IRLS because it deals with less frequency points. The authors call this new algorithm the “generalized Remez algorithm” or GRemez because its structure is equivalent to the Remez algorithm for linear phase FIR filter design [35]. Note that the GRemez algorithm is similar to a multiple exchange algorithm for the Chebyshev problem by Tseng [36]. The GRemez algorithm is summarized as a block diagram in Fig. 26.8.

Not only can the GRemez be used for the general constrained norm problem, but IIR filters can also be designed by the GRemez with the least-squares techniques presented in the “Weighted Least-Squares” subsection to find either a close-to-optimal solution or a local optimal solution.

## 26.6 Summary

### General Comment

This chapter has given a brief overview of various digital filter design methods. The theoretical ideas of frequency response and impulse response were reviewed in order to introduce the important design methods. In addition, the mathematical idea of optimizing with respect to a norm was discussed because many newer methods utilize numerical optimization to design general classes of filters. Readers are encouraged to find more details in the references that include many excellent DSP and digital filtering books [1–6].

Because digital filters must be designed for many diverse applications, a large number of design approaches are available; however, most filter applications can be addressed with an optimization algorithm when the general filter design problem is formed under the weighted norm of the complex error. This general problem can be difficult to solve in some cases. Fortunately, it is quite simple to design the most desirable filters, i.e., least-squares and Chebyshev FIR filters with linear-phase. Furthermore, filters with more general characteristics can be designed by methods presented in section 26.5. We introduce the generalized Remez algorithm in the “Weighted Least-Squares” section in order to design both FIR and IIR filters under the weighted norm formulation.

Filter design methods presented in this paper are usually quite efficient, but some still require a fair amount of computation. For example, even though the least-squares method requires an amount of computation proportional to the cube of the filter order,  $O(M^3)$ , it is considered to be a relatively efficient design method using a norm minimization. Fortunately, the design time is hardly noticed on today’s desktop computers, which have very fast processors.

Many other important issues in filter design were not treated here. These include filter order selection, filter pole location sensitivity, effect of implementing filter with fixed-point arithmetic, and multidimensional filter design [37–39]. Some details about these issues can be found in the references. In addition, the design of two-dimensional (2-D) filters has not been treated. Some of the optimization methods discussed here will also work for the 2-D case, but much of the theory of Chebyshev approximation no longer applies, so methods that exploit special features such as the Alternation Theorem will no longer be efficient.

## Computer Tools

General filter design methods that are able to handle virtually all of the desired filter characteristics of common applications were discussed; however, most users would not want to be involved with details of programming the optimization algorithms. So, software applications have been built to help users skip the computer programming step and concentrate on entering the filter specifications for their application. Two types of interface for the design software are common: (1) allow users to set up the full design specification and (2) allow limited specifications.

The second type is generally implemented as a graphical user interface (GUI) that helps the user visualize all the steps of the design from creating the passband and stopband, setting the filter type (FIR or IIR), selecting the optimization tool, running the design program, and showing the designed filter responses. GUI software hides most of the design steps in the interest of simplicity, but it imposes a limitation on the amount of information that the user can see.

More advanced users probably need to design filters with more sophisticated specifications, more control on the error, or a wider variety of filter types. Therefore, they may need to enter the parameters manually in a command line to run the optimization function of the design algorithm. This normally requires some experience in the programming language and sometimes knowledge of the design program's source code.

One example of filter design programs can be found in the MATLAB® environment with its signal processing toolbox. Most of the design methods of filter design are available in the SP toolbox, and additional ones might be obtained by contracting the author who proposed the method. In MATLAB, the information for running the signal processing toolbox can be seen by typing "help signal." One attempt to make DSP simple to use is the MATLAB GUI program "sptool" that can upload and download signals, design and apply filters, and analyze the signal spectra. By pushing the button "New Design," the filter design GUI is called and the program gives the user an ability to design frequency selective filters by most of the conventional methods. Actually, the design GUI takes input parameters, changes them into the proper format, and then performs the design by calling design functions such as "butter," "cheby1," "cheby2," "ellip," "firls," and "remez." For more varieties of filter types, filters may be designed by calling "cremez," "fircls," etc., with appropriate parameters in the MATLAB command line. The authors have also developed the function "gremez" and "gremez\_gui" as a MATLAB functions that can be downloaded from "<http://users.ece.gatech.edu/mcclella/gremez>".

### 27.1 Introduction

---

Information and communication systems play bigger and bigger role in our modern society—the so-called information society. Sound (audio and speech) is one of the most important signals in these systems and the growing need for audio and speech processing (transmission, storing, etc.) generates new scientific problems (e.g., formulates new questions about data acquisition, compression, and coding), stimulates new technologies and techniques, as well as creates new areas of science and technology in informatics, communications, artificial intelligence, psychoacoustics, etc.

Applications of digital audio processing systems are in audio production, storage, distribution, exchange, broadcasting, transmission, Internet services, etc. Modern multimedia coding standards (e.g., moving picture expert group (MPEG) standards: MPEG-4, MPEG-7, and MPEG-21) [3,18–20,34,36] cover the whole range of audio signals starting from high fidelity audio, through the regular quality of audio and speech, down to relatively low quality mobile-access and synthetic speech and audio.

In order to evaluate various audio coding systems it is necessary to qualify the audio quality they offer. Generally, three main parameters are used to describe the quality of audio: bandwidth, fidelity, and spatial realism.

For high-fidelity (wideband) audio a bandwidth of at least 20 kHz is needed. The acoustic signals with higher frequencies are not audible by human beings. Compact disc (CD)—the today's most popular standard for digital audio representation—offers a bandwidth of 20–20,000 Hz. Traditional (analog) radio covers the bandwidth of up to 15 kHz for frequency modulation (FM) and up to 4.5 kHz only for

amplitude modulation (AM). Wideband speech standard has a bandwidth of 50–7000 Hz, while the telephone speech is reduced to a bandwidth of merely 300–3400 Hz.

Fidelity is a (subjective) measure of perceptibility of impairment (noise) present in the reproduced audio. Audio fidelity is usually determined subjectively by means of an averaged judgment called the mean opinion score (MOS). It is typically based on a 5-point grading scale: 5—impairment imperceptible, 4—perceptible but not annoying, 3—slightly annoying, 2—annoying, 1—very annoying [35].

Spatial realism of an audio representation system describes the naturalness and quality of directional information about places of particular sound sources contained in the reproduced sound. The spatial realism depends first of all on the number of audio channels. Typical configurations are: 1-channel audio (mono); 2-channel audio (stereo); multichannel audio (surround sound), e.g., 4-channel (3 front and 1 rear), 5-channel (3 front and 2 rear), or 8-channel (6 front and 2 rear). An additional low-frequency enhancement (LFE) or *subwoofer* channel, supplementing the low frequency content (in a bandwidth of approximately 15–150 Hz), can be added in any of these cases (e.g., a 5.1-channel format is a 5-channel configuration plus subwoofer).

## 27.2 Elements of Technical Acoustics

For the purpose of this chapter, sound can be defined as a mechanical oscillation of an elastic medium that potentially can be heard. If acoustic vibrations are too high in frequency to be heard, they are referred to as ultrasonic oscillations. Consequently, if they are too low in frequency, they are called infrasonic oscillations. The sound starts in approximately 20 Hz and extends up to 20 kHz (thus it covers a bandwidth of approximately 10 octaves) [32,54,55].

A source of sound undergoes rapid changes of position (and/or size, or shape) that disturb positions of adjacent molecules of the surrounding medium (in most cases the atmosphere). Thus, these molecules start to oscillate about their equilibrium positions. These disturbances propagate elastically to neighboring particles and then gradually to larger and larger distances, thus constituting an acoustic wave traveling through the medium. The acoustic wave speed in air equals

$$c = c_0 \sqrt{1 + \frac{\vartheta}{273}} \quad (27.1)$$

where  $\vartheta$  is the room temperature in degrees of celsius and  $c_0 = 331$  m/s is the sound speed at  $\vartheta_0 = 0^\circ\text{C}$ . At room temperature ( $\vartheta = 20^\circ\text{C}$ ) the speed of sound is calculated to be 343 m/s.

A sound wave compresses and dilates the elastic medium it passes through, generating associated pressure fluctuations. The minimum fluctuation to which the ear responds is extremely small, e.g., at a frequency of 1000 Hz the just noticeable effective air pressure amplitude is approximately  $20 \mu\text{Pa}$ , i.e., less than  $10^{-9}$  of the standard atmospheric pressure (equal to  $1000 \text{ hPa} = 10^5 \text{ Pa}$ ). The limit of danger followed by the threshold of pain corresponds to effective air pressure amplitude one million ( $10^6$ ) times larger, but still less than one-thousandth of the atmospheric pressure [24].

Because of this wide range of acoustic pressure amplitudes, it has become conventional to specify the sound pressure level (SPL),  $L_p$ , in terms of a decimal logarithm with the (dimensionless) unit of the decibel (dB)

$$L_p = 20 \log_{10} \frac{p}{p_0} \quad (27.2)$$

where  $p_0 = 20 \mu\text{Pa}$ .

Another quantity, which is often used, is the sound intensity level,  $L_I$ , defined in decibel as

$$L_I = 10 \log_{10} \frac{I}{I_0} \quad (27.3)$$

The reference in this case is the sound intensity  $I_0 = 10^{-12} \text{ W/m}^2$ . For a free progressive acoustic wave in air, sound pressure level and sound intensity level are approximately equal.

## 27.3 Parametric Modeling of Audio Signals

A natural representation of an audio signal is its waveform  $x(t)$  describing the sound pressure changes in time. Signal  $x(t)$  occurs at a microphone output, excites the speaker, and generally, represents sound in analog audio processing systems. On the other hand, in digital systems, in order to reduce the required bit rate, the physical signal  $x(t)$  can be replaced by a number of parameters, e.g., describing the way the audio signal originates. The major problem, however, that immediately arises and has to be overcome, consists in a fact that there exists no unique plausible model for production of all kinds of audio signals. On the contrary, for different types of audio, only different models (if any) can be proposed [19,20,41].

For example, for speech efficient parametric description models can be developed by means of modeling of the human vocal tract [13]. Such parametric speech source models describe the speech production process by, first, modeling an excitation (noise for unvoiced speech and a periodic signal for voiced speech), and second, by representing the human voice tract by means of an appropriate infinite impulse response (IIR) filter. This is the so-called linear prediction coding (LPC) scheme [37].

Another signal example, for which an extremely efficient parametric description exists, is music. This description is the well-known musical score notation. Indeed, a kind of such a description has been applied in the musical instrument digital interface (MIDI). Although the musical score notation is extremely efficient and it does not probably exist any other representation for music that would be more efficient, the score as a means for audio coding has two major drawbacks. First of all, the whole information about the individual performer is lost. Second, an automatic transcription of audio into the musical score is very difficult. Thus, compromise solutions have to be searched for. Structured audio—a part of the MPEG-4 standard—uses such techniques. An audio signal is split into individual, meaningful source objects and is treated as a composition of them [18,34,35]. This approach is also used in the newest standards MPEG-7 and MPEG-21 [19,20,34].

One of the most promising approaches to the parametric description of a wide class of audio signals consists in removing the redundancy contained in the original audio signal representation  $x(t)$ . This can be done by splitting the signal into a number of almost uncorrelated components. The simplest and the most popular method is the time-to-frequency transformation by means of an appropriate analysis filter bank [52]. For example, in the MUSICAM standard the whole audio band, which is in this case 24 kHz wide, is split into 32 uniform subbands of the width  $24,000/32 = 750 \text{ Hz}$  each. Another widely used uniform filter bank is based on a modified discrete cosine transform (MDCT) [40]. Nonuniform, e.g., octave filter banks can also be used. An optimized octave filter bank based on the so-called wave digital filters (WDFs) [11] is proposed in [43].

Efficient parametric description of audio signals, which is, in fact, a generalization of an octave filter bank approach and, in other words, is a simplified score-type representation, is the so-called discrete wavelet transformation (DWT). In order to introduce the DWT concept, it should first be noticed that the signal  $x(t)$  can often be expressed as a linear expansion

$$x(t) = \sum_m c_m \psi_m(t) \quad (27.4)$$

where  $m$  is an integer index,  $c_m$  are the real-valued expansion coefficients (parameters describing the signal), and  $\psi_m(t)$  is a set of real-valued functions of time  $t$  called the expansion set. The expansion set is called *basis* if the representation (27.4) is unique, i.e., if functions  $\psi_m(t)$  are linearly independent. The most interesting case is the orthogonal or even orthonormal basis. For example, for a Fourier series, the orthogonal basis functions  $\psi_m(t)$  are  $\cos k\omega_0 t$  and  $\sin k\omega_0 t$ , where  $\omega_0$  is related to the signal period  $T$  according to equation  $\omega_0 = 2\pi/T$ .

For the discrete wavelet expansion, called DWT, a two-dimensional set of coefficients  $a_{kl}$  is constructed in such a way that

$$x(t) = \sum_{k=-\infty}^{\infty} \sum_{l=-\infty}^{\infty} 2^{k/2} a_{kl} \psi(2^k t - l) \quad (27.5)$$

where the function  $\psi(t)$ , called *wavelet* (small wave), generates the expansion set  $\psi(2^k t - l)$ , which is an orthogonal basis. The wavelet  $\psi(t)$  is an oscillating and quickly decaying function, which has its energy sufficiently well localized in time and in frequency. Several different wavelet classes have already been proposed [5].

Introducing another basic function  $\varphi(t)$ , called the *scaling function*, a multiresolution signal representation, starting from some resolution  $k$ , can be formulated:

$$x(t) = \sum_{l=-\infty}^{\infty} 2^{k/2} b_{kl} \varphi(2^k t - l) + \sum_{\kappa=k}^{\infty} \sum_{l=-\infty}^{\infty} 2^{\kappa/2} a_{\kappa l} \psi(2^\kappa t - l) \quad (27.6)$$

Two fundamental self-similarity equations have to be fulfilled:

$$\varphi(t) = \sum_n \sqrt{2} h_0(n) \varphi(2t - n) \quad (27.7a)$$

$$\psi(t) = \sum_n \sqrt{2} h_1(n) \varphi(2t - n) \quad (27.7b)$$

where  $h_0(n)$  and  $h_1(n)$  are impulse responses of two discrete-time complementary filters—a lowpass filter and a highpass filter, respectively. For a finite even length  $N$ , responses  $h_0(n)$  and  $h_1(n)$  are related to each other by

$$h_1(n) = (-1)^n h_0(N - 1 - n), \quad n = 0, \dots, N - 1 \quad (27.8)$$

If resolution  $k$  is large enough,  $\kappa = k$  can only be taken into account in expansion (27.6). In other words, we can assume that

$$x(t) = \sum_{l=-\infty}^{\infty} 2^{k/2} b_{kl} \varphi(2^k t - l) + \sum_{l=-\infty}^{\infty} 2^{k/2} a_{kl} \psi(2^k t - l) \quad (27.9)$$

Thus, from Eqs. (27.7a) and (27.7b) we conclude that  $x(t)$  is a signal of resolution  $k + 1$  and can be modeled as

$$x(t) = \sum_{n=-\infty}^{\infty} 2^{(k+1)/2} b_{(k+1)n} \varphi(2^{k+1} t - n) \quad (27.10)$$

Assuming that functions  $\varphi(2^k t - l)$  and  $\psi(2^k t - l)$  in expansion (27.9) form an orthonormal basis, after some manipulations, we conclude that

$$b_{kl} = \sum_n h_0(n - 2l) b_{(k+1)n} \quad (27.11a)$$

$$a_{kl} = \sum_n h_1(n - 2l) b_{(k+1)n} \quad (27.11b)$$

If the signal  $x(t)$  is of finite duration, the sums in expressions (27.9) and (27.10) are finite. The sets  $\{b_{(k+1)n}\}$  and  $\{b_{kl}, a_{kl}\}$  form alternative parametric descriptions for the signal  $x(t)$ . Although both sets have the same

FIGURE 27.1 Two-band filter bank: (a) analysis bank, (b) synthesis bank.

FIGURE 27.2 Discrete wavelet transformation (DWT): (a) two-band analysis tree, (b) two-band synthesis tree.

number of parameters, description  $\{b_{kl}, a_{kl}\}$  is somehow more efficient because parameters  $a_{kl}$  are less important than  $b_{kl}$  and consequently  $\{b_{(k+1)n}\}$ . From Eqs. (27.11a) and (27.11b) we conclude that parameters  $b_{kl}$  and  $a_{kl}$  result from a lowpass and a highpass filtering of parameters  $b_{(k+1)n}$ , respectively, with a two-band splitting filter bank of impulse responses  $h_0(-n)$  and  $h_1(-n)$ , respectively, followed by a down sampling with factor 2 (Fig. 27.1(a)). This procedure can be continued many times in order to obtain even more efficient parametric representation. If only parameters  $b_{kl}$  are split, which is the case in the classical DWT, a kind of an octave signal analysis filter bank results (Figs. 27.2(a) and 27.3). If also parameters  $a_{kl}$  are split (wavelet packet) and/or a multiband splitting filter bank is used (multiband wavelet system) [5], very flexible analysis filter banks can be realized (Fig. 27.4), e.g., those simulating along the frequency axis the distribution of a set of nonoverlapping *peripheral auditory filters* (cf., section 27.4).

Another quite efficient approach for the parametric description of audio is the so-called *sinusoidal modeling* often used for the analysis and synthesis of musical instrument sounds [41]. The audio signal  $x(t)$  is modeled by a set of tones and noise.

$$x(t) = \sum_k a_k(t) \sin\left(\int_{\tau=0}^t \omega_k(\tau) d\tau + \phi_k\right) + \text{noise} \quad (27.12)$$

The tones have slowly varying parameters: amplitude  $a_k(t)$  and frequency  $w_k(t)$ . Additionally, an appropriate noise model has to be used. A perceptually acceptable noise model can be obtained by adding

**FIGURE 27.3** Time-frequency (scale) signal representation patterns: (a) an initial  $(k + 1)$ -resolution scale pattern corresponding to expression (27.10); DWT pattern after three transformation steps (the first step is made according to Eq. (27.9)).

**FIGURE 27.4** Time-frequency (scale) signal representation patterns: (a) a pattern after two transformation steps with a four-band wavelet basis, (b) an example of a two-band wavelet packet transformation.

some sinusoids with different frequencies and random phases. Alternative methods are based on the noise spectrum modeling.

An additional envelope model (with particular envelope attack and decay rates) can be added for some of the sinusoids in order to improve the sinusoidal model efficiency for highly nonstationary signals.

A dual approach to that described by Eq. (27.12) is also possible. The signal  $x(t)$  is first transformed into the frequency domain, e.g., by means of the discrete cosine transform (DCT), and then the sinusoidal modeling is realized in the frequency domain [41].

## 27.4 Psychoacoustics and Auditory Perception

Understanding of psychoacoustics phenomena occurring during the auditory perception by humans is crucial for the design of efficient audio coding algorithms. An efficient audio coder (the so-called perceptual coder) should not only reduce redundant components in the audio representation, using an appropriate parametric audio model (cf., section 27.3), but it also should remove irrelevant components from the source signal, i.e., those, which are inaudible by humans (Fig. 27.17).

**FIGURE 27.5** Critical bandwidth and ERB as functions of the passband center frequency: (a) critical bandwidth according to Eq. (27.13), (b) ERB according to Eq. (27.14a).

Signal processing, which takes place in the human auditory system, can generally be divided into two stages: a preliminary phase realized in the acoustic auditory organs (ears) and the advanced phase done in auditory nervous system (in the brain). The auditory part of the inner ear, known as the cochlea because of its snail-like shape, performs a kind of spectral analysis. The acoustic harmonic tones generate place selective oscillations distributed along the so-called basilar membrane, which extends down the cochlea. In result, the frequency is mapped into a place on the basilar membrane and a frequency scale can be laid out at the basilar membrane with low frequencies near the apex and high frequencies near the base of the cochlea. According to the authors' results the cochlear response is not a kind of a Fourier-like transformation but, neglecting the nonlinearities, it is rather a kind of the continuous wavelet transformation (CWT) [5]. Consequently, the cochlear response can be interpreted as if it were produced by a filter bank composed of highly overlapping bandpass filters with increasing passbands. These filters are referred to as the *peripheral auditory filters*.

Two widely accepted approaches are used for estimation of the passbands of the peripheral auditory filters. The older approach is based on the notion of *critical bands*  $\Delta f_c$  [12,45,56]. The widths of the critical bands vary from ca. 100 Hz for low frequencies (lower than 300 Hz) to about one-third of an octave for high frequencies (Fig. 27.5(a)). The critical bandwidth as a function of its center frequency can be estimated in hertz using expression

$$\Delta f_c = 25 + 75(1 + 1.4f^2)^{0.69} \quad (27.13)$$

in which frequency  $f$  is given in kilohertz [45].

The newer approach results from measurements of the frequency response shape of the peripheral auditory filters and uses a concept of equivalent rectangular bandwidth (ERB) [32,44]. ERB is a bandwidth of the equivalent ideal (rectangular) passband filter, which has the same center passband frequency as the respective peripheral auditory filter, transmits the same amount of power when excited with the same white noise, and has the passband gain equal to the maximum passband gain of the respective auditory filter. ERB as a function of frequency can be approximated in hertz as

$$\text{ERB} = 6.23f^2 + 93.3f + 28.52 \quad (27.14a)$$

where frequency  $f$  is again given in kilohertz (cf. Fig. 27.5(b)). Sometimes, a slightly simpler formula is

**TABLE 27.1** Critical Bandwidth and Equivalent Rectangular Bandwidth (ERB) as Functions of the Respective Center Frequency

Center Frequency $f_c$ (Hz)	Critical Bandwidth $\Delta f_c$ (Hz)	ERB (Hz)	$\Delta f_c/\text{ERB}$
50	100	33	3.0
100	100	38	2.7
200	100	47	2.2
500	120	77	1.5
1000	160	128	1.3
2000	300	240	1.3
5000	900	651	1.4
10,000	2300	1585	1.5

**FIGURE 27.6** Equal-loudness contours for pure tones.

used [32,44]

$$\text{ERB} = 24.7(4.37f + 1) \tag{27.14b}$$

Chosen values of  $\Delta f_c$  and ERB are listed in Table 27.1. Critical bandwidth is greater than ERB even three times for low frequencies but for higher frequencies, starting with ca. 500 Hz, it is 1.3–1.5 times larger only.

Approximately 24 nonoverlapping critical bands cover the whole audible frequency range, but it does not mean that there exist 24 peripheral auditory filters only. In fact, they occur as continuously distributed filters along the frequency axis and any audible tone creates an individual peripheral auditory filter centered on it.

The ear canal acts as a resonator and increases the sound pressure at the tympanic membrane in the frequency range of 1.5–5 kHz, with a maximum at 3.5 kHz by about 10–15 dB. The sensitivity of the ear varies strongly with the frequency and reaches the maximum exactly in this band. In Fig. 27.6 equal-loudness contours for pure tones are plotted. They are labeled in units of loudness called phons. By definition, the loudness in phons is numerically equal to SPL in decibels at the frequency  $f = 1000$  Hz. The lowest curve in Fig. 27.6 represents the threshold of audibility (in quiet). This curve can be approximated with expression [47] in decibels

$$L_{p\text{tp}} = 3.64f^{-0.8} - 6.5e^{-0.6(f-3.3)^2} + 10^{-3}f^4 \tag{27.15}$$

FIGURE 27.7 Threshold of audibility in quiet approximated by Eq. (27.15).

FIGURE 27.8 Region of audibility.

where frequency  $f$  is as before given in kilohertz. The threshold of audibility computed with formula (27.15) is shown in Fig. 27.7.

A kind of positive feedback improves the sensitivity and selectivity of the basilar membrane oscillations. Its function can be compared with that of the so-called “reaction” used in early radio receivers to increase their amplification and to improve their frequency selectivity. The positive feedback effect decreases as sound intensity increases. Thus, the cochlea is less selective for intense sounds than for weak sounds. In result, the peripheral auditory filters are nonlinear, thereby extending the overall dynamic range of the hearing system to the range of approximately 120 dB (cf., Fig. 27.6).

Figure 27.8 shows the whole region of audibility extending from the threshold of audibility to the limit of danger (and further up to the threshold of pain). It also illustrates two important subregions: the speech region and the region of music. The rest of the audibility area is a reserve of the human hearing system. Speech covers the frequency band of ca. 200 Hz to 5 kHz and the dynamic range ca. 50 dB. Music occupies larger area, i.e., the frequency band of 50 Hz to 10 kHz and the dynamic range of ca. 70 dB. For the representation of high quality audio it is, however, necessary to cover and reproduce practically the whole region of audibility, i.e., the frequency band of 20 Hz to 20 kHz and the dynamic range of at least 80–90 dB.

Because of diffraction produced by the head, the sound that reaches the ears depends on the sound source direction. The difference between the arrival time of a sound at each of the two ears together with the difference in the intensity of the sound that reaches each ear is used by the auditory nervous system to determine the location of the sound source. This ability manifests mostly in the horizontal plane. In audio coding systems it is represented by stereo (2-channel) or more exactly by surround (multichannel) sound.

The spectral components of a sound are coded for intensity and time in the auditory nervous system, but not always all components are audible. This interesting phenomenon called *masking* is extremely important for efficient digital coding of audio. Masking is a kind of interference with the audibility of a sound (called probe or maskee) caused by the presence of another sound (called masker), if both these sounds are close enough to each other in frequency and occur simultaneously or closely to each other in time. If a lower level probe is inaudible, because of a simultaneous existence of a higher level masker, this effect is referred to as the *simultaneous masking*. If an inaudible probe precedes the masker or follows the masker, this phenomenon is called *temporal masking*. Masking is typically described by the minimum shift of the probe intensity level above its threshold of audibility in quiet, necessary for the probe to be heard in the presence of the masker.

Four different cases for masking can be distinguished: tone-masking-tone, noise-masking-tone, tone-masking-noise, and noise-masking-noise. The latter two cases are particularly important for the design of effective perceptual audio coders, because masking can be exploited to make the quantization noise inaudible. The first two cases were, however, so far, much more intensively investigated. In Fig. 27.9 a simultaneous tone-masking-tone effect relative to the threshold of audibility in quiet is illustrated. Masker is a pure harmonic tone of frequency 1.2 kHz and of three different sound pressure levels: 40, 50, and 60 dB. The following effects can be observed. First, the higher the level of the masker, the greater is the masking. Second, masking is largest for probe frequencies slightly above or below the masker frequency. Third, masking decreases as probe frequency gets closer to that of the masker. This phenomenon is observed for tone-masking-tone case only and is caused by audible beats between the two tones, which make the presence of the probe more apparent. Fourth, masking is greater on frequencies above the masker frequency than on frequencies below it. Fifth, due to a nonlinearity of the human hearing system, the masking curve has similar shape for various masker harmonics. This phenomenon is also typical for the tone-masking-tone case only.

Analyzing curves in Fig. 27.9 and taking the threshold of audibility in Fig. 27.6 or Fig. 27.7 into account, the maximum probe-to-masker ratios (PMRs) can be determined. For example, for a 40 dB SPL masker the maximum PMR is  $15 + 3 - 40 = -22$  dB (the maximum level of the fully masked probe

**FIGURE 27.9** Simultaneous tone-masking-tone effect relative to the threshold of audibility in quiet with a masker of frequency 1.2 kHz and of three different levels (SPL): (a) 40 dB, (b) 50 dB, and (c) 60 dB.

**FIGURE 27.10** Critical band index in Bark according to Eq. (27.17).

relative to the threshold of audibility for the curve in Fig. 27.9(a) is almost 15 dB and the threshold of audibility for the tone of frequency 1.2 kHz is about 3 dB SPL). Similarly, for 50 and 60 dB maskers the maximum PMRs are calculated to be  $-22.5$  and  $-23$  dB, respectively.

Masking curves for tone-masking-noise are similar but smoother, because no audible bits occur in this case. In order to reduce the influence of audible bits also in the tone-masking-tone case, a tone-like narrow-band noise instead of a pure tone should be used as masker. In practical audio signals this situation is observed rather than appearance of audible bits. That is why both cases with the tone as masker can be reduced to only one: a tone-like masker. The maximum PMR can be approximated by expression [14] in decibels

$$\text{PMR}_t = -(14.5 + z) \quad (27.16)$$

in which  $z$  is numerically equal to the critical band index in Bark [54] defined as

$$z = 13 \arctan(0.76f) + 3.5 \arctan(f/7.5)^2 \quad (27.17)$$

where frequency  $f$  is in kilohertz. The curve determined by Eq. (27.17) is plotted in Fig. 27.10.

When a wideband flat noise is used to mask a pure tone, masking is much stronger than that just considered. It should, however, be stressed that only a narrow frequency band (the critical band) of the noise centered at the tonal frequency causes masking of this tone. If the bandwidth of the previously wideband masking noise is made narrower than the respective critical bandwidth (noise with the constant power spectral density is considered) and if the previous probe tone level was just below the masking threshold, then the intensity of this tone has to be lowered before it can be masked again. On the other hand, if the noise bandwidth is wider than this critical bandwidth, no significant change in the masking effect can be observed. In this case the maximum PMR, illustrated in Fig. 27.11, can be determined in decibels by expression [23]

$$\text{PMR}_n = -2.0 - 2.05 \arctan(f/4) - 0.75 \arctan(f^2/2.56) \quad (27.18)$$

where frequency  $f$  is again given in kilohertz. Pessimistically, a constant value  $\text{PMR}_n \approx -5.5$  dB can be used independently from frequency. Simultaneous noise-masking-tone effect relative to the threshold of audibility in quiet with a masker of center frequency  $f_c = 1.2$  kHz, the critical bandwidth, and 40 dB SPL, is illustrated in Fig. 27.12.

FIGURE 27.11 Maximum PMR for noise masker.

FIGURE 27.12 Simultaneous noise-masking-tone effect relative to the threshold of audibility in quiet with a masker of center frequency of 1.2 kHz, critical bandwidth, and 40 dB SPL.

Although masking is typically measured as a shift of the threshold level of hearing above the threshold level of audibility in quiet, its mathematical model should be based on the additivity of signal powers (linear scale) rather than on the additivity of levels (logarithmic scale). In this context a notion of psychoacoustic excitation is widely used [32]. Particular excitations are approximately additive in terms of power; however, it is also convenient to introduce the excitation level (i.e., excitation described in the logarithmic scale), because the masking threshold level  $L_{tm}$  can be modeled as the excitation level shifted by the PMR. In all masking cases the simplest mathematical description for the masking threshold level  $L_{tm}$  is a triangular shape shown in Fig. 27.13. In the abscissa axis the critical band index  $z$  in Bark is used. The masking threshold peak can be determined in decibel by the maximum PMR according to the following equation [14,22]:

$$PMR = \alpha PMR_t + (1 - \alpha) PMR_n \quad (27.19)$$

where  $0 \leq \alpha \leq 1$  is the masker tonality index defined in such a way that  $\alpha = 0$  if the masker is a white noise and  $\alpha = 1$  if the masker is a tone. Parameter  $\alpha$  can be determined using the so-called spectral flatness measure (SFM) of the masker, defined as a decimal logarithm of the geometric average to the arithmetic average ratio of the masker power spectral density distribution in the masker frequency band.

FIGURE 27.13 Simplified model of the masking threshold level  $L_{tm} = L_{tm}(z, z_c, L_p, \alpha)$ .

$SFM_{max} = 0$  dB for a white noise masker and  $SFM_{min} = -60$  dB for a pure tone masker. Parameter  $\alpha$  could be computed as

$$\alpha = SFM/SFM_{min} \quad (27.20a)$$

but due to possible computational inaccuracies the result computed using expression (27.20a) could be greater than 1. Therefore, a slightly more complicated expression should be used

$$\alpha = \min(SFM/SFM_{min}, 1) \quad (27.20b)$$

The rising slope  $S_r$  of the masking threshold triangle is approximately constant and equals [47]

$$S_r = (25 \div 27) \quad (27.21a)$$

The falling slope  $S_f$  (dB/Bark) is smaller and depends on the masker SPL,  $L_p$ , in decibel and its center frequency,  $f_c$ , in kilohertz

$$S_f = -24 + 0.2L_p - 0.23f_c^{-1} \quad (27.21b)$$

In most typical situations, the falling slope can be approximated as  $S_f \approx -10$  dB/Bark.

Consequently, the masking threshold level  $L_{tm}$  is a function of the critical band index  $z$ , the masker center position  $z_c$ , the masker SPL,  $L_p$ , and the masker tonality index  $\alpha$ , i.e.,  $L_{tm} = L_{tm}(z, z_c, L_p, \alpha)$ . If many simultaneous maskers occur together, the overall masking effect as a function of frequency can be determined by the global threshold of hearing  $L_{ptg}$  (Fig. 27.14). In order to determine this threshold, additivity of signal powers or respective psychoacoustic excitations should be taken into account. Thus, the following approximate expression can be used

$$L_{ptg}(z) = 10 \log_{10} \left( 10^{L_{ptq}(z)/10} + \sum_i 10^{L_{tm}(z, z_{cj}, L_{pj}, \alpha_j)/10} \right) \quad (27.22)$$

where  $L_{ptq}(z)$  is the threshold of audibility in quiet,  $L_{tm}(z, z_{cj}, L_{pj}, \alpha_j)$  are particular masking threshold levels, and index  $j$  indicates the  $j$ th masker.

Finally, the signal-to-mask ratio (SMR) can be computed in decibels as

$$SMR_j = L_{pj} - L_{ptg}(z_j) \quad (27.23)$$

FIGURE 27.14 Global hearing threshold  $L_{ptg}$  for several simultaneous maskers as a function of frequency.

FIGURE 27.15 Temporal masking effect.

where  $z_j$  corresponds to the smallest  $L_{ptg}$  within the critical band of the  $j$ th masker. This is usually the left-hand side edge of this critical band.

Masking also occurs when the signal either precedes or follows the masker (Fig. 27.15). This is the already mentioned phenomenon of temporal masking. In backward masking (pre-masking) the signal precedes the masker, while in forward masking (post-masking) the signal follows the masker. The pre-masking effect appears in 10–20 ms before the masker, while the post-masking effect is by one order of magnitude longer, i.e., in the order of 50–200 ms after the masker ends. In order to take the post-masking into consideration, the signal power  $P_j = 10^{L_{pj}/10}$  occurring in time  $t$  should be seemingly increased according to equation

$$P_{sj}(t) = P_j(t) + c_j(\Delta t)P_j(t - \Delta t) \quad (27.24)$$

in which the post-masking coefficient  $c_j(\Delta t)$  is given by

$$c_j(\Delta t) = \exp(-\Delta t/\tau_j) \quad (27.25)$$

but  $\tau_j$  is a time constant depending on the  $j$ th critical band. In result, the simultaneous masking threshold rises according to the increased level  $L_{psj} = 10 \log_{10} P_{sj}$ .

All described masking effects are exploited for data compression in modern perceptual audio coders (e.g., in the MUSICAM procedure, MPEG standards, etc.).

## 27.5 Principles of Audio Coding

In order to digitally process audio, it is first necessary to sample and quantize the data, i.e., to convert the analog signal  $x_c(t)$  into a digital form. This is realized in an analog-to-digital converter (ADC). The digital data can then be compressed and encoded in a digital audio coder (transmitter), transmitted through a communication channel, decoded in a receiver, and finally recovered in a digital-to-analog converter (DAC). A general scheme of a digital audio processing system is shown in Fig. 27.16.

Sampling of a continuous-time signal

$$x = x_c(t), \quad -\infty < t < \infty \tag{27.26}$$

is a process of time discretization. It consists in representing the signal  $x_c(t)$  with a series of samples

$$x_n = x(n) = x_c(t_n), \quad n = 0, \pm 1, \pm 2, \dots \tag{27.27}$$

referred to as the *discrete-time signal* or *sampled-data signal*. Uniform time discretization with sampling period  $T_s > 0$  and rate

$$F_s = 1/T_s \tag{27.28}$$

is defined by

$$x_n = x(n) = x_d(nT_s) = x_c(t_n), \quad t_n = nT_s - \tau, \quad n = 0, \pm 1, \pm 2, \dots \tag{27.29}$$

where  $\tau > 0$  is some (usually unavoidable) system delay.

It should be stressed that scaling coefficients  $b_{(k+1)n}$  in Eq. (27.10) approximate signal samples, i.e.,  $x_n \approx b_{(k+1)n}$ , because for high enough scale  $k + 1$  the scaling functions  $\phi(2^{k+1}t - n)$  act as “delta functions.” Sampling period is in this case equal to  $T_s = 1/2^{k+1}$ .

According to the sampling theory, a low-band continuous-time signal  $x_c(t - \tau)$ , i.e., the signal, whose spectrum extends from zero to some maximum frequency, can be reconstructed on the basis of the discrete-time signal  $x(n)$ , if the sampling rate  $F_s$  is greater or at least equal to the *Nyquist sampling rate*, which is twice as high as the greatest frequency contained in the continuous-time signal spectrum, or in other words, if the whole signal spectrum lies below  $F_s/2$ , called the *Nyquist frequency*. In practice, sampling rate  $F_s$  has to be somewhat greater than the Nyquist sampling rate [37]. Typical sampling rates for audio are:

FIGURE 27.16 General scheme of a digital audio processing system.

8 ksamples/s for telephony (the signal spectrum extends up to 4 kHz, and thus covers most of the frequencies contained in speech), 32 ksamples/s for medium quality digital audio (audible frequency band up to 16 kHz is covered), 44.1 ksamples/s for a CD standard (audio frequency band up to 22.05 kHz is represented), 48 and 96 ksamples/s for high quality digital audio (the represented frequencies range up to 24 and 48 kHz, respectively).

An important generalization of the classic sampling theory applies to band signals [8]. A continuous-time signal, whose spectrum is limited to some frequency band

$$\Delta f = f_2 - f_1, \quad f_2 > f_1 \quad (27.30)$$

can be sampled with a sampling rate of at least  $F_s = 2\Delta f$  only (i.e., critically sampled), if both spectrum border frequencies  $f_1$  and  $f_2$  in Eq. (27.30) are consecutive multiples of the Nyquist frequency  $F_s/2$ , i.e., if

$$f_1 = kF_s/2 \quad \text{and} \quad f_2 = (k+1)F_s/2 \quad (27.31)$$

where  $k$  is an integer. Such a signal is referred to as the *integer-band signal*. Audio signals are not by themselves integer-band signals but they can be split with an analysis filter bank to some subband signals, which all are integer-band signals, and thus, can be critically sampled. This is indeed the case in many digital audio coders, e.g., in the MUSICAM standard the input audio signal, initially sampled with 48 ksamples/s, is split into 32 subbands with bandwidths of  $24,000/32 = 750$  Hz each. Signals in each subband are sampled with  $48/32 = 1.5$  ksamples/s sampling rate.

Another signal discretization process is quantization, i.e., the procedure of converting a signal with continuously distributed values into a signal with discrete values. Unlike sampling, which, under some conditions, can be considered lossless, i.e., the original signal can—at least theoretically—be perfectly recovered after sampling, quantization is an inherently lossy operation [8,37].

The error due to the quantization has a nature of noise and is referred to as the *quantization noise*. Although this noise is unavoidable and cannot be removed from the signal, it can be made inaudible by controlling its level and forcing it to lie under the threshold of audibility. Masking effects, discussed in section 27.4, can be very effectively exploited with this end in view.

The quantization noise is usually analyzed under the following simplifying assumptions:

- The quantization steps are uniform.
- The number of quantization levels is high.

The first assumption is not fulfilled in many quantization techniques for audio signals. This is because the perception of noise does not depend on its absolute power but on the signal-to-noise ratio (SNR). Thus, it is reasonable to quantize audio signals nonuniformly, with quantization steps proportional to the signal values. If the steps are not uniform, then the quantization error will be a function of the input signal, and consequently, it will not be an additive noise any more. Fortunately, in most procedures for the quantization of audio signals, quantization steps are at least range by range uniform and the first assumption can be considered as approximately valid. The second assumption is usually satisfactorily fulfilled. Due to this assumption the quantization noise has a uniform probability density distribution and is not correlated with the signal.

Denote by  $Q$  the quantization step and by  $p(x)$  the probability distribution function of the quantization error. Then

$$\int_{-Q/2}^{Q/2} p(x) dx = 1 \quad (27.32)$$

where

$$p(x) = \begin{cases} 1/Q & \text{for } x \in [-Q/2, Q/2] \\ 0 & \text{otherwise} \end{cases} \quad (27.33)$$

From Eqs. (27.32) and (27.33), the average quantization noise power  $p_q$  can be calculated as

$$P_q = \int_{-\infty}^{\infty} x^2 p(x) dx = \int_{-Q/2}^{Q/2} \frac{x^2}{Q} dx = \frac{Q^2}{12} \quad (27.34)$$

The signal-to-noise ratio in decibels is then

$$\text{SNR} = 10 \log_{10} \left( \frac{P_s}{P_q} \right) \quad (27.35)$$

where  $P_s$  is the time-averaged signal power. Assume that the ADC has a full scale of  $m$  bits. Then the maximum input signal amplitude is

$$A = (2^m - 1)Q \quad (27.36)$$

and thus

$$P_s \propto [(2^m - 1)Q]^2 \quad (27.37)$$

From Eqs. (27.34), (27.35), and (27.37) it follows that

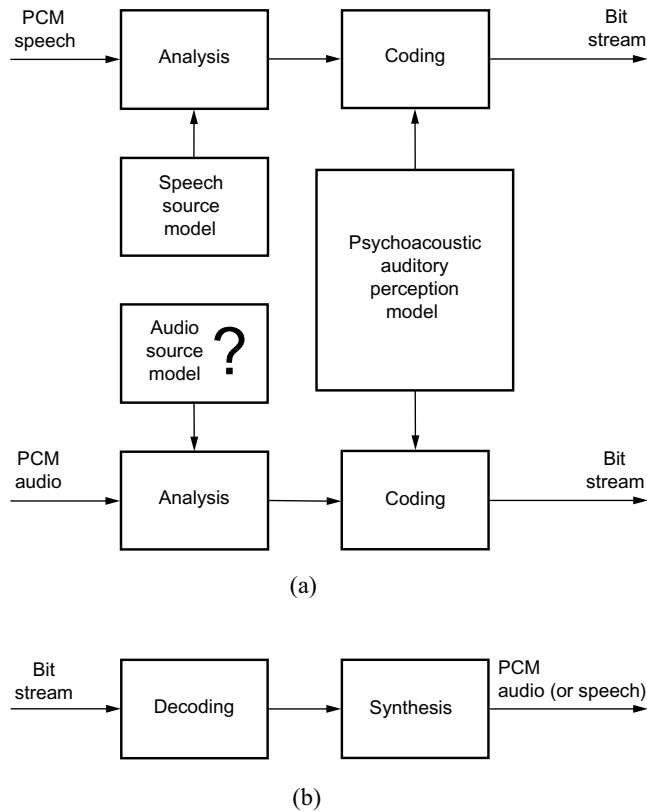

$$\text{SNR}(m) = 20m \log_{10} 2 + \text{const} \approx 6.02m + \text{const} \quad (27.38)$$

Thus, each additional bit in the quantized signal resolution means ca. 6 dB improvement in the SNR (or equivalently in the dynamic range). The “const” in expression (27.38) is of secondary importance. Its value depends on the signal probability density distribution and the ADC range. For instance, for an ADC range equal to  $(-4\sqrt{P_s}, 4\sqrt{P_s})$ , the respective value is  $\text{const} \approx -7.3$  dB.

Representing a signal just as a stream of uniformly quantized samples is referred to as the pulse code modulation (PCM). Typical resolutions in bits per sample (bps) are 16 bps, 24 bps, and even 30 bps. For instance, for a CD standard with two stereo channels, 44.1 ksamples/s sampling rate and 16 bit resolution, the resulting audio bit rate is  $2 \times 44,100 \times 16 = 1.41$  Mb/s. In reality, the CD standard has a large overhead bit rate due to 49-bit representation of every 16-bit sample. The resulting total bit rate is thus equal to  $(49/16) \times 1.41 = 4.32$  Mb/s.

PCM representation is not an efficient method for high quality audio. In order to reduce the required bit rate, various data compression and coding techniques can be used. Simple but not very efficient approaches preserve the signal waveform and are therefore referred to as *lossless* coding techniques (section 27.8). Data compression facility of lossless audio coders is rather moderate. Average achievable bit per sample values are only slightly greater than 4.5 bps [35]. Sophisticated techniques, which are still subject of an intensive research, allow for a drastic reduction of this value—at least by one order of magnitude. These coding techniques are *lossy* in the sense that they corrupt the signal; however, this corruption, can be controlled in such a way that it is inaudible. Such audio coders are called *transparent* (section 27.9). In order to efficiently and transparently compress audio and/or speech, the knowledge about the speech and audio production (the parametric audio coding discussed in section 27.3) as well as the knowledge concerning the human auditory perception (discussed in section 27.4, resulting in the perceptual audio coding) should be exploited (Fig. 27.17).

**FIGURE 27.17** Efficient audio (and speech) compression by exploiting the knowledge about the audio (and speech) production and perception: (a) coder scheme, (b) decoder scheme.

## 27.6 Digital Audio Signal Processing Systems

Fast development of very large scale integration (VLSI) electronics chips (digital signal processors (DSPs), ADCs and DACs, audio codecs, etc.) gives the possibility of effective digital processing of audio signals. The general scheme of a digital audio processing system is shown in Fig. 27.16. Using novel facilities of DSPs, not only sophisticated digital filters and filter banks, but also whole audio codecs can usually be realized in real time with a single processor, i.e., without the necessity of using expensive multiprocessor systems.

Real-time implementation of DSP algorithms is possible due to new features of modern DSPs [7]. Among the most important are:

- Hardware multiplier and long accumulator
- Hardware type and multibus architecture
- An on-chip memory with no additional wait state cycles
- Time division multiplexed (TDM) port for communication between multiple DSPs
- Bit-reversed addressing used in fast Fourier transformation (FFT) algorithms
- Circular buffers—a key feature of many DSP routines (e.g., in the realization of finite impulse response (FIR) digital filters)
- Multiple data registers important, e.g., for storing of temporary data

New facilities of modern DSPs give the possibility for substantial reduction of the number of operations. A single DSP processor can be used for multichannel and/or multitasking applications, both realized in

**TABLE 27.2** Main Features of Fixed-Point DSPs

Processor Family	Bus Interface (bits)	Instruction Rate (MHz)	Core MIPS	RAM (bits)	ROM (KWords)
ADSP-218x	16	33–75	33–75	128 K–1.6 M	—

TMS320C55x	16	160–200	320–400	2.5 M	16
TMS320C62x	32	150–300	1200–2400	1–7 M	—
TMS320C64x	32	400–600	3200–4800	8.5 M	—

**FIGURE 27.18** A digital audio signal processing system.

real-time. Although floating-point processors give very effective calculation performance, the fixed-point processors are also often used, because they are characterized by a much lower supply energy consumption (e.g., 0.05 mW/MIPS for the TMS320C55x processors) and are, moreover, much cheaper [50].

In order to facilitate communication with the host processor (computer), modern DSPs are equipped with a special interface—the host port interface (HPI) [49]. Using the HPI, the host processor has an access to the memory of the digital signal processor. Physical connection of processors uses 8- or 16-bit parallel data bus and several control lines. The HPI performs also a boot operation of the DSP. Due to this possibility an additional boot memory is not necessary. Selected DSPs provide also a glueless interface to the peripheral component interconnect (PCI) bus.

The next interesting feature of modern DSPs is the use of a buffered serial port (BSP) [49]. BSP makes a high-speed communication with external devices, e.g., ADCs and DACs, possible. In relation to a typical serial port, BSP offers enhanced features, which allow for a direct read/write operations from/to the memory connected to the signal processor without any participation of its central processing unit (CPU). The BSP interrupts to CPU are generated after filling halves of the buffer. This mechanism makes it possible to effectively cooperate with multichannel ADCs and DACs or to accumulate samples for FFT analysis. The described features, such as the HPI and the BSP, can substantially simplify the audio digital signal processing system (cf., Fig. 27.18) [25,28].

Floating-point DSPs, with the support for the IEEE-754 standard of 32-bit floating-point format, are based on new architecture concepts in order to guarantee a very high computational efficiency. Among these concepts are:

- Texas Instruments' VelociTI, which is an advanced very long instruction word (VLIW) architecture [51],
- Analog Devices super Harvard architecture (SHARC) with a single instruction multiple data (SIMD) facility [1].

Effective utilization of these highly parallel architectures needs an efficient C-compiler and an assembly optimizer.

Comparison of selected fixed- and floating-point DSP processors is presented in Tables 27.2 and 27.3 [1,33,50,51].

**TABLE 27.3** Main Features of Floating-Point DSPs

Processor Name	Instruction Rate (MHz)	Peak MFLOPS	1024-point Complex FFT (ms)	Accumulator Size (bits)	On-chip Memory (bits)

## 27.7 Audio Processing Basics

### DFT and Related Transformations

Discrete Fourier transformation (DFT) is a powerful tool for the analysis of discrete-time signals. A block of  $N$  samples  $x(n)$ ,  $n = 0, 1, \dots, N - 1$ , is considered and its harmonic components are extracted under assumption that they also describe an infinitely long, block wise periodic extension of signal  $x(n)$ . DFT is defined as follows:

$$X(k) = \frac{1}{N} \sum_{n=0}^{N-1} x(n) W_N^{kn}, \quad k = 0, 1, \dots, N-1 \quad (27.39a)$$

where  $W_N = e^{-j(2\pi/N)}$ . The inverse discrete Fourier transformation (IDFT) is then given by

$$x(n) = \sum_{k=0}^{N-1} X(k) W_N^{-nk}, \quad n = 0, 1, \dots, N-1 \quad (27.39b)$$

Computation of DFT and IDFT is usually realized using the so-called FFT algorithms, which reduce the computational complexity of DFT from  $\propto N^2$  to  $\propto N \log N$  under assumption that  $N = 2^K$ , where  $K$  is a natural number. Two main FFT types can be distinguished: decimation in time and decimation in frequency.

Assuming a typical DSP, realization of an FFT of the length  $N = 512$ , requires about 200 words of the program memory and  $4N + 1050$  words of data memory. Using a fixed-point DSP, the number of necessary instruction cycles is about 33,000. Assuming a moderate instruction cycle period of 25 ns, sampling rate of 44.1 kHz ( $T_s = 22.676 \mu\text{s}$ ). Accumulation time of 512 input samples is  $512 \times T_s = 11.61$  ms. FFT analysis takes  $33,000 \times 25 \text{ ns} = 0.825$  ms only. This example shows that even a multichannel “online” audio range FFT analysis is easily possible with common DSPs [28,48].

A block of  $N$  samples  $x(n)$  can be mirrored before it is periodically extended. This results in the so-called discrete cosine transformation (DCT). Because of the mirroring symmetry, DCT gives sharper spectrum than DFT. This is the main advantage of this transformation.

In perceptual audio coders, signals are often mapped into the frequency domain by means of the so-called modified discrete cosine transformation (MDCT) [40]. This is a type of DCT with overlapped power complementary time windows (Fig. 27.19). By this means blocking and time aliasing effects are cancelled. Denote by  $x_l(n)$ ,  $n = 0, 1, \dots, N - 1$ , time-domain signal samples in the  $l$ th block of  $N$  samples. MDCT is defined as

$$X_l(k) = \sum_{n=0}^{N-1} w(n)x_l(n) \cos \left[ \frac{\pi}{2N} \left( 2n + 1 + \frac{N}{2} \right) (2k + 1) \right] \quad \text{for } k = 0, 1, \dots, \frac{N}{2} - 1 \quad (27.40a)$$

where  $X_l(k)$  are samples in the frequency domain,  $N$  is the number of input samples,  $N/2$  is the frequency-domain blocklength,  $w(k)$  is the time window function. Division of the input signal into MDCT block

FIGURE 27.19 Overlapped, power complementary MDCT windows.

is quite flexible. A long block can be split into a shorter block. Figure 27.19 presents possible transitions MDCT windows between long and short block modes. The length of the block depends on stationarity of the input signal.

The respective inverse discrete cosine transform (IMDCT) is defined as

$$y_l(n) = w(n) \frac{N}{4} \sum_{k=0}^{N/2-1} X_l(k) \cos\left(\frac{\pi}{2N} \left(2n+1 + \frac{N}{2}\right) (2k+1)\right) \quad \text{for } n = 0, 1, \dots, N-1 \quad (27.40b)$$

The input signal is recovered with an overlap add operation

$$\tilde{x}_l(n) = y_{l-1}\left(n + \frac{N}{2}\right) + y_l(n) \quad \text{for } n = 0, 1, \dots, \frac{N}{2} - 1 \quad (27.40c)$$

which cancels the time-domain aliasing.

## FIR Filters

Basic operation in digital audio signal processing is frequency selective filtering. It can be realized in frequency domain, e.g., using FFT and in time domain using finite impulse response (FIR) and infinite impulse response (IIR) filters. Mostly FIR filters are used because they are always stable and can be easily designed with perfect linear phase characteristic.

Assuming an ideal filter frequency response given by

$$H(e^{j\omega}) = \sum_{n=-\infty}^{+\infty} h(n) e^{-j\omega n} \quad (27.41)$$

where

$$h(n) = \frac{1}{2\pi} \int_{-\infty}^{+\infty} H_d(e^{j\omega}) e^{j\omega n} d\omega \quad (27.42)$$

the respective FIR filter impulse response is

$$h_{\text{FIR}}(n) = w_N(n) h(n) \quad (27.43)$$

**TABLE 27.4** Impulse Response of Ideal Filters

Filter Type	Impulse Response
Lowpass	$h_d(n) = \begin{cases} \frac{\sin(n\omega_c)}{n\pi} & n \neq 0 \\ \frac{\omega_c}{\pi} & n = 0 \end{cases}$
Highpass	$h_d(n) = \begin{cases} \frac{\sin(n\omega_c)}{n\pi} & n \neq 0 \\ 1 - \frac{\omega_c}{\pi} & n = 0 \end{cases}$
Passband	$h_d(n) = \begin{cases} \frac{\sin(n\omega_2) - \sin(n\omega_1)}{n\pi} & n \neq 0 \\ \frac{\omega_2 - \omega_1}{\pi} & n = 0 \end{cases}$
Stopband	$h_d(n) = \begin{cases} \frac{\sin(n\omega_1) - \sin(n\omega_2)}{n\pi} & n \neq 0 \\ 1 + \frac{\omega_2 - \omega_1}{\pi} & n = 0 \end{cases}$

**FIGURE 27.20** Frequency response of an FIR lowpass filter designed with the Parks–McClellan method.

where  $w_N(n)$  is a specially selected time window (e.g., Hanning, Hamming, Blackman, or Kaiser window), used in order to reduce the so-called Gibbs phenomenon [37]. Depending on filter type, the ideal filter coefficients can be calculated using equations listed in Table 27.4 [9].

Another, more advanced, method for the design of FIR filters, is an optimization procedure developed by Parks and McClellan (also known as the Remez method) [9]. This method is implemented in the MATLAB environment with two functions: *remezord* to estimate the filter order and *remez* to compute the filter coefficients [30]. This optimization method should be used, if a relatively high stopband attenuation is required, e.g., with a 20-bit resolution for representation of signal samples, we usually need a stopband attenuation of approximately 120 dB. As a design example, Fig. 27.20 presents the frequency response of a lowpass FIR filter designed with the Parks–McClellan method, with the normalized cutoff frequency of  $\pi/64$ . This filter can be used as a prototype filter for the design of analysis and synthesis filter banks for audio coders, according, e.g., to the MUSICAM and MPEG-1 standards.

FIGURE 27.21 Symmetrical FIR filter.

Using modern DSP's FIR filters can easily be implemented with the MACD instruction, which realizes multiplication, accumulation, and data move. When used with repeat next instruction (RPT) MACD becomes a single-cycle instruction once the RPT pipeline is started. The theoretical maximum length  $L$  of the FIR filter can be computed as

$$L = \frac{T_s}{T_c k} \quad (27.44)$$

where  $T_s$  is the sampling period,  $T_c$  is the instruction cycle, and  $k$  is the number of converted channels. Assuming sampling rate of 48 ksamples/s, 25 ns instruction cycle of the DSP and 6 output channels, we can realize FIR filters with the maximum length of about 138 [25].

Another method for the implementation of FIR filters in DSPs consists in the use of two further new features of modern DSPs, namely the circular addressing and the FIRS instruction. This possibility can be effectively used, if the filter has a symmetric impulse response  $h(n)$  (cf., Fig. 27.21), i.e., if the filter output signal is given by

$$y(n) = \sum_{k=0}^{N/2-1} h(n) \{x(n-k) + x[n-(N-1-k)]\} \quad (27.45)$$

The FIRS instruction can add two data values (stored in a circular buffer) in parallel with the multiplication of this result by a filter coefficient. Once the repeat pipeline is started, this instruction becomes also a single-cycle instruction. A computational complexity is in this case reduced by half and makes it possible to realize FIR filters with the double length as compared with the programming technique previously described[48].

## IIR Filters

Although FIR filters have important advantages as linear phase, stability, robustness, easy design, and implementation, their infinite impulse response (IIR) counterparts will have complexity (order) reduced by some orders of magnitude. Therefore, IIR filters are advantageous over and above FIR filters in particular applications. IIR filters are typically designed starting with an analogue reference filter and then performing the bilinear transformation [8]. Denote by  $H(s)$  transfer function of the analog reference filter. Then the resulting IIR filter transfer function  $H(z)$  is calculated as

$$H(z) = H(s) \Big|_{s=\frac{2}{T_s} \frac{z-1}{z+1}} \quad (27.46)$$

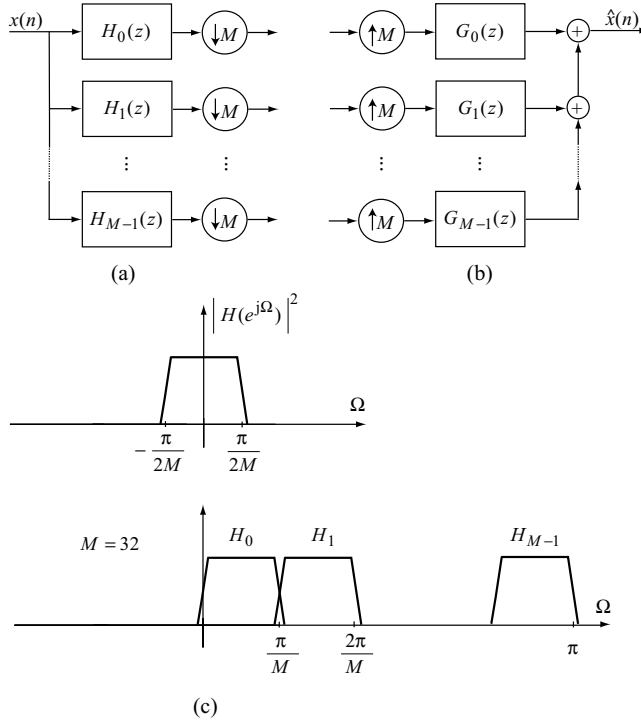

FIGURE 27.22 Filter banks: (a) analysis filter bank, (b) synthesis filter bank.

where  $T_s$  is the sampling period. The respective transformation of the analog frequency  $\omega_a$  into the digital frequency  $\omega_d$  is given by

$$\omega_d = \frac{2}{T_s} \arctan\left(\frac{T_s}{2} \omega_a\right) \quad (27.47)$$

## Filter Banks

A filter bank is a collection of digital filters with a multiple input and/or a multiple output [52]. The filter bank with one input and  $M$  outputs is referred to as the *analysis filter bank*. On the other hand, the *synthesis filter bank* consists of  $M$  inputs and one output (cf., Fig. 27.22). Splitting of the input signal into decimated subbands via an analysis filter bank and then reconstructing the initial signal from subband signals with a respective synthesis filter bank is referred to as the subband coding (SBC) technique commonly used for lossless or nearly lossless data compression.

A filter bank in the main path of the MPEG-1 audio coder [39] consists of 32 subband filters with a normalized bandwidth of  $\pi/(32T_s)$ , where  $T_s$  is the input audio signal sampling period. The impulse responses of particular filters in this filter bank are defined as

$$H_i(n) = h(n) \cos\left[\frac{(2i+1)(n-16)\pi}{64}\right] \quad (27.48)$$

where  $h(n)$  is an impulse response of the prototype lowpass filter. In the analysis filter bank case, the output signal in  $i$ th subband is defined as a convolution

$$S_i(m) = \sum_{n=0}^{511} x(m-n) * H_i(n) \quad (27.49)$$

In the MPEG-1 encoder an efficient polyphase filter bank realization is implemented, using the following steps:

1. Thirty-two new input samples  $x(n)$  are shifted into a 512-point FIFO buffer.
2. Five hundred and twelve samples  $x(n)$  are multiplied by the modified (the so-called analysis window) coefficients  $C(n)$ .

$$Z(n) = C(n)x(n) \quad (27.50a)$$

where  $C(n) = -h(n)$  if the integer part of  $n/64$  is odd, otherwise  $C(n) = h(n)$ ,  $n = 0, 1, \dots, 511$ .

3. Intermediate result is calculated

$$Y(k) = \sum_{j=0}^7 Z(k + 64j) \quad \text{for } k = 0, 1, \dots, 63 \quad (27.50b)$$

4. Thirty-two new output samples are computed

$$S_i = \sum_{k=0}^{63} M_i(k)Y(k) \quad \text{for } i = 0, 1, \dots, 31 \quad (27.50c)$$

where  $M_i(k) = \cos\{[(2i + 1)(k - 16)\pi]/64\}$  are the modulation (or analysis) matrix coefficients.

## Sampling Rate Conversion

Currently, digital audio signals are used with various sampling rates. Typical values are 8, 16, 22.05, 32, 44.1, 48, and even 96 ksamples/s. Thus, an “online” sampling rate conversion is a very important task in digital audio signal processing algorithms. This, task can nowadays be realized using modern digital signal processors [6]. Generally, three different approaches are possible:

- Natural approach based on, first, interpolation with factor integer  $M$ , and then, decimation with factor  $N$  (Fig. 27.23),
- Time-domain approach based on direct interpolation (or decimation) in time, i.e., on the realization of a sequence of noninteger delays (Fig. 27.24),

FIGURE 27.23 Basic system for sampling rate conversion.

FIGURE 27.24 Time relationships between input and output samples.

FIGURE 27.25 Sampling rate conversion with multistage oversampling.

FIGURE 27.26 Sampling rate conversion in frequency domain: (a) interpolation, (b) decimation.

- Frequency-domain approach based on: first, a blockwise DFT; second, on respective spectrum modification in each block—a throw-in of zero spectral samples in the middle of the DFT spectrum for interpolation or cutting out of some of spectral samples in the middle of the DFT spectrum for decimation (cf., Fig. 27.26); and third, the backward blockwise IDFT transformation (cf., the *interpft* function in the MATLAB environment [30]).

**TABLE 27.5** Sampling Rate Conversion Factors

Sampling Rate Rate Conversion [ksamples/s]	Upsampling Coefficient $M$	Downsampling Coefficient $N$	Least Common Multiple of a Pair of Sampling Rates
16 → 48	3	1	48000
32 → 48	3	2	96000
16 → 44.1	441	160	7056000
32 → 44.1	441	320	14112000
44.1 → 48	160	147	7056000

**TABLE 27.6** Sampling Rate Conversion to/from  
44 ksamples/s

Sampling Rate Rate Conversion [ksamples/s]	Upsampling Coefficient $M$	Downsampling Coefficient $N$
16 → 44	11	4
32 → 44	11	8
44 → 48	12	11

These first two approaches can be mixed, resulting in substantial reduction of the required intermediate sampling rate.

A scheme of the simplest system for the synchronic sampling rate conversion is shown in Fig. 27.23. The output samples are calculated using difference equations, which utilize the up- and downsampling and the filtering in between. Table 27.5 presents the respective up- and downsampling factors for the considered sampling rate conversions. These factors are equal to the least common multiple of a pair of sampling rates (the input sampling rate and the output sampling rate), divided by the respective sampling rate. Because the up- and downsampling factors for the rate conversion to/from 44.1 ksamples/s are inadmissibly large, a slightly lower sampling rate, namely 44 ksamples/s (cf., Table 27.6) can usually be accepted. This would introduce a small, not audible, error with a relative value of  $\delta = 0.22676\%$ .

The filtering operation between an interpolator and a decimator should be realized via a lowpass filter with gain  $M$  and the normalized cutoff frequency  $\omega_c = \min(\pi/M, \pi/N)$  [52]. The respective FIR filter can be designed, e.g., using the Parks–McClellan method. Depending on the converted rates and the desired signal resolution (16 or 20 bits, corresponding to the stopband attenuation of 96 or 120 dB, respectively) the required length  $L$  of FIR filters varies between 154 and 198 [6]. Depending on the upsampling coefficient  $M$ , the number of effective filter taps, which have to be calculated, is reduced to  $L/2M$ .

Sampling rate alteration using the time domain approach can be applied in asynchronous systems. An output signal sample can be determined using the following relationship:

$$\Delta t_{i+1} = (\Delta t_i + T_{\text{out}}) \bmod T_{\text{in}} \quad (27.51)$$

where  $T_{\text{in}}$  is the input sampling interval,  $T_{\text{out}} = t_{i+1} - t_i$  is the output sampling interval,  $t_{i+1}$  is the instant in which a new output sample should occur. The above relationships are illustrated in Fig. 27.24. Input samples are indicated with solid lines and output samples with dotted lines.

One of the simplest time domain sampling rate conversion methods is a high oversampling and then choosing appropriate output samples (those, which are the nearest to the required positions in time). A multistage approach of this type is illustrated in Fig. 27.25 [27].

Interpolators with factors 64 and 128 are controlled by a time-analysis unit, which measures the ratio between the input and the output sampling rates. An advantage of this method (in comparison with the natural method) is the possibility for the use of the same filter coefficients for different sampling rate conversion ratios, and thus, a simplified realization of the interpolation filters.

Time domain conversion can also be based on various numerical methods, e.g., on polynomial interpolation. Lagrange interpolation or spline interpolation can effectively be used [42,53]. In the case of an  $N$ th-order spline with a function defined in interval  $[x_k, \dots, x_{k+m}]$  as

$$M_k^N(x) = \sum_{i=k}^{k+m} a_i \phi_i(x) \quad (27.52)$$

where

$$\phi_i(x) = (x - x_i)_+^N = \begin{cases} 0 & x < x_i \\ (x - x_i) & x \geq x_i \end{cases}$$

a 6th-order interpolation is used with a simple FIR filter to compensate  $\text{sinc}^7$ -distortion in the frequency domain caused by the spline interpolator [53].

## 27.8 Lossless Audio Coding

---

### Pulse Code Modulation

The most typical digital waveform coding is the pulse code modulation (PCM), in which a stream uniformly distributed digitally coded samples, which represent a given analog continuous-time signal is used. Basic PCM coder consists of an antialiasing filter, sample device and a quantizer. In practice, in order to improve the subjective audio quality, the quantizer should have a nonlinear (logarithmic) characteristic based on, e.g., a 13-segment A-law and a 15-segment  $\mu$ -law used in telephone systems. The normalized characteristics are given by [2]

- A-law

$$f(x) = \begin{cases} \frac{Ax}{1 + \ln A} & 0 \leq x \leq \frac{1}{A} \\ \frac{1 + \ln Ax}{1 + \log A} & \frac{1}{A} \leq x \leq 1 \end{cases} \quad (27.53)$$

- $\mu$ -law

$$f(x) = \frac{\ln(1 + \mu x)}{\ln(1 + \mu)} \quad \text{for } 0 \leq x \leq 1 \quad (27.54)$$

For the compression from 16 bits to 8 bits typical values of the coefficients are  $A = 87.6$  and  $\mu = 255$ .

In most cases, PCM bit stream has highly redundant information. Thus, using a number previous samples of the input signal, we can predict the next sample with a relatively small error. This feature is used in differential pulse code modulation (DPCM), in which a difference between input sample and its estimation is coded. The prediction is realized with appropriate FIR filter. In these case in which the statistics of the input signal changes in time or is unknown, the prediction should be made adaptive. An adaptive coding is realized in an adaptive difference pulse code modulation (ADPCM). The respective schemes, i.e., those of the ADPCM encoder and the ADPCM decoder are shown in Fig. 27.27.

A special case of the DPCM approach is delta modulation (DM). The DM encoder is very simple to implement because it uses a 1-bit quantizer and a first order predictor (cf. Fig. 27.28). The encoder is so strongly simplified, so high sampling rates are required. Among the disadvantages of DM are possible

FIGURE 27.27 ADPCM: (a) encoder, (b) decoder.

FIGURE 27.28 Delta modulation system.

FIGURE 27.29 CVSD encoder.

slope overload and granularity noise. They can, however, be easily reduced by adaptive versions of DM, i.e., ADM.

Continuous variable slope delta modulation (CVSD) is an example of the ADM. CVSD effectively reduces the DM slope overload [29]. An interesting advantage of this method is its resistance to transmission errors. Figure 27.29 presents structure of the CVSD encoder.

The output signal of the CVSD encoder is given by

$$y(n) = \text{sgn}\{x(n) - \hat{x}(n-1)\} \quad (27.55)$$

where  $x(n)$  is the input PCM sample,  $\hat{x}(n)$  is the estimated sample.

The parameter  $\alpha$  depends on the signal slope, i.e.,  $J$  bits in  $K$  output bits of  $y(n)$ :

$$\alpha = \begin{cases} 1 & J \text{ bits are the same} \\ 0 & \text{else} \end{cases} \quad (27.56)$$

The quantization step  $\Delta(n)$  is increased or decreased using  $\alpha$  parameter:

$$\Delta(n) = \begin{cases} \min\{\Delta(n-1) + \Delta_{\min}, \Delta_{\max}\} & \text{for } \alpha = 1 \\ \max\{\beta\Delta(n-1), \Delta_{\min}\} & \text{for } \alpha = 0 \end{cases} \quad (27.57)$$

where

$\beta$  = step decreasing coefficient,  
 $\Delta_{\min}$  = minimum step size,  
 $\Delta_{\max}$  = maximum step size.

The estimated value  $\hat{x}(n-1)$  is given by

$$\hat{x}(n-1) = hd(n-1) \quad (27.58)$$

where

$$d(n-1) = \begin{cases} \min\{\hat{d}(n-1), d_{\max}\} & \text{for } \hat{d}(n-1) \geq 0 \\ \max\{\hat{d}(n-1), d_{\min}\} & \text{for } \hat{d}(n-1) < 0 \end{cases}$$

$h$  is the accumulator decay coefficient.

## Entropy Coding Using Huffman Method

The entropy coding is a lossless bit stream reduction and can be used on its own or a supplement to other methods, e.g., after the DPCM. This coding approach is based on the statistical redundancy, when the signal samples, or sequences (blocks) have different probabilities. The entropy of a signal is defined as the following average:

$$H(p_1, \dots, p_n) = -\sum_{i=1}^n p_i \log_2 p_i \quad (27.59)$$

where  $-\log_2 p_i$  is an information of the  $i$ th codeword and  $p_i$  is the probability of its occurrence. The most popular method for the entropy coding is the Huffman coding method [15], in which the optimal code can be found using an iterative procedure based on the so-called *Huffman tree*. The Huffman coding is, e.g., used in MPEG-1 audio standard to reduce the amount of output data in layer III. The set of 32 Huffman tables are specially tuned for statistics of the MDCT coefficients divided into some regions and subregions [38].

## 27.9 Transparent Audio Coding

A need for reduction of bit rate required for the transmission of high quality audio signals draws a growing attention to lossy audio coding techniques. Lossy audio coding will be fully acceptable, if it is perceptually transparent, i.e., if the corruption of the audio signal waveform is inaudible. An efficient transparent audio coding algorithm (Fig. 27.17) should:

- remove redundancy contained in the original audio signal,
- remove the perceptual irrelevancy.

FIGURE 27.30 General scheme of the transparent audio coder.

The first task requires an efficient parametric description of audio, e.g., a plausible mathematical model of its production. Although this is a relatively simple task for speech, and at least a conceivable one for music, for general audio signals this is a very complex problem. Therefore, instead of a real audio production model, a compromise solution can be used, namely a general signal analysis model, e.g., in the frequency domain or in the scale-of-resolution domain (cf., section 27.3), reducing redundancy (correlation) of the signal components. In both cases, the signal is split into almost uncorrelated components with a proper analysis filter bank. At the receiver side these components are recombined via a corresponding synthesis filter bank. This procedure should allow perfect or at least nearly perfect signal reconstruction under ideal conditions.

The second task should be realized by means of a precise psychoacoustic hearing model, which should take all masking effects into account. This subject has been discussed in section 27.4. The hearing model provides information about the dynamic range, which is necessary for the proper representation of parameters (signal components) contained in the signal analysis model. Thus, it allows for efficient dynamic bit allocation to particular signal parameters or components.

A general scheme of the transparent audio coder is shown in Fig. 27.30. The input audio signal is first analyzed via an analysis filter bank. Taking different possible analysis filter banks into account, state-of-the-art coders can be divided into two historically relevant categories: subband coders (SBCs) and transform coders (TCs). TCs operate usually with much greater frequency resolution than SBCs. In typical SBCs uniform polyphase analysis filter banks are used (cf., section 27.7). On the other hand, TCs typically employ the MDCT [40]. Other types of analysis filter banks, e.g., octave filter banks, can also be very efficiently used. They can be realized with the discrete wavelet transformation (DWT) discussed in section 27.3 or with wave digital filters WDFs [43]. Another approach, which is implemented in MPEG-1 layer III audio coder, is a hybrid filter bank, which is combination of a coarse frequency resolution subband filter bank followed by a fine frequency resolution transformation (MDCT in this case).

Parallely, the input signal is also analyzed with a psychoacoustic model filter bank. This filter bank should estimate a number of nonoverlapping peripheral auditory filters, which cover the whole audible frequency range. In those audio coders, which for parametric signal description exploit octave analysis filter banks, this can be just the same filter bank [43]; however, typically, the psychoacoustic model filter bank is realized separately with the FFT.

Using the psychoacoustic auditory model a global dynamic threshold of hearing is computed, e.g., by using the way shown in Eq. (27.22) or more precisely in Eq. (27.66b). Then in each analysis filter subband the respective  $SMR_i$  is computed with Eq. (27.67). Finally, the mask-to-noise ratio MNR is computed as

$$MNR_i(m) = SNR(m) - SMR_i \quad (27.60)$$

where, by  $SNR(m)$ , the signal-to-noise ratio determined by Eq. (27.38), resulting from an  $m$ -bit quantization, is denoted. Within the  $i$ th critical band the quantization noise will be inaudible as long as the  $MNR_i(m)$  is positive. This observation can be used for efficient dynamic bit allocation, which can be

realized, e.g., with the following procedure:

- The bit allocation unit searches for the analysis filter subband with the lowest MNR and allocates code bits to this subband; then the  $\text{SNR}(m)$  value is updated for this subband and the actual MNR is computed with Eq. (27.60).
- The process is repeated until no more code bits can be allocated.

An important problem, resulting from the transformation of the audio signal (via an analysis filter bank) into the frequency domain, is the appearance of *pre-echoes*, occurring in silent signal periods followed by sudden sound attacks (e.g., of a percussive character). This phenomenon is caused by quantization errors, which are irrelevant in loud and stationary signal parts but are immediately audible in silent signal parts. In TCs, the inverse transform in the receiver distributes the quantization errors over the whole block of samples cut with the respective time window. In SBCs, this effect occurs due to transients. A possible method for suppression of pre-echos is the adaptive window switching (cf., Fig. 27.19) [46]. Windows of short lengths should be used in nonstationary parts of the signal, while in stationary signal parts wide windows (improving the overall coding efficiency) should be used. Typically, the block size vary between  $N = 64$  and  $N = 1024$ .

Further reduction of audio bit rate is still possible by resignation from the full perceptual transparency. In many cases, especially in multimedia and/or in mobile-access applications, a not annoying reduction of fidelity of some audio components of secondary importance, is acceptable. The whole audio scene can be divided into a number of individual audio objects: a conversation, a background noise, a background music, sounds produced by particular sources, etc. These objects can be coded and transmitted separately. Furthermore, some of them may be added synthetically at the receiver. Such coding philosophy is used in the so-called *structured audio format* implemented in the MPEG-4 standard (cf., section 27.10). By this means, a very flexible scalability of audio quality can be realized. This is very useful when audio has to be transmitted through channels of varying capacity and/or is to be received with decoders of various quality and complexity.

## 27.10 Audio Coding Standards

---

### MUSICAM and MPEG Standards

Among standards for digital coding of high quality audio, the most important role play moving picture expert group (MPEG) standards designed for various communications and multimedia applications. They are elaborated as a result of efforts of the working group WG 11 within the International Organization for Standardization (ISO/IEC).

The first result was MPEG-1 standard IS 11172 designed (in its audio part) for a two-channel audio, approximately with a CD quality [16]. This standard consists of three layers I, II, and III, of increasing efficiency. For transparent transmission, they enable bit rates of 384, 192, and 128 kb/s, respectively. MPEG-1 supports sampling rates of 32, 44.1, and 48 ksamples/s. Layer II of MPEG-1 is based on the masking-pattern universal subband integrated coding and multiplexing (MUSICAM) standard designed for digital audio broadcasting (DAB) system. Layer III of MPEG-1 has become very popular in Internet due to \*.mp3 audio files.

The next step of the standardization was MPEG-2 AAC (advanced audio coding) standard IS 13818 designed for high definition television (HDTV) [17]. It offers a multichannel (surround) sound for high spatial realism, provides low bit rate audio (below 64 kb/s), and also supports low sampling rates of 16, 22.05, and 24 ksamples/s.

The third generation standard MPEG-4 has been designed for a broad area of various communications (especially mobile access) and multimedia applications and is characterized by high flexibility, scalability, and universalism [18]. It supports bit rates between 2 and 64 kb/s and offers additional services as text-to-speech (TTS) conversion, structured audio format, and interface between TTS and synthetic moving face models (talking heads), which are driven from speech.

A new standard MPEG-7, named the *multimedia content description interface*, is aimed to support as broad range of communications and multimedia applications as possible [19]. MPEG-7 audio merges five different technologies: the audio description framework (scalable series, low-level descriptors, and uniform silence segments), musical instrument timbre descriptors, sound recognition tools, spoken content descriptors, and melody descriptors. In order to describe the low-level audio features, regions of similarity and dissimilarity within the sound are searched for. This can be done either using samples taken at regular intervals or segments of samples. The relevant samples are then further manipulated to form a scalable series, which allows to progressively down-sample the data contained in a series, according to the application, bandwidth, or storage requirements.

The scope of newest MPEG-21 standard is the integration of technologies enabling transparent and augmented use of multimedia resources across a wide range of networks and devices to support functions such as content creation, content production, content distribution, content consumption and usage, content packaging, intellectual property management and protection, content identification and description, financial management, user privacy, terminals and network resource abstraction, content representation and event reporting [20].

MUSICAM as well as MPEG-1 layers I and II coders have the same structure shown in Fig. 27.31. The input audio signal is transmitted via a 32-band polyphase analysis filter bank (Fig. 27.22(a)) with equally spaced passbands, according to Eqs. (27.50a–c). All subband filters with impulse responses  $H_i(n)$ ,  $i = 0, 1, \dots, 31$ , determined by Eq. (27.48), are obtained by modulation of a single prototype lowpass filter with the impulse response  $h(n)$ , as is illustrated in Fig. 27.22(c). Their output signals are critically decimated. For a 48 ksamples/s sampling rate, each subband filter has a passband width of 750 Hz. Although these filters are highly overlapping, they can guarantee a perfect (or at least a nearly perfect) signal reconstruction (via the synthesis filter bank in Fig. 27.22(b)) due to the power complementarity. For instance, at multiples of 750 Hz the respective filters, i.e., those with neighboring passbands exhibit a 3 dB attenuation.

Samples of subband signal components are quantized with a number of uniform midtread quantizers with 3, 5, 7, ..., 65,535 possible levels. Blocks of samples are formed (e.g., blocks of 12 samples in layer I) and divided by a scalefactor  $s_{sf}$  selected in such a way that the sample with the largest magnitude is scaled to 1. By this means a quite large overall dynamic range of approximately 126 dB is reached. Proper quantizers are selected with the dynamic bit allocation algorithm described in section 27.9, controlled

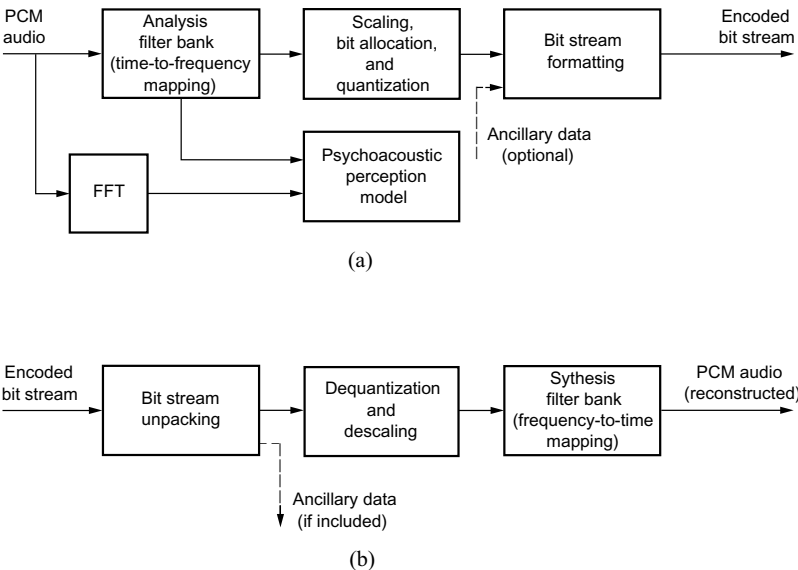

FIGURE 27.31 Structure of MUSICAM and MPEG-1 layer I and II coders: (a) encoder, (b) decoder.

by a psychoacoustic audibility model, in order to meet the bit rate and the global threshold of hearing requirements. The whole procedure is described below.

The psychoacoustic model filter bank is based on a 512-point FFT for layer I and on a 1024-point FFT for layers II and III. First, samples of the spectral power density  $P(k)$  and the respective level  $L_p(k)$  in decibels are computed:

$$P(k) = |X(k)|^2 \quad (27.61a)$$

$$L_p(k) = 10 \log_{10} P(k) \quad (27.61b)$$

where  $X(k)$  are DFT spectrum samples defined by Eq. (27.39a). Next in each of  $i = 0, 1, \dots, 31$  subbands the signal SPL is computed as

$$L_{pi} = \max[L_{p_{\max i}}, 20 \log_{10}(32768 s_{\text{sf max } i}) - 10] \quad (27.62)$$

where  $L_{p_{\max i}}$  is the maximum  $L_p(k)$  value in  $i$ th subband.

Next, the relevant masker levels  $L_{pm}(z_j)$  are searched for: tone masker levels  $L_{ptm}(z_j)$ ,  $j = 1, 2, \dots, m_{tm}$ , and noise masker levels  $L_{pnm}(z_j)$ ,  $j = 1, 2, \dots, m_{nm}$ . Then, the masking indices are computed (in dB):

$$a_{tm}(z_j) = -1.525 - 0.275z_j - 4.5 \quad (27.63a)$$

$$a_{nm}(z_j) = -1.525 - 0.175z_j - 0.5 \quad (27.63b)$$

where by  $z_j$  the  $j$ th critical band index in Bark is denoted.

Individual masking threshold levels are computed (in dB) as

$$L_{ttm}(z, z_j, L_{pm}) = L_{ptm}(z_j) + a_{tm}(z_j) + v(\Delta z, z_j) \quad (27.64a)$$

$$L_{tnm}(z, z_j, L_{pm}) = L_{pnm}(z_j) + a_{nm}(z_j) + v(\Delta z, z_j) \quad (27.64b)$$

for tone maskers and for noise maskers, respectively. The so-called masking function  $v(\Delta z, z_j)$  is defined by

$$v(\Delta z, z_j) = \begin{cases} 17(\Delta z + 1) - 0.4L_{pm}(z_j) + 6 & \text{for } \Delta z < -1 \\ (0.4L_{pm}(z_j) + 6)\Delta z & \text{for } -1 \leq \Delta z < 0 \\ -17\Delta z & \text{for } 0 \leq \Delta z < 1 \\ (\Delta z - 1)(-17 + 0.15L_{pm}(z_j)) + 17 & \text{for } 1 \leq \Delta z \end{cases} \quad (27.65)$$

where  $\Delta z = z - z_j$ . Expression (27.65) gives significant values in range  $-3 \leq \Delta z \leq 8$  only. Outside this region we can assume that  $v(\Delta z, z_j) \rightarrow -\infty$ .

Using expression (27.22), the global threshold of hearing  $L_{ptg}$  (Fig. 27.14) can now be computed (in dB):

$$L_{ptg}(z) = 10 \log_{10} \left( 10^{L_{ptq}(z)/10} + \sum_{j=1}^{m_{tm}} 10^{L_{ttm}(z, z_j, L_{pm})/10} + \sum_{j=1}^{m_{nm}} 10^{L_{tnm}(z, z_j, L_{pm})/10} \right) \quad (27.66a)$$

where  $L_{ptq}(z)$  is the threshold of audibility in quiet. Consequently,

$$L_{ptg \min}(i) = \min(L_{ptg}(z_j)) \quad (27.66b)$$

for  $i$ th subband is computed over all critical bands  $j$  contained in this subband. Now in each subband the signal-to-mask ratio SMR<sub>*i*</sub> can be computed (in dB):

$$\text{SMR}_i = L_{pi} - L_{ptg \min}(i) \quad (27.67)$$

FIGURE 27.32 AC-3 encoder.

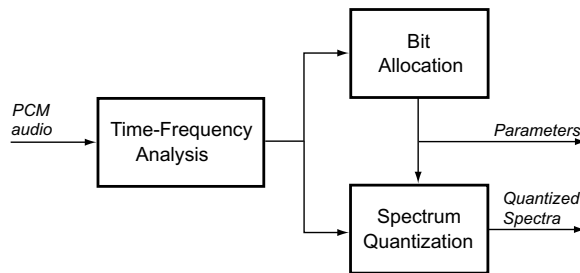

FIGURE 27.33 ATRAC encoder.

Finally, the dynamic bit allocation algorithm based on maximization of the mask-to-noise ratio  $MNR_i(m)$  defined with Eq. (27.60) assign bits to each block and each subband.

## Dolby AC-3 Standard

Dolby AC-3 standard gives the possibility for multichannel audio compression (from 1 to 5.1 channels) [3]. The bit stream ranges from 32 to 640 kb/s. Coding operation in AC-3 format is realized using time division aliasing cancellation (TDAC) filter bank. The sample block of length 512 transformed into frequency domain and each sample block is overlapped by 256 samples. Spectral components are represented in floating-point format and the exponents and mantissas are coded separately. A set of exponents is coded into the spectral envelope. One AC-3 synchronization frame is composed for six audio blocks (1536 audio samples). Simplified AC-3 encoder is presented in Fig. 27.32. The psychoacoustic model used in the AC-3 standard divides the audio band (0–24 kHz) into 50 subbands.

## Adaptive Transform Acoustic Coding ATRAC Standard

An adaptive transform acoustic coder (ATRAC) is developed by Sony and is designed for the MiniDisk system [3]. The bit stream of 16-bit audio signal with sampling rate 44.1 ksamples/s (705.6 kbps) is reduced into 146 kbps. The input audio signal (512 samples per channel) is decomposed into spectral coefficients, which are grouped into 52 block floating units (BFUs). The spectral coefficients are normalized in each BFU, which then are quantized to the specified word length. Using QMF filters, the time-frequency analysis unit divides input signal into three subbands: 0–5.5 kHz, 5.5–11 kHz, and 11–22 kHz. Each subband is transformed into the frequency domain using the MDCT. Fig. 27.33 presents the general scheme of the ATRAC encoder.

### 28.1 Introduction

---

Rapid increases in performance and decreases in cost of computing platforms and digital image acquisition and display subsystems have made digital images ubiquitous. Continued improvements promise to make digital video as widely used, opening a broad range of new application areas. In this chapter, some of the key aspects of this evolving data type are examined.

#### Some Historical Perspective

The use of image sequences substantially predates modern video displays (see, e.g., [1]). As might be expected, the primary initial motivation for using these sequences was the depiction of motion. One of the earlier approaches to motion picture display was invented by the mathematician William George Horner in 1834. Originally called the Daedaleum (after Daedalus, who was supposed to have made figures of men that seemed to move), it was later called the Zoetrope (life turning) or the Wheel of Life. The Daedaleum works by presenting a series of images, one at a time, through slits in a circular drum, as the drum is rotated.

Although this device is very simple, it illustrates some important concepts. First and foremost, the impression of motion conveyed by a sequence of images is illusory. It is the result in part of a property

FIGURE 28.1 A noninterlaced video signal.

FIGURE 28.2 A noninterlaced scanning raster.

of the human visual system (HVS) referred to as persistence of vision. An image is perceived to remain for a period of time after it has been removed from view. This illusion is the basis of all motion picture displays. When the drum in the device is rotated slowly, the images appear (as they are) a disjoint sequence of still images. As the speed of rotation increases (the images are displayed at a higher rate), a point is reached at which motion is perceived, even though the images appear to “flicker.” Further increasing the speed of rotation, a point is reached at which flicker is no longer perceived (the critical fusion frequency). Finally, the slits in the drum illustrate a critical aspect of this illusion. In order to perceive motion from a sequence of images, the stimulus the individual images represent must be removed for a period of time between each presentation. If not, the sequence of images simply merges into a blur, and no motion is perceived.

These concepts (rooted in the nature of human visual motion perception) are fundamental, and are reflected in all motion picture acquisition and display systems.

## Video

Unlike image sequences on film, video is represented as a 1-D signal, derived by scanning the camera sensor. The fact that the signal is derived by scanning imposes a particular signal structure, an example of which is shown in Fig. 28.1 for a noninterlaced system.

In principle, scanning can be done in many ways. The simplest in concept is noninterlaced line-continuous scanning (which yields the video signal just discussed). This approach is also referred to as progressive scanning. Viewed in the 2-D plane (either at the camera or display), this approach appears as shown in Fig. 28.2.

The bandwidth of the resulting video signal is relatively high. Transmitting a frame of 485 lines,<sup>1</sup> with a 4:3 aspect ratio (NTSC resolution), at 60 frames per second requires roughly twice the available channel bandwidth (6 MHz). Sixty updates per second are needed to avoid wide area flicker, dictated by the temporal response of the HVS. One approach to reducing the signal bandwidth is to send half as many samples (lines). This cannot be accomplished by reducing the frame rate to 30 frames per second, because

<sup>1</sup>NTSC consists of 525 lines, but only ~485 lines are active.

**FIGURE 28.3** An NTSC frame, formed by interlacing two fields (2:1 interlace).

**FIGURE 28.4** The effect of interlace on an edge in horizontal motion.

an unacceptable degree of flicker is introduced. Reducing the spatial resolution of each frame results in unacceptable blurring. Interlaced scanning is a compromise between the two approaches.

As used in NTSC television, each complete scan (a frame) contains 525 lines and occurs every  $1/30$  s. The frame consists of two fields (even and odd),  $262\frac{1}{2}$  lines each. These fields are interlaced to form the frame. Fields are scanned every  $1/60$  s (reducing flicker). Because two fields are interlaced to form one frame, this is called 2:1 interlace. Two interlaced fields (NTSC) are shown in [Fig. 28.3](#).

Image acquisition and display via scanning has several disadvantages. Nonideal aspects of the scanning system (e.g., nonzero spot size), and under some circumstances the act of scanning itself, lead to a reduction in vertical resolution below that predicted by the sampling theorem. The ratio of the actual to ideal resolution is called the Kell factor  $k$ ,  $0 \leq k \leq 1$ . Typical values of  $k$  are  $.6 < k < .8$ , with interlaced systems having lower  $k$ . Scanning also causes distortion when objects in the scene are in motion. For example, a vertical line in motion will result in a tilted scanned image (not due to the tilt of the scan line, but because points on the line at the bottom of the screen are reached later than points at the top). Finally, different points in space within the frame do not correspond to the same point in time. Viewed in the spatiotemporal volume, each frame is tilted, with the upper left corner of the frame corresponding to a significantly earlier time than the lower right corner. This can make the accurate analysis of the image sequence difficult.

Interlaced scanning has additional disadvantages. Interlaced display systems suffer from interline flicker (particularly in regions of the image with nearly horizontal structure). Interlacing results in reduced vertical resolution, which increases aliasing. It also increases the complexity of subsequent processing or analysis (such as motion estimation). Interoperability with other systems, such as computer workstations (which use noninterlaced displays), is made difficult. Still images extracted from interlaced video (“freeze frames”) are generally of poor quality. Often only “freeze fields” are provided. This last point can be seen by considering the case of an edge in horizontal motion ([Fig. 28.4](#)). To merge two fields to get a still

FIGURE 28.5 An image sequence represented as a spatiotemporal volume, raytraced to exhibit its internal structure.

image of reasonable quality, or to get a good progressively scanned sequence from an interlaced one, is a nontrivial problem.

### Image Sequences as Spatiotemporal Data

As discussed previously, the scanning process makes the precise specification of an image sequence difficult (since every spatial point exists at a different time). Interlace complicates matters further. In the remainder of this chapter, the simplifying assumption will be made that each point in a frame corresponds to the same point in time. This is analogous to the digitization of motion picture film, or the sequence which results from a CCD camera with a shutter. It is a reasonable assumption in progressive or interlaced video systems when scene motion is slow compared to the frame rate. The series of frames are no longer tilted in the spatiotemporal domain and can be “stacked” in a straightforward way to form a spatiotemporal volume (see Fig. 28.5).

## 28.2 Some Fundamentals

Following are some notational conventions and basic principles used in the balance of this chapter. A continuous sequence is denoted as  $u(x, y, t)$ ,  $v(x, y, t)$ , etc., where  $x, y$  are the continuous spatial variables and  $t$  is the continuous temporal variable. Similarly, a discrete sequence is denoted as  $u(m, n, p)$ ,  $v(m, n, p)$ , etc., where  $m, n$  are the discrete (integer) spatial variables and  $p$  is the discrete (integer) temporal variable.

### A 3-D System

As in 1-D and 2-D, a 3-D discrete system can be defined as

$$y(m, n, p) = \mathcal{H}[x(m, n, p)] \tag{28.1}$$

where  $\mathcal{H}$  is the system function. In general, this function need be neither linear nor shift invariant. If the system is both linear and shift invariant (LSI), it can be characterized in terms of its impulse response  $h(m, n, p)$ . The linear shift invariant system response can then be written as

$$\begin{aligned} y(m, n, p) &= \sum_{m'=-\infty}^{\infty} \sum_{n'=-\infty}^{\infty} \sum_{p'=-\infty}^{\infty} x(m', n', p')h(m - m', n - n', p - p') \\ &\equiv x(m, n, p) * h(m, n, p) \end{aligned} \tag{28.2}$$

where ‘\*’ denotes (discrete) convolution. Similarly, for the continuous case,

$$g(x, y, t) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} f(x', y', t') h(x - x', y - y', t - t') dx' dy' dt' \quad (28.3)$$

## The 3-D Fourier Transform

The 3-D continuous Fourier transform can be expressed as

$$F(\xi_x, \xi_y, \xi_t) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} f(x, y, t) e^{-j2\pi(x\xi_x + y\xi_y + t\xi_t)} dx dy dt \quad (28.4)$$

where  $\xi_x$ ,  $\xi_y$ , and  $\xi_t$  are the spatiotemporal frequency variables and  $f(x, y, t)$  is a continuous spatiotemporal signal. As in the 2-D case, the 3-D Fourier transform is separable:

$$F(\xi_x, \xi_y, \xi_t) = \int_{-\infty}^{\infty} \left[ \int_{-\infty}^{\infty} \left[ \int_{-\infty}^{\infty} f(x, y, t) e^{-j2\pi x \xi_x} dx \right] e^{-j2\pi y \xi_y} dy \right] e^{-j2\pi t \xi_t} dt \quad (28.5)$$

Also as in the 1-D and 2-D cases, if

$$g(x, y, t) = h(x, y, t) * f(x, y, t) \quad (28.6)$$

then

$$G(\xi_x, \xi_y, \xi_t) = H(\xi_x, \xi_y, \xi_t) F(\xi_x, \xi_y, \xi_t) \quad (28.7)$$

If  $h(x, y, t)$  is the LSI system impulse response, then  $H(\xi_x, \xi_y, \xi_t)$  is the frequency response of the system.

The spatiotemporal discrete Fourier transform is defined as

$$v(h, k, l) = \sum_{m=0}^{N-1} \sum_{n=0}^{N-1} \sum_{p=0}^{N-1} u(m, n, p) W_N^{hm} W_N^{kn} W_N^{lp} \quad (28.8)$$

where  $0 \leq h, k, l \leq N - 1$  and  $W_N = e^{-j2\pi/N}$ .

The inverse transform is

$$u(m, n, p) = \frac{1}{N^3} \sum_{h=0}^{N-1} \sum_{k=0}^{N-1} \sum_{l=0}^{N-1} v(h, k, l) W_N^{-hm} W_N^{-kn} W_N^{-lp} \quad (28.9)$$

where  $0 \leq m, n, p \leq N - 1$ .

## Moving Images in the Frequency Domain

Following the discussion in [2], a moving monochrome image can be represented by an intensity distribution  $f(x, y, t)$ . The image is static if  $f(x, y, t) = f(x, y, 0)$  for all  $t$ . The velocity of the image can be expressed via the image velocity vector

$$\vec{r} = (r_x, r_y) \quad (28.10)$$

If the (initially static) image translates at a constant velocity  $\vec{r}$ , then

$$f_r(x, y, t) = f(x - r_x t, y - r_y t, t) \quad (28.11)$$

Consider the case of a simple 2-D “image”  $f(x, t)$ . Let

$$\vec{a} = \begin{pmatrix} x \\ t \end{pmatrix} \quad \text{and} \quad \vec{b} = \begin{pmatrix} \xi_x \\ \xi_t \end{pmatrix} \quad (28.12)$$

where  $\xi_x$  and  $\xi_t$  are the spatial and temporal frequency variables. Then the transform pair can be written as

$$f(\vec{a}) \xrightarrow{\mathcal{F}} F(\vec{b}) \quad (28.13)$$

Now, translation can be represented as a coordinate transformation

$$\vec{a}' = \begin{pmatrix} x - r_x t \\ t \end{pmatrix} = \mathbf{A} \vec{a} \quad (28.14)$$

where

$$\mathbf{A} = \begin{bmatrix} 1 & -r_x \\ 0 & 1 \end{bmatrix} \quad (28.15)$$

and  $r_x$  is the horizontal speed.

Using the expression for the Fourier transform after an affine coordinate transformation (any combination of scaling, rotation, and translation),

$$f(\vec{a}') \xrightarrow{\mathcal{F}} F[(\mathbf{A}^{-1})^T \vec{b}] \quad (28.16)$$

where

$$(\mathbf{A}^{-1})^T = \begin{bmatrix} 1 & 0 \\ r_x & 1 \end{bmatrix} \quad (28.17)$$

so that

$$f(x - r_x t, t) \xrightarrow{\mathcal{F}} F(\xi_x, \xi_t + r_x \xi_x) \quad (28.18)$$

### Example

Consider a simple static image with only two components (Fig. 28.6). As the image undergoes translation with horizontal speed  $r_x$ , all temporal frequencies are shifted by  $-r_x \xi_x$ . Spatial frequency coordinates remain unchanged. That is, all frequency components of an image moving with velocity  $r_x$  lie on a line through the origin, with slope  $-r_x$ .

FIGURE 28.6 A two-component, 1-D signal in translational motion.

FIGURE 28.7 A two-component, 2-D signal in translational motion.

Extending the analysis to the 3-D case ( $f(x, y, t)$ ), let the velocity  $\vec{r} = (r_x, r_y)$ . Then

$$f(x - r_x t, y - r_y t, t) \xrightarrow{\mathcal{F}} F(\xi_x, \xi_y, \xi_t + r_x \xi_x + r_y \xi_y) \quad (28.19)$$

Each temporal frequency is shifted by the dot product of the spatial frequency vector  $\vec{s} = (\xi_x, \xi_y)$  and the image velocity vector  $\vec{r} = (r_x, r_y)$ . If the image was originally static, then

$$\xi_t = -\vec{r} \cdot \vec{s} = -(r_x \xi_x + r_y \xi_y) \quad (28.20)$$

Geometrically, the image motion changes the static image transform (which lies in the  $(\xi_x, \xi_y)$  plane) into a spectrum in a plane with slope  $-r_y$  in the  $(\xi_y, \xi_t)$  plane and  $-r_x$  in the  $(\xi_x, \xi_t)$  plane. As in the 2-D case, the shifted points lie on a line through the origin. Note that this represents a relatively sparse occupation of the frequency domain (of interest for compression applications). A 3-D volume of data has been “compressed” into a plane. This compactness is not observed in the spatiotemporal domain.

In summary, the spectrum of a stationary image lies in the  $(\xi_x, \xi_y)$  plane. When the image undergoes translational motion, the spectrum occupies an oblique plane which passes through the origin. The orientation of the plane indicates the speed and direction of the motion. It is, therefore, possible to associate energy in particular regions of the frequency domain with particular image velocity components. By filtering specific regions in the frequency domain, these image velocity components can be detected. As will be seen shortly, other effects (such as the visual impact of temporal aliasing) can also be understood in the frequency domain.

### 3-D Sampling

In its simplest form (regular sampling on a rectangular grid, the method used here), 3-D sampling is a straightforward extension of 2-D (or 1-D) sampling (Fig. 28.8). Given a bandlimited sequence

$$f(x, y, t) \xrightarrow{\mathcal{F}} F(\xi_x, \xi_y, \xi_t) \quad (28.21)$$

with

$$F(\xi_x, \xi_y, \xi_t) = 0 \quad \text{whenever} \quad |\xi_x| > \xi_{x_0}, \quad |\xi_y| > \xi_{y_0}, \quad \text{or} \quad |\xi_t| > \xi_{t_0} \quad (28.22)$$

the continuous sequence can be reconstructed from a discrete set of samples whenever

$$\xi_{x_s} > 2\xi_{x_0}, \quad \xi_{y_s} > 2\xi_{y_0}, \quad \text{and} \quad \xi_{t_s} > 2\xi_{t_0} \quad (28.23)$$

FIGURE 28.8 A sampled spatiotemporal signal (image sequence).

FIGURE 28.9 An image sequence with insufficiently high sampling in the temporal dimension.

where  $\xi_x$ ,  $\xi_y$ ,  $\xi_z$  are the sampling frequencies. Equivalently, the sequence can be reconstructed if the intervals between samples are such that

$$\Delta x < \frac{1}{2\xi_{x_0}}, \quad \Delta y < \frac{1}{2\xi_{y_0}}, \quad \text{and} \quad \Delta t < \frac{1}{2\xi_{t_0}}. \quad (28.24)$$

If any of the sampling frequencies fall below the specified rates, the neighboring spectra (replications of the continuous spectrum, produced by the sampling process) overlap, and aliasing results. A case for which the temporal sampling frequency is too low is shown in Fig. 28.9. The appearance of aliasing in the spatial domain, where it commonly manifests as a jagged approximation of smooth high contrast edges, is relatively familiar and intuitive. The effect of sampling at too low a rate temporally is perhaps less so.

Consider the earlier simple example of a 1-D image with only two components, moving with velocity  $v_x$ . The continuous case, as derived previously, is shown in Fig. 28.10.  $\xi_{x_0}$  is the frequency of the static image.

FIGURE 28.10 A continuous, two-component, 1-D signal in translational motion.

FIGURE 28.11 A reconstruction of a sampled 1-D signal with temporal aliasing.

Suppose this image is sampled along the temporal dimension at a sampling frequency  $\xi_t$  less than the Nyquist rate ( $\xi_{tN} = 2r_x \xi_{x0}$ ), and the image is reconstructed via an ideal lowpass filter with temporal cutoff frequencies at plus and minus half the sampling frequency (Fig. 28.11). What is the visual effect of the aliased components?

As seen previously, the velocity of motion is reflected in the slope of the line connecting the components. For the situation shown, a sinusoidal grid (of the same frequency as the original) moving in the *opposite direction*, with speed  $r_x \xi_{x0} - (\xi_{tN} - \xi_t)$  is observed. As the sampling frequency drops, the velocity decreases, eventually reaching zero. Continued reduction in  $\xi_t$  results in motion in the *same direction* as the original image, increasing in velocity until (at  $\xi_t = 0$ ) the velocities of the two components are identical.

In the simple example just considered, the image was spatially homogeneous, so that the effects of aliasing were seen throughout the image. In general, this is not the case. As in the 1-D and 2-D cases, the temporal aliasing effect is seen in regions of the sequence with sufficiently high temporal frequency components to alias. Circumstances leading to high temporal frequencies include high velocity (large values of  $r_x$  in our simple example) and high spatial frequency components with some degree of motion (high  $\xi_{x0}$  in our example). Higher spatial frequency components require slower speeds to cause aliasing.

A well-known example of temporal aliasing is the so-called “wagon wheel” effect, in which the wheels of a vehicle appear to move in a direction opposite to that of the vehicle itself. The wheels have

both high spatial frequency components (due to their spokes) and relatively high rotational velocity. Hence, aliasing occurs (the wheels appear to rotate in reverse). The vehicle itself, however, which is moving more slowly and is also generally composed of lower spatial frequency components, moves forward (does not exhibit aliasing effects).

## 28.3 The Perception of Visual Motion

---

Visual perception can be discussed at a number of different levels: the anatomy or physical structure of the visual system; the physiology or basic function of the cells involved; and the psychophysical behavior of the system (the response of the system to various stimuli). Following is a brief discussion of visual motion perception. A more extensive treatment can be found in [3].

### Anatomy and Physiology of Motion Perception

The retina (the hemispherical surface at the back of the eye) is the sensor surface of the visual system, consisting of two major types of sensor elements. The rods are long and thin structures, numbering approximately 120 million. They provide scotopic (“low-light”) vision and are highly sensitive to motion. The cones are shorter and thicker, and substantially fewer in number (approximately 6 million per retina). They are less sensitive than the rods, providing photopic (“high-light”) and color vision. The cones are much less sensitive to motion.

The rods and cones are arranged in a roughly hexagonal array. However, they are not uniformly distributed over the retina. The cones are packed in the fovea (hence color vision is primarily foveal). The rods are primarily outside the fovea. As a result, motion sensitivity is higher outside the fovea, corresponding to the periphery of the visual field.

Visual information leaves each eye via the optic nerve. The nerves from each eye split at the optic chiasma, pass through the lateral geniculate nucleus, and continue to the visual cortex. Information is retinotopically mapped on the cortex (organized as in the original scene, but reversed). Note, however, that the mapping is not one-to-one (one retinal rod or cone to one cortical cell). As mentioned previously, approximately 120 million rods and 6 million cones are found in each eye, but only 1 million fibers in the associated optic nerve. This 126:1, apparently visually lossless compression, is one of the motivations for studying perceptually inspired image and video compression techniques, as discussed later in this chapter.

To achieve this compression, each cortical cell receives information from a set of rods and/or cones. This set makes up the *receptive field* for that cell. The response of a cortical cell to stimuli at different points in this field can be measured (e.g., via a moving spot of light) and plotted just as one might plot the impulse response of a 2-D filter.

Physiologically, nothing mentioned so far seems specifically adapted to the detection (or measurement) of motion. It might be reasonable to expect to find cells, which respond selectively to, e.g., the direction of motion. There appear to be no such cells in the human retina (although other species do have retinal cells that respond in this way); however, cells in the mammalian striate cortex exhibit this behavior (the complex cells).

How these cells come to act this way remains under study. However, most current theories fit a common organizational structure [4], shown in Fig. 28.12. The input receptive fields are sensitive both to the spatial location and spatial frequency of the stimulus. The role, if any, of orientation is not widely agreed upon. The receptive field outputs are combined, most likely in a nonlinear fashion, in the directionally sensitive subunits to produce an output highly dependent on the direction and/or velocity of the stimulus. The output of these subunits are then integrated both spatially and temporally.

Consider the hypothetical directionally sensitive mechanism in more detail for the case of rightward moving patterns (Fig. 28.13). For example, suppose the receptive fields are symmetric, and C is a comparator which requires both inputs to be high to output a high value. If a pattern, which stimulates receptive field 1 (RF1), moves a distance  $\Delta x$  in time  $\Delta t$  so that it falls within receptive field 2 (RF2), then the comparator will “fire.”

FIGURE 28.12 A common organizational structure for modeling complex cell behavior.

FIGURE 28.13 A mechanism for the directionally sensitive detection of motion.

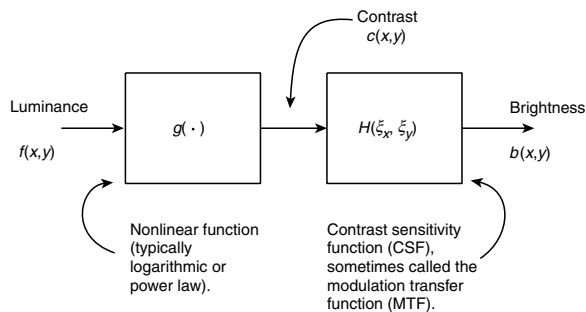

FIGURE 28.14 A simple block diagram modeling spatial vision.

Although it is simple, such a model establishes a basic link between moving patterns on the retina and the perception of motion. Additional insight can be obtained by considering the problem from a systems perspective.

## The Psychophysics of Motion Perception

### Spatial Frequency Response

In the case of spatial vision, much can be understood by modeling the visual system as shown in Fig. 28.14. The characteristics of the filter  $H(\xi_x, \xi_y)$  have been estimated by determining the threshold visibility of sine wave gratings. The resulting measurements indicate visual sensitivity as a function of spatial frequency that is approximately lowpass in nature. The response peaks in the vicinity of 5 cycles/degree, and falls off rapidly beyond 10 cycles/degree.

If it were separable (that is,  $H(\xi_x, \xi_y)$  could be determined by finding  $H(\xi_x)$  and  $H(\xi_y)$  independently), with  $H(\xi_x) = H(\xi_y)$ , or isotropic, the spatial response could be characterized via a single 1-D function. Although the assumption of separability is often useful, the spatial CSF of the human visual system is not, in fact, separable. It has been shown that visual sensitivity is reduced at orientations other than vertical and horizontal. This may be due to the predominance of vertical and horizontal structures in the visual environment, leading to the development or evolution of the visual system to be particularly sensitive at (or conversely, less sensitive away from) these orientations. This is referred to as the “oblique effect.”

### Temporal Frequency Response

The most straightforward approach to extending the above spatial vision model to include motion is to modify the CSF to include temporal frequency sensitivity, so that  $H(\xi_x, \xi_y)$  becomes  $H(\xi_x, \xi_y, \xi_t)$ .

One way to estimate the temporal frequency response of the visual system is to measure the flicker response. Although the flicker response varies with intensity and with the spatial frequency of the stimulus, it is again generally lowpass, with a peak in response in the vicinity of 10 Hz. The attenuation of the response above 10 Hz increases rapidly, so that at 60 Hz (the field rate of NTSC television) the flicker response is very low.

It is natural, as in the 2-D case, to ask whether the spatiotemporal frequency response  $H(\xi_x, \xi_y, \xi_t)$  is separable with respect to the temporal frequency. There is evidence to believe that this is not the case. The flicker response curves for high and low spatial frequency patterns do not appear consistent with a separable spatiotemporal response.

### Reconstruction Error

To a first approximation, the data discussed above indicate that the HVS behaves as a 3-D lowpass filter, with bandlimits (for bright displays) at 60 cycles/degree along the spatial frequency axes, and 70 Hz temporally. This approximation is useful in understanding errors, which may occur in reconstructing a continuous spatiotemporal signal from a sampled one. Consider the case of an image undergoing simple translational motion. This spatiotemporal signal occupies an oblique plane in the frequency domain. With sampling, the spectrum is replicated (with periods determined by the sampling frequencies along the respective dimensions) to fill the infinite 3-D volume. The spectrum of a sufficiently sampled (aliasing-free) image sequence produced in this way is shown in Fig. 28.15.

The 3-D lowpass reconstruction filter (the spatiotemporal CSF) can be approximated as an ideal lowpass filter, as shown in Fig. 28.16. As long as the cube in Fig. 28.16 completely encloses the spectrum

FIGURE 28.15 The spectrum of a sampled image undergoing uniform translational motion.

FIGURE 28.16 An ideal 3-D, lowpass reconstruction filter, with cutoff frequencies determined by the spatiotemporal contrast sensitivity function.

centered at DC, without including neighboring spectra, there is no reconstruction error. This case included no aliasing. If aliasing is included (the sample rate during acquisition is too low), the aliased components will be visible only if they fall within the passband of the CSF filter.

The above frequency domain analysis explains some important aspects of human visual motion perception. Other observations are not as easily explained in this way, however. As observed in [5], perceived motion is local (different motions can be seen in different areas of the visual field) and spatial-frequency specific (individual motion sensors respond differently (selectively) to different spatial frequencies). These two observations suggest an underlying representation that is local in both the spatiotemporal and spatiotemporal-frequency domains. Examples of such representations will be discussed in the following subsection.

## The Effects of Eye Motion

The analysis of motion perception described previously assumed a “passive” view. That is, any change in the pattern of light on the retinal surface is due to motion in the scene. That this is not the case can be seen by considering the manner in which static images are viewed. They are not viewed as a whole, but in a series of “jumps” from position to position. These “jumps” are referred to as *saccades* (French for “jolt” or “jerk”).

Even at the positions where the eye is “at rest” it is not truly static. It undergoes very small motions (microsaccades) of 1–2 min of arc. In fact, the eye is essentially never at rest. It has been shown that if the eye is stabilized, vision fades away after about a second. The relevance of this to the current discussion is that although the eye is in constant motion, so that the intensity patterns on the retina are constantly changing, when viewing a static scene no motion is perceived. Similar behavior is observed when viewing dynamic scenes [6]. Obviously, however, in the case of dynamic scenes motion is often perceived (even though the changes in intensity patterns on the retina are not necessarily greater than for static images).

Two hypotheses might explain these phenomena. The first is that the saccades are so fast that they are not sensed by the visual system; however, this does not account for the fact that motion is seen in dynamic scenes, but not static ones. The second is that the motion sensing system is “turned off” under some circumstances (the theory of corollary discharge). The basic idea is that the motor signals that control eye movement are also involved in the perception of motion, so that when intensity patterns on the retina change and there is a motor signal present, no motion is perceived. When intensity patterns change but there is no motor signal, or if there is no change in intensity patterns but there is a motor signal, motion is perceived. The latter situation corresponds to the tracking of moving objects (smooth pursuit).

The first hypothesis (the less plausible of the two) can be easily modeled with temporal linear filters. The second, more interesting behavior can be modeled with a simple comparator network.

## 28.4 Image Sequence Representation

---

### What Does “Representation” Mean?

The term “representation” may require some explanation. Perhaps the best way to do so is to consider some examples of familiar representations. For simplicity, 2-D examples will be used. Extension to 3-D is relatively straightforward.

#### The Pixel Representation

The pixel representation is so common and intuitive that it is usually considered to be “the image.” More precisely, however, it is a linear sum of weighted impulses:

$$u(m, n) = \sum_{m'=0}^{N-1} \sum_{n'=0}^{N-1} u(m', n') \delta(m - m', n - n') \quad (28.25)$$

where  $u(m, n)$  is the image,  $u(m', n')$  are the coefficients of the representation (numerically equal to the pixel values in this case), and the  $\delta(m - m', n - n')$  play the role of basis functions.

#### The DFT

The next most familiar representations (at least to engineers) is the DFT, in which the image is expressed in terms of complex exponentials:

$$u(m, n) = \frac{1}{N^2} \sum_{h=0}^{N-1} \sum_{k=0}^{N-1} v(h, k) W_N^{-hm} W_N^{-kn} \quad (28.26)$$

where  $0 \leq m, n \leq N - 1$  and

$$W_N = e^{-j2\pi/N} \quad (28.27)$$

In this case  $v(h, k)$  are the coefficients of the representation and the 2-D complex exponentials  $W_N^{-hm} W_N^{-kn}$  are the basis functions.

The choice of one representation over the other (pixel vs. Fourier) for a given application depends on the image characteristics that are of most interest. The pixel representation makes the spatial organization of intensities in the image explicit. Because this is the basis of the visual stimulus, it seems more “natural.” The Fourier representation makes the composition of the image in terms of complex exponentials (“frequency components”) explicit. The two representations emphasize their respective characteristics (spatial vs. frequency) to the exclusion of all others. If a mixture of characteristics is desired, different representations must be used.

### Spatial/Spatial-Frequency Representations

A natural mixture is to combine frequency analysis with spatial location. An example of a 1-D representation of this type (a time/frequency representation) is a musical score. The need to know not only what the frequency content of a signal is, but where in the signal the frequency components exist is common to many signal, image, and image sequence processing tasks [7]. A variety of approaches [8,9] can be used to develop a representation to facilitate these tasks. The most intuitive approach is the finite-support Fourier transform.

## The Finite-Support Fourier Transform

This approach to local frequency decomposition has been used for many years for the analysis of time-varying signals. In the 2-D continuous case,

$$F_{x,y}(\xi_x, \xi_y) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} f_{x,y}(x', y') e^{-j2\pi(\xi_x x' + \xi_y y')} dx' dy' \quad (28.28)$$

where

$$f_{x,y}(x', y') = f(x', y')h(x - x', y - y') \quad (28.29)$$

$f(x', y')$  is the original image, and  $h(x - x', y - y')$  is a window centered at  $(x, y)$ .

The properties of the transform depend a great deal on the properties of the window function. Under certain circumstances (i.e., for certain windows) the transform is invertible. The most obvious case is for nonoverlapping (e.g., rectangular) windows.

The windowed transform idea can, of course, be applied to other transforms, as well. An example that is of substantial practical interest is the discrete cosine transform, with a rectangular nonoverlapping window:

$$F(h, k) = \alpha(h)\alpha(k) \sum_{m=0}^{N-1} \sum_{n=0}^{N-1} f(m, n) \cos\left(\frac{(2m+1)h\pi}{2N}\right) \cos\left(\frac{(2n+1)k\pi}{2N}\right) \quad (28.30)$$

where  $h, k = 0, 1, \dots, N-1$ ,

$$\alpha(h) = \begin{cases} \sqrt{\frac{1}{N}} & \text{for } h = 0 \\ \sqrt{\frac{2}{N}} & \text{otherwise} \end{cases} \quad (28.31)$$

$\alpha(k)$  is defined similarly, and the window dimensions are  $N \times N$ . This transform is the basis for the well-known JPEG and MPEG compression algorithms.

## The Gabor Representation

This representation was first proposed for 1-D signal analysis by Dennis Gabor in 1946 [10]. In 2-D [11], an image can be represented as the weighted sum of functions of the form

$$g(x, y) = \hat{g}(x, y) e^{j2\pi[\xi_{x_0}(x-x_0) + \xi_{y_0}(y-y_0)]} \quad (28.32)$$

where

$$\hat{g}(x, y) = \frac{1}{2\pi\sigma_x\sigma_y} e^{-\frac{1}{2}\left[\left(\frac{x-x_0}{\sigma_x}\right)^2 + \left(\frac{y-y_0}{\sigma_y}\right)^2\right]} \quad (28.33)$$

is a 2-D Gaussian function,  $\sigma_x$  and  $\sigma_y$  determine the extent of the Gaussian along the respective axes,  $(x_0, y_0)$  is the center of the function in the spatial domain, and  $(\xi_{x_0}, \xi_{y_0})$  is the center of support in the frequency domain. A representative example of a Gabor function is shown in Fig. 28.17.

Denoting the distance between spatial centers as  $D$  and the distance between their centers of support in the frequency domain as  $W$ , the basis is complete if  $WD = 2\pi$ . These functions have a number of interesting aspects. They achieve the lower limits of the Heisenburg uncertainty inequalities:

$$\Delta x \Delta \xi_x \geq \frac{1}{4\pi}, \quad \Delta y \Delta \xi_y \geq \frac{1}{4\pi} \quad (28.34)$$

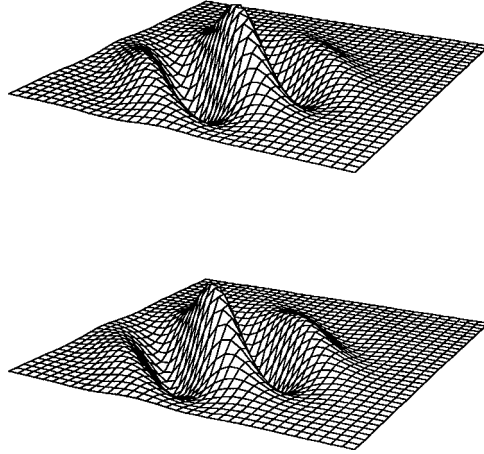

FIGURE 28.17 The real (top) and imaginary (bottom) parts of a representative 2-D Gabor function.

where  $\Delta_x$ ,  $\Delta_y$ ,  $\Delta_{\xi_x}$ , and  $\Delta_{\xi_y}$ , are the effective widths of the functions in the spatial and spatial-frequency domains. By this measure, then, these functions are optimally local. Their real and imaginary parts also agree reasonably well with measured receptive field profiles. The basis is not orthogonal, however. Specifically, the Gabor transform is not equivalent to the finite-support Fourier transform with a Gaussian window. For a cross-section of the state of the art in Gabor transform-based analysis, see [12].

### The Derivative of Gaussian Transform

In 1987, Young [13] proposed a receptive field model based on the Gaussian and its derivatives. These functions, like the Gabor functions, are spatially and spectrally local and consist of alternating regions of excitation and inhibition in a decaying envelope. Young showed that Gaussian derivative functions more accurately model the measured receptive field data than do the Gabor functions [14].

In [15], a spatial/spatial-frequency representation based on shifted versions of the Gaussian and its derivatives was introduced (the derivative of Gaussian transform (DGT)). As with the Gabor transform, although this transform is nonorthogonal, with a suitably chosen basis it is invertible. The DGT has significant practical advantage over the Gabor transform in that both the basis functions and coefficients of expansion are real-valued.

The family of 2-D separable Gaussian derivatives centered at the origin can be defined as

$$\begin{aligned} g_{0,0}(x, y) &= g_0(x)g_0(y) \\ &= e^{-(x^2+y^2)}/2\sigma^2 \end{aligned} \quad (28.35)$$

$$\begin{aligned} g_{m,n}(x, y) &= g_m(x)g_n(y) \\ &= \frac{d^{(m)}}{dx^{(m)}}g_0(x)\frac{d^{(n)}}{dy^{(n)}}g_0(y) \end{aligned} \quad (28.36)$$

This set can then be shifted to any desired location. The variance  $\sigma$  defines the extent of the functions in the spatial domain. There is an inverse relationship between the spatial and spectral extents, and the value of this variable may be constant or may vary with context.

The 1-D Gaussian derivative function spectra are bimodal (except for that of the original Gaussian, which is itself a Gaussian) with modes centered at  $\pm\Omega_m$  rad/pixel:

$$\Omega_m = \frac{\sqrt{m}}{\sigma} \quad (28.37)$$

where  $m$  is the derivative order. The order of derivative necessary to center a mode at a particular frequency is therefore

$$m = (\Omega_m \sigma)^2 \quad (28.38)$$

### The Wigner Distribution

The previous examples indicate that a local frequency representation need not have an orthogonal basis. In fact, it need not even be linear. The Wigner distribution was introduced by Eugene Wigner in 1932 [16] for use in quantum mechanics (in 1-D). In 2-D, the Wigner distribution can be written as

$$W_f(x, y, \xi_x, \xi_y) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} f\left(x + \frac{\alpha}{2}, y + \frac{\beta}{2}\right) f^*\left(x - \frac{\alpha}{2}, y - \frac{\beta}{2}\right) e^{-j2\pi(\alpha\xi_x + \beta\xi_y)} d\alpha d\beta \quad (28.39)$$

where the asterisk denotes complex conjugation. The Wigner distribution is real valued, so does not have an explicit phase component (as seen in, e.g., the Fourier transform). A number of discrete approximations to this distribution (sometimes referred to as pseudo-Wigner distributions) have also been formulated.

### Spatial/Scale Representations (Wavelets)

Scale is a concept that has proven very powerful in many applications, and may under some circumstances be considered as fundamental as frequency. Given a set of (1-D) functions

$$W_{jk}(x) = W(2^j x - k) \quad (28.40)$$

where the indices  $j$  and  $k$  correspond to dilation (change in scale) and translation, respectively, a signal decomposition

$$f(x) = \sum_j \sum_k b_{jk} W_{jk}(x) \quad (28.41)$$

emphasizes the scale (or resolution) characteristics of the signal (specified by  $j$ ) at specific points along  $x$  (specified by  $k$ ), yielding a multiresolution description of the signal.

A class of functions  $W_{jk}(x)$  that have proven extremely useful are referred to as wavelets. A detailed discussion of wavelets is beyond the scope of this chapter (see [17–19] for excellent treatments of this topic); however, an important aspect of any representation (including wavelets) is the resolution of the representation, and how it can be measured.

### Resolution

In dealing with joint representations, resolution is a very important issue. It arises in a number of ways. In discussing the Gabor representation, it was noted that the functions minimized the uncertainty inequalities, e.g.,

$$\Delta x \Delta \xi_x \geq \frac{1}{4\pi} \quad (28.42)$$

Note that it is the product that is minimized. Arbitrarily high resolution cannot be achieved in both domains simultaneously, but can be traded between the two domains at will. The proper balance depends on the application. It should be noted that the “effective width” measures  $\Delta x$ ,  $\Delta \xi_x$ , etc. (normalized second moment measures) are not the only way to define resolution. For example, the degree of energy concentration could

**FIGURE 28.18** The resolution of a time/frequency representation and a wavelet representation in the time-frequency plane.

be used (leading to a different “optimal” set of functions, the prolate spheroidal functions). The appropriateness of the various measures again depends on the application. Their biological (psychophysical) relevance remains to be determined.

All the previously mentioned points are relevant for both spatial/spatial-frequency and spatial/scale representations (wavelets). Wavelets, however, present some special considerations. Suppose one wishes to compare the resolutions of time/frequency and wavelet decompositions? Specifically, what is the resolution of a multiresolution method? This question can be illustrated by considering the 1-D case, and examining the behavior of the two methods in the time-frequency plane (Fig. 28.18).

In the time/frequency representation, the dimensions  $\Delta t$  and  $\Delta \xi_t$  remain the same throughout the time-frequency plane. In wavelet representations the dimensions vary, but their product remains constant. The resolution characteristics of wavelets may lead one to believe that the uncertainty of a wavelet decomposition may fall below the bound in Eq. (28.42). This is not the case. The tradeoff between  $\Delta t$  and  $\Delta \xi_t$  simply varies. The fundamental limit remains.

A final point relates more specifically to the representation of image sequences. The HVS has a specific (bandlimited) spatiotemporal frequency response. Beyond indicating the maximum perceivable frequencies (setting an upper bound on resolution) it seems feasible to exploit this point further, to achieve a more efficient representation. Recalling the relationship between motion and temporal frequency, a surface with high spatial frequency components, moving quickly, has high temporal frequency components. When it is static, it does not. The characteristics of the spatiotemporal CSF may lead us to the conclusions that static regions of an image require little temporal resolution, but high spatial resolution, and that regions in an image undergoing significant motion require less spatial resolution (due to the lowered sensitivity of the CSF), but require high temporal resolution (for smooth motion rendition).

The first conclusion is essentially correct (although not trivial to exploit). The second conclusion, however, neglects eye tracking. If the eye is tracking a moving object, the spatiotemporal frequency characteristics experienced by the viewer are very similar to those in the static case, i.e., visual sensitivity to spatial structure is not reduced significantly.

## 28.5 The Computation of Motion

Many approaches are used for the computation of motion (or, more precisely, the estimation of motion based on image data). Before examining some of these approaches in more detail, it is worthwhile to review the relationship between the motion in a scene and the changes observed in an image of the scene.

### The Motion Field

The motion field [20] is determined by establishing a correspondence between the motion of points in the scene (the real world) and the motion of points in the image plane. This correspondence is found geometrically, and is independent of the brightness patterns in the scene (e.g., the presence or absence of surface textures, changes in luminance, etc.).

FIGURE 28.19 The motion field based on a simple pinhole camera model.

Consider the situation in Fig. 28.19. At a particular instant in time, a point  $P_{\text{image}}$  in the image corresponds to some point  $P_{\text{object}}$  on the surface of an object. The two points are related via the perspective projection equation. Now, suppose the object point  $P_{\text{object}}$  has velocity  $(v_x, v_y, v_z)$  relative to the camera. The result is a velocity  $(v'_x, v'_y)$  for the point  $P_{\text{image}}$  in the image plane. The relationship between the velocities can be found by differentiating the perspective projection equation with respect to time. In this way, a velocity vector can be assigned to each image point, yielding the motion field.

## Optical Flow

Usually, the intensity patterns in the image move as the objects to which they correspond move. Optical flow is the motion of these intensity patterns. Ideally, optical flow and the motion field correspond; but this is not always the case. For a perfectly uniform sphere rotating in front of an imaging system, there is shading over the surface of the sphere (due to the shape of the sphere), but it does not change with time. The optical flow is zero everywhere, while the motion field is not. For a fixed sphere illuminated by a moving light source, the shading changes with time, although the sphere is not in motion. The optical flow is nonzero, while the motion field is zero.

Furthermore, optical flow is not uniquely determined by local information in the changing image. Consider, for example, a region with uniform brightness which does not vary with time. The “most likely” optical flow value is zero, but (as long as there are corresponding points of equal brightness in both images) there are many “correct” flow vectors. What we would like is the motion field, but what we have access to is optical flow. Fortunately, the optical flow is usually not too different from the motion field.

## The Calculation of Optical Flow

Wide variety of approaches are used for the calculation of optical flow. The first, below, is a conceptually simple yet very widely used method. This approach is particularly popular for video compression, and is essentially that used in MPEG-1 and 2.

### Optical Flow by Block Matching

The calculation of optical flow by block-matching is the most commonly used motion estimation technique. The basic approach is as follows. Given two successive images from a sequence, the first image is partitioned into nonoverlapping blocks (e.g.,  $8 \times 8$  pixels in size, Fig. 28.20(left)). To find the motion vector for each block, the similarity (e.g., via mean-squared error) between the block and the intensities in the neighborhood of that block in the next frame (Fig. 28.20(right)) is calculated. The location that shows the best match is considered the location to which the block has moved. The motion vector for the block is the vector connecting the center of the block in frame  $n$  to the location of the best match in frame  $n + 1$ .

FIGURE 28.20 Motion estimation by block matching.

The approach is simple, but a number of things must be considered. The size of the search neighborhood must be established, which in turn determines the maximum velocity that can be estimated. The search strategy must be decided, including the need to evaluate every potential match location and the precision with which the match locations must be determined (e.g., is each pixel a potential location? Is subpixel accuracy required?). The amount of computation time/power available is a critical factor in these decisions. Even at its simplest, block matching is computationally intensive. If motion estimates must be computed at frame rate (1/30 s) this will have a strong effect on the algorithm design. A detailed discussion of these and related issues can be found in [21].

### Optical Flow via Intensity Gradients

The calculation of optical flow via intensity gradients, as proposed by Horn and Shunck [22], is a classical approach to motion estimation.

Let  $f(x, y, t)$  be the intensity at time  $t$  for the image point  $(x, y)$ , and let  $r_x(x, y)$  and  $r_y(x, y)$  be the  $x$  and  $y$  components of the optical flow at that point. Then for a small time interval  $\delta t$ ,

$$f(x + \underbrace{r_x \delta t}_{\delta x}, y + \underbrace{r_y \delta t}_{\delta y}, t + \delta t) = f(x, y, t) \quad (28.43)$$

This single equation is not sufficient to determine  $r_x$  and  $r_y$ . It can, however, provide a constraint on the solution. Assuming that intensity varies smoothly with  $x$ ,  $y$ , and  $t$ , the left hand side of equation 28.43 can be expanded in a Taylor's series:

$$f(x, y, t) + \delta x \frac{\partial f}{\partial x} + \delta y \frac{\partial f}{\partial y} + \delta t \frac{\partial f}{\partial t} + \text{higher-order terms} = f(x, y, t) \quad (28.44)$$

Ignoring the higher order terms, canceling  $f(x, y, t)$ , dividing by  $\delta t$  and letting  $\delta t \rightarrow 0$ ,

$$\frac{\partial f}{\partial x} r_x + \frac{\partial f}{\partial y} r_y + \frac{\partial f}{\partial t} = 0 \quad (28.45)$$

or

$$f_x r_x + f_y r_y + f_t = 0 \quad (28.46)$$

where  $f_x$ ,  $f_y$ , and  $f_t$  are estimated from the image sequence.

This equation is called the *optical flow constraint equation*, since it constrains  $r_x$  and  $r_y$  of the optical flow. The values of  $(r_x, r_y)$  which satisfy the constraint equation lie on a straight line in the  $(r_x, r_y)$  plane. A local brightness measurement can identify the constraint line, *but not a specific point on the line*. Note that this problem cannot really be solved via, e.g., adding an additional constraint. It is a fundamental aspect of the image data. A "true" solution cannot be guaranteed, but a solution can be found.

FIGURE 28.21 An instance of the aperture problem.

To view this limitation in another way, the constraint equation can be rewritten in vector form, as

$$(f_x, f_y) \cdot (r_x, r_y) = -f_t \quad (28.47)$$

so that the component of optical flow in the direction of the intensity gradient  $(f_x, f_y)^T$  is

$$\frac{f_t}{\sqrt{f_x^2 + f_y^2}} \quad (28.48)$$

However, the component of the optical flow perpendicular to the gradient (along iso-intensity contours) cannot be determined. This is a manifestation of the *aperture problem*. If the motion of an oriented element is detected by a unit that is small compared with the size of the moving element, the only information that can be extracted is the component of motion perpendicular to the local orientation of the element. For example, looking at a moving edge through a small aperture (Fig. 28.21), it is impossible to tell whether the actual motion is in the direction of *a* or of *b*.

One way to work around this limitation is to impose an explicit smoothness constraint. Motion was implicitly assumed smooth earlier, when a Taylor's expansion was used and when the higher order terms were ignored. Following this approach, an iterative scheme for finding the optical flow for the image sequence can be formulated:

$$\begin{aligned} r_x(k, l)^{n+1} &= \overline{r_x(k, l)^n} - \frac{\lambda f_x^2 \overline{r_x(k, l)^n} + \lambda f_x f_y \overline{r_y(k, l)^n} + \lambda f_x f_t}{1 + \lambda(f_x^2 + f_y^2)} \\ &= \overline{r_x(k, l)^n} - \lambda f_x \frac{f_x \overline{r_x(k, l)^n} + f_y \overline{r_y(k, l)^n} + f_t}{1 + \lambda(f_x^2 + f_y^2)} \end{aligned} \quad (28.49)$$

and

$$r_y(k, l)^{n+1} = \overline{r_y(k, l)^n} - \lambda f_y \frac{f_x \overline{r_x(k, l)^n} + f_y \overline{r_y(k, l)^n} + f_t}{1 + \lambda(f_x^2 + f_y^2)} \quad (28.50)$$

where the superscripts  $n$  and  $n + 1$  indicate the iteration number,  $\lambda$  is a parameter allowing a tradeoff between smoothness and errors in the flow constraint equation, and  $\bar{r}_x(k, l)$  and  $\bar{r}_y(k, l)$  are local averages of  $r_x$  and  $r_y$ . The updated estimates are thus the average of the surrounding values, minus an adjustment (which in velocity space is in the direction of the intensity gradient).

The previous discussion relied heavily on smoothness of the flow field. However, there are places in image sequences where discontinuities *should* occur. In particular, the boundaries of moving objects should exhibit discontinuities in optical flow. One approach taking advantage of smoothness but allowing discontinuities is to apply segmentation to the flow field. In this way, the boundaries between regions with smooth optical flow can be found, and the algorithm can be prevented from smoothing over these boundaries. Because of the “chicken-and-egg” nature of this method (a good segmentation depends on a good optical flow estimate, which depends on a good segmentation ...), it is best applied iteratively.

### Spatiotemporal-Frequency-Based Methods

It was shown in section 28.2 that motion can be considered in the frequency domain, as well as in the spatial domain. A number of motion estimation methods have been developed with this in mind. If the sequence to be analyzed is very simple (has only a single motion component, for example) or if motion detection alone is required, the Fourier transform can be used as the basis for motion analysis, as examined in [23–25]; however, due to the global nature of the Fourier transform, it cannot be used to determine the location of the object in motion. It is also poorly suited for cases in which multiple motions exist (i.e., when the scene of interest consists of more than one object moving independently), since the signatures of the different motions are difficult (impossible, in general) to separate in the Fourier domain. As a result, although Fourier analysis can be used to illustrate some interesting phenomena, it cannot be used as the basis of motion analysis methods for the majority of sequences of practical interest.

To identify the locations and motions of objects, frequency analysis localized to the neighborhoods of the objects is required. Windowed Fourier analysis has been proposed for such cases [26], but the accuracy of a motion analysis method of this type is highly dependent on the resolution of the underlying transform, in both the spatiotemporal and spatiotemporal-frequency domains. It is known that the windowed Fourier transform does not perform particularly well in this regard. Filterbank-based approaches to this problem have also been proposed, as in [27]. The methods examined below each exploit the frequency domain characteristics of motion, and provide spatiotemporally localized motion estimates.

#### Optical Flow via the 3-D Wigner Distribution

Jacobson and Wechsler [28] proposed an approach to spatiotemporal-frequency, based derivation of optical flow using the 3-D Wigner distribution (WD). Extending the 2-D definition given earlier, the 3-D WD can be written as

$$W_f(x, y, t, \xi_x, \xi_y, \xi_t) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} f\left(x + \frac{\alpha}{2}, y + \frac{\beta}{2}, t + \frac{\tau}{2}\right) \cdot f^*\left(x - \frac{\alpha}{2}, y - \frac{\beta}{2}, t - \frac{\tau}{2}\right) \times e^{-j2\pi(\alpha\xi_x + \beta\xi_y + \tau\xi_t)} d\alpha d\beta d\tau \quad (28.51)$$

It can be shown that the WD of a linearly translating image with velocity  $\vec{r} = (r_x, r_y)$  is

$$W_f(x, y, t, \xi_x, \xi_y, \xi_t) = \delta(r_x\xi_x + r_y\xi_y + \xi_t) \cdot W_f(x - r_x t, y - r_y t, \xi_x, \xi_y) \quad (28.52)$$

which is nonzero only when  $r_x\xi_x + r_y\xi_y + \xi_t = 0$ .

For a linearly translating image, then, the local spectra  $W_{f_{x,y,t}}(\xi_x, \xi_y, \xi_t)$  contain energy only in a plane (as in the Fourier case) the slope of which is determined by the velocity. Jacobson and Wechsler proposed to find this plane by integrating over the possible planar regions in these local spectra (via a so-called “velocity polling function”), using the plane of maximum energy to determine the velocity.

FIGURE 28.22 The (stylized) power spectra of a set of 3-D Gabor filters.

FIGURE 28.23 Velocity estimation in the frequency domain via estimation of the slope of the spectrum.

### Optical Flow Using 3-D Gabor Filters

Heeger [29] proposed the use of 3-D Gabor filters to determine this slope. Following the definition discussed for 2-D, a 3-D Gabor filter has the impulse response

$$g(x, y, t) = \hat{g}(x, y, t) e^{j2\pi[\xi_{x_0}(x-x_0) + \xi_{y_0}(y-y_0) + \xi_{t_0}(t-t_0)]} \quad (28.53)$$

where

$$\hat{g}(x, y, t) = \frac{1}{(2\pi)^{3/2} \sigma_x \sigma_y \sigma_t} e^{-\frac{1}{2} \left[ \left( \frac{x-x_0}{\sigma_x} \right)^2 + \left( \frac{y-y_0}{\sigma_y} \right)^2 + \left( \frac{t-t_0}{\sigma_t} \right)^2 \right]} \quad (28.54)$$

To detect motion in different directions, a family of these filters is defined, as shown in Fig. 28.22.

In order to capture velocities at different scales (high velocities can be thought of as occurring over large scales, because a large distance is covered per unit time), these filters are applied to a Gaussian pyramidal decomposition of the sequence. Given the energies of the outputs of these filters, which can be thought of as sampling spatiotemporal/spatiotemporal-frequency space, the problem is analogous to that shown in Fig. 28.23. The slope of the line (corresponding to the slope of the plane which characterizes motion)

must be found via a finite set of observations. In this method, this problem is solved under the assumption of a random texture input (the plane in the frequency domain consists of a single constant value).

### Optical Flow via the 3-D Gabor Transform

One shortcoming of a filterbank approach (if the filters are not orthogonal or do not provide a complete basis) is the possibility of loss. Using the 3-D Gabor functions as the basis of a transform resolves this problem. A sequence of dimension  $N \times M \times P$  can then be expressed at each discrete point  $(x_m, y_n, t_p)$  as

$$f(x_m, y_n, t_p) = \sum_{j=0}^{J-1} \sum_{k=0}^{K-1} \sum_{l=0}^{L-1} \sum_{q=0}^{Q-1} \sum_{r=0}^{R-1} \sum_{s=0}^{S-1} c_{x_q, y_r, t_s, \xi_{x_j}, \xi_{y_k}, \xi_{t_l}} \cdot g_{x_q, y_r, t_s, \xi_{x_j}, \xi_{y_k}, \xi_{t_l}}(x_m, y_n, t_p) \quad (28.55)$$

where  $J \cdot K \cdot L \cdot Q \cdot R \cdot S = N \cdot M \cdot P$  for completeness, the functions  $g_{x_q, y_r, t_s, \xi_{x_j}, \xi_{y_k}, \xi_{t_l}}(x_m, y_n, t_p)$  denote the Gabor basis functions with spatiotemporal and spatiotemporal-frequency centers of  $(x_q, y_r, t_s)$  and  $(\xi_{x_j}, \xi_{y_k}, \xi_{t_l})$  respectively, and  $c_{x_q, y_r, t_s, \xi_{x_j}, \xi_{y_k}, \xi_{t_l}}$  are the associated coefficients. Note that these coefficients are not found by convolving with the Gabor functions, since the functions are not orthogonal. See [30] for a survey and comparison of methods for computing this transform.

In the case of uniform translational motion, the slope of the planar spectrum is sought, yielding the optical flow vector  $\vec{r}$ . A straightforward approach to estimating the slope of the local spectra [31,32] is to form vectors of the  $\xi_x$ ,  $\xi_y$ , and  $\xi_t$  coordinates of the basis functions that have significant energy for each point in the sequence at which basis functions are centered. From equation 20, the optical flow vector and the coordinate vectors  $\vec{\xi}_x$ ,  $\vec{\xi}_y$ , and  $\vec{\xi}_t$  at each point are related as

$$\vec{\xi}_t = -(r_x \vec{\xi}_x + r_y \vec{\xi}_y) = -\mathbf{S} \vec{r} \quad (28.56)$$

where  $\mathbf{S} = (\vec{\xi}_x | \vec{\xi}_y)$ . An LMS estimate of the optical flow vector at a given point can then be found using the pseudo inverse of  $\mathbf{S}$ :

$$\vec{r}_{\text{est}} = -(\mathbf{S}^T \mathbf{S})^{-1} \mathbf{S}^T \vec{\xi}_t \quad (28.57)$$

In addition to providing a means for motion estimation, this approach has also proven useful in predicting the apparent motion reversal associated with temporal aliasing [33].

### Wavelet-Based Methods

A number of wavelet-based approaches to this problem have also been proposed. In [34–37], 2-D wavelet decompositions are applied frame-by-frame to produce multi-scale feature images. This view of motion analysis exploits the multiscale properties of wavelets, but does not seek to exploit the frequency domain properties of motion. In [38], a spatiotemporal (3-D) wavelet decomposition is employed, so that some of these frequency domain aspects can be utilized. Leduc et al. explore the estimation of translational, accelerated, and rotational motion via spatiotemporal wavelets in [39–44]. Decompositions designed and parameterized specifically for the motion of interest (e.g., rotational motion) are tuned to the motion to be estimated.

## 28.6 Image Sequence Compression

Image sequences represent an enormous amount of data (e.g., a 2-hour movie at the US HDTV resolution of  $1280 \times 720$  pixels, 60 frames/second progressive, with 24 bits/pixel results in 1194 Gbytes of data). This data is highly redundant, and much of it has minimal perceptual relevance. One approach to reducing this volume of data is to apply still image compression to each frame in the sequence (generally referred to as intraframe coding). For example, the JPEG still image compression algorithm can be applied frame by frame (sometimes referred to as Motion-JPEG or M-JPEG). This method, however, does not take advantage of the substantial correlation, which typically exists between frames in a sequence. Compression techniques which seek to exploit this temporal redundancy are referred to as interframe coding methods.

FIGURE 28.24 A hybrid (predictive/transform) encoder.

FIGURE 28.25 A predictive/transform decoder.

## Motion Compensated Prediction/Transform Coders

Predictive coding is based on the idea that to the degree that all or part of a frame in a sequence can be predicted, that information need not be transmitted. As a result, it is usually the case that the better the prediction, the better the compression that can be achieved. The simplest possible predictor is to assume that successive frames are identical (differential coding); however, the optical flow, which indicates the motion of intensity patterns in the image sequence, can be used to improve the predictor. *Motion compensated prediction* uses optical flow information, together with a reconstruction of the previous frame, to predict the content of the current frame.

Quantization (and the attendant loss of information) is inherent to lossy compression techniques. This loss, if introduced strategically, can be exploited to produce a highly compressed sequence, with good visual quality. Transforms (e.g., the DCT), followed by quantization, provide a convenient mechanism to introduce (and control) this loss. Following this approach, a hybrid (motion compensated prediction/transform) encoder and decoder are shown in Figs. 28.24 and 28.25. This hybrid algorithm (with the addition of entropy coders and decoders) is the essence of the H.261, MPEG-1, MPEG-2, and US HDTV compression methods [45].

## Perceptually Based Methods

Although algorithms such as MPEG exploit the properties of visual perception (principally in the formulation of quantization matrices), it is not especially central to the structure of the algorithm. There is, for example, no explicit model of vision underlying the MPEG-1 and 2 algorithms. In perceptually-based (sometimes called second generation) methods, knowledge of the HVS takes a much more central role. This view of the problem is particularly effective (and necessary) when designing compression algorithms intended to operate at very high compression ratios (e.g., over 200:1).

The methods in this subsection are inspired by specific models of visual perception. The first is an approach based on a very comprehensive vision model, performing spatial and temporal frequency decomposition via filters designed to reflect properties of the HVS. The second and third are techniques using visually relevant transforms (the Gabor and derivative of Gaussian transforms, respectively) in an otherwise conventional hybrid (predictive/transform) framework. Finally, a method based on spatiotemporal segmentation (following the contour/texture model of vision) will be discussed.

### **The Perceptual Components Architecture**

The perceptual components architecture [46] is a framework for the compression of color image sequences based on the processing thought to take place in the early HVS. It consists of the following steps. The input RGB image sequence is converted into an opponent color space (white/black (WB), red/green (RG), and blue/yellow (BY)). The sequence is filtered spatially with a set of frequency and orientation selective filters, inspired by the frequency and orientation selectivity of the HVS. Filters based on the temporal frequency response of the visual system are applied along the temporal dimension. The filtered sequences are then subsampled using a hexagonal grid, and subsampled by a factor of two in the temporal dimension. Uniform quantization is applied within each subband, with higher frequency subbands quantized more coarsely. The WB (luminance) component is quantized less coarsely overall than the RG and BY (chrominance) components. The first-order entropy of the result provides an estimate of the compression ratio.

Note that there is no prediction or motion compensation. This is a 3-D subband coder, where temporal redundancy is exploited via the temporal filters. For a  $256 \times 256$ , 8 frame segment of the “football” sequence (a widely used test sequence depicting a play from an American football game), acceptable image quality was achieved for about 1 bit/pixel (from 24 bits/pixel). Although this is not very high compression, the sequence used is more challenging than most. Another contributing factor is that the subsampled representation is 8/3 the size (in terms of bits) of the original, which must be overcome before any compression is realized.

### **Very-Low-Bit-Rate Coding Using the Gabor Transform**

In discussing the Gabor transform previously, it was stated that the basis functions of this transform are optimally (jointly) local. In the context of coding, there are three mechanisms that can be exploited to achieve compression, all of which depend on locality: the local correlation between pixels in the sequence; the bounded frequency response of the human visual system (as characterized by the CSF); and visual masking (the decrease in visual sensitivity near spatial and temporal discontinuities). To take advantage of local spatial correlation, the image representation upon which a compression method is based must be spatially local (which is why images are partitioned into blocks in JPEG, MPEG-1&2, H.261, etc.). If the CSF is to be exploited (e.g., by quantizing high frequency coefficients coarsely) localization in the spatial-frequency domain is required. To exploit visual masking, spatial locality (of a fairly high degree) is required.

The Gabor transform is inherently local in space, so the partitioning of the image into blocks is not required (hence no blocking artifacts are observed at high compression ratios). Its spatial locality also provides a mechanism for exploiting visual masking, while its spatial-frequency locality allows the bandlimited nature of the HVS to be utilized.

An encoder and decoder based on this transform are shown in [Figs. 28.26](#) and [28.27](#) [47]. Note that they are in the classic hybrid (predictive/transform) form. This codec does not include motion compensation, and is for monochrome image sequences.

Applying this method to a 128-by-128, 8 bit/pixel version of the Miss America sequence resulted in reasonable image quality at a compression ratio of approximately 335:1.<sup>2</sup> At 24 frames per second, the associated bit rate is 9.4 kbits/s (a bitrate consistent, e.g., with wireless videotelephony).

---

<sup>2</sup>Not including the initial frame, which is intracoded to 9.1 kbits (a compression ratio of 14).

FIGURE 28.26 A Gabor transform-based video encoder.

FIGURE 28.27 The associated Gabor transform-based decoder.

### Video Coding Using the Derivative of Gaussian Transform

As mentioned previously, the derivative of Gaussian transform (DGT) has properties similar to the Gabor transform, but with the practical advantage that it is real-valued. This makes it particularly well-suited to video compression. In [48] the hybrid codec structure shown in Figs. 28.24 and 28.25 is adapted to the DGT, replacing the DCT (and IDCT), and adapting the quantization scheme to fit the visibility of the DGT basis, via a simple quantization mask.

Comparable results to those of the standard H.261 (DCT-based) codec are obtained for bitrates around 320 kbits/s (5 channels in the p\*64 model).

### Object-Based Coding by Split and Merge Segmentation

Object-based coding reflects the fact that scenes are largely composed of distinct objects, and that these objects are perceived as boundaries surrounding fields of shading or texture (the contour/texture theory of vision). Encoding an image or sequence in this way requires segmentation to identify the constituent objects. This view of compression, which also facilitates interaction and editing, underlies the MPEG-4 video compression standard [49]. Although the method that will be described is different in detail from MPEG-4, as one of the earliest documented object-based systems, it illustrates many important aspects of such systems.

In this approach [50], 3-D (spatiotemporal) segmentation is used to reduce the redundant information in a sequence (essentially identifying objects within the sequence), while retaining information critical to the human observer. The sequence is treated as a single 3-D data volume, the voxels of which are grouped into regions via split and merge. The uniformity criterion used for the segmentation is the goodness-of-fit to a 3-D polynomial. The sequence is then encoded in terms of region boundaries (a binary tree structure) and region interior intensities (the coefficients of the 3-D polynomial).

The data volume is first split such that each region is a parallelepiped over which the gray level variation can be approximated within a specified mean squared error (Fig. 28.28). Regions are split by quadrants, following the octree strategy. A region adjacency graph is constructed, with nodes corresponding to each region and links between the nodes assigned a cost indicating the similarity of the regions. A high cost indicates low similarity. Regions are merged, starting with regions with the lowest cost, and the region adjacency graph is updated. The resulting regions are represented using a pyramidal (binary tree) structure, with the regions labeled so that adjacent regions have different labels.

FIGURE 28.28 The split phase.

Using 16 frames from the “Secretary” sequence, the compression ratio achieved was 158:1 (a bitrate of 83 kbits/s). A total of 5740 parallelepipeds (1000 regions) were used.

## 28.7 Conclusions

---

In this chapter, some of the fundamental aspects and algorithms in the processing of digital video were examined. Continued improvements in computing performance make many methods that previously required specialized platforms (or were primarily of research interest due to computational requirements) practical. In addition to bringing high-end applications to the desktop, numerous new applications are thus enabled, in areas as diverse as medical imaging, entertainment, and human-computer interaction.

### 29.1 Introduction

---

During the last few years, signal processing integrated circuits (programmable or not) have become primary experimentation grounds for low power digital design techniques. There have been two main motivating factors for this design trend. The first (and most significant) is the abundant proliferation and market penetration of cellular phones. During the first phase in the life cycle of cellular systems, programmable digital signal processings (DSPs) were used to implement the voice coding component. As DSPs became more powerful and flexible, they took over most of the baseband tasks within a cellular handset such as channel coding (convolutional coding and decoding), encryption/decryption, and demodulation/equalization [1]. Consumer preferences placed significant importance on handset size and battery life and this in turn created pressure in the design community to produce higher performance and lower power signal processors. The second motivating factor is the introduction of a new breed of consumer electronic devices such as digital cameras, portable digital video and audio players, wireless-enabled personal digital assistants that require substantial signal processing capability and at the same time are battery-powered and can benefit substantially from reduced energy consumption.

The low-power trends in the signal processing domain will definitely continue in the coming years with the introduction of 3G wireless and the corresponding wideband code-division multiple-access (WCDMA) physical transmission channel, and also with emerging wireless computing platforms such as sensor data processing systems [2].

In this chapter, an overview of commonly used low-power techniques in programmable digital signal processors, as well as embedded DSP subsystems for custom applications, are presented.

## 29.2 Power Dissipation in Digital Circuits

This section provides a brief overview of power dissipation basics to render this document self-contained. Four major sources of power dissipation are used in digital circuits:

- Switching or dynamic power ( $P_{sw}$ )
- Short-circuit or direct-path power ( $P_{sc}$ )
- Leakage power ( $P_{leak}$ )
- Static power ( $P_{stat}$ )

The total chip power is given by the following Eq. (29.1):

$$P_{total} = P_{sw} + P_{sc} + P_{leak} + P_{stat} \tag{29.1}$$

The switching power dissipation is the dominant component and is due to the charging and discharging of all capacitive nodes in the circuit. It is given by Eq. (29.2):

$$P_{sw} = aCV_{DD}^2 f \tag{29.2}$$

where  $a$  is the switching activity ( $0 \leq a \leq 1$ ),  $C$  is the total capacitance of all capacitive nodes in the circuit,  $V_{DD}$  is the supply voltage, and  $f$  is the clock frequency. In case the internal nodes of the circuit do not experience a full voltage swing from 0 V to  $V_{DD}$ , Eq. (29.2) is modified as follows:

$$P_{sw} = aCV_{DD}V_{swing} f \tag{29.3}$$

where  $V_{swing}$  is the low voltage swing.

Short-circuit power ( $P_{sw}$ ) is dissipated when there is a transient direct path from  $V_{DD}$  to ground during switching: During the rising (or falling) transition of static CMOS gates from  $V_{TN}$  to  $V_{DD} - V_{TP}$  ( $V_{DD} - V_{TP}$  to  $V_{TN}$ ) a direct path from  $V_{DD}$  to ground exists through a PMOS and NMOS stack that are both in their ON region. If the rise and fall times of the digital circuit are kept well under control (a small fraction of the period), short-circuit power is rarely a design issue. A comprehensive analysis on short-circuit power in static CMOS circuits can be found in [3].

Two main types of leakage power are available. The first is subthreshold leakage and involves finite channel conductance in the NMOS and PMOS OFF regions. The second is reverse bias junction leakage and it involves source and drain-to-substrate PN junction leakage. Figure 29.1 shows the subthreshold and junction leakage components.

The subthreshold current is typically the dominant component of leakage power. Low-voltage process technologies that rely on reduced threshold voltages to maintain performance are especially susceptible to increased subthreshold leakage. Threshold reduction results in large increases in leakage currents as  $I_{dsat}$  a percentage of device. Leakage currents can be especially important in low activity embedded DSP systems (i.e., pagers) that are mostly in standby mode. In such cases, system battery life is mainly dependent on  $P_{leak}$ . Techniques for reducing  $P_{leak}$  include the use of multiple  $V_T$  devices (MTCMOS) [4] and substrate bias control variable threshold CMOS [5]. Commercial signal processors use such techniques for leakage reduction [6].

FIGURE 29.1 Leakage current components.

FIGURE 29.2 Power dissipation trends in TI DSPs (data reproduced from [1]).

### 29.3 Low-Power Design in Programmable DSPs

Programmable, general-purpose DSPs have experienced substantial reduction in power dissipation over the last 15–20 years. Figure 29.2 (data reproduced from [1]) shows an exponential reduction in power per million multiply-accumulate operations per second (MMACS) for a family of Texas Instruments’ (TI) DSPs (TMS320). In this section, we examine several design trends that have contributed to increased power efficiency.

#### Voltage Scaling

As shown in Fig. 29.2, the design supply voltage of programmable DSPs has been reduced substantially during the last 15–20 years. DSP performance is mostly driven by the sample data rate on which the processor operates as opposed to pure clock frequency, as is the case in the general-purpose microprocessor world. Adding multiple execution units in parallel to speed up DSP computational kernels with small code dependencies permits designers to reduce the required clock frequencies and in response reduce the supply voltage with important power benefits [7,8]. Voltage scaling may also be implemented without proportional performance degradation if the threshold voltages are scaled accordingly. In such case, techniques such as multiple-threshold CMOS (MTCMOS) are employed [6] to control leakage power. Voltage scaling has a dramatic effect on power efficiency due to the square law dependence on  $V_{DD}$  in Eq. (29.2).

#### Architectural Power Optimizations

Traditionally, programmable DSP chips have included support for frequently used DSP operations and addressing modes. Such operations include multiple parallel multiply-accumulate operations used to implement efficiently computation kernels such as FIR/IIR filters and linear transformation operations [9]. In the last few years, we have seen programmable DSPs that include native support for Vitterbi decoding [7]. The Vitterbi algorithm [10] is a computationally efficient maximum likelihood estimator for convolutional decoding used in cellular phone and modem applications. Programmable DSPs usually include hardware support for an Add Compare Select (ACS) operation used to eliminate the nonoptimal trellis paths during the decoding process [9]. The (TI) TMS320C54x architecture includes an explicit compare, select and store unit (CSSU), which decouples the path metric computation from the path selection process.

Maximum datapath efficiency and minimum control overhead has become of paramount importance in DSPs because of reduced power dissipation in addition to performance benefits [11]. Increased datapath parallelism can allow the DSP designer to reduce the clock frequency and power supply for

additional power benefits. Efficient hardwired instructions can reduce control overhead and minimize communication among functional units thus reducing switched capacitance in Eq. (29.2).

General-purpose DSPs typically include instructions that place them in multiple levels of standby modes [6]. As an example, a DSP processor can be in full operational mode, in level 2 standby mode (computational units powered down, peripheral circuits and PLL on), in level 1 standby mode (only PLL on) or in sleep mode (everything including PLL is powered down except for a small sleep circuit capable of ramping up the PLL and powering on the rest of the units). Digital PLL designs help in the implementation of multiple idle states because they facilitate fast PLL frequency ramping sequences and fast switching between various standby modes. Depending on the application, such software-induced standby modes can provide substantial power savings.

DSP algorithms usually involve the repetitive execution of a small set of instructions (kernel). Most programmable DSPs include hardware support for tight loops. A standard software loop implementation requires the maintenance and update of a loop index, a compare instruction, and a conditional branch to the beginning of the loop. The loop overhead can easily slow down a DSP kernel by a substantial factor. DSPs include hardware support for both single and multiple instruction loops (i.e., REPEAT instruction) [11]. A single instruction loop repeats a single instruction multiple times without maintaining a loop index and by fetching it only once from memory. A multiple instruction loop on the other hand must repeatedly fetch the instructions from memory each time the processor executes the loop. Hiraki et al. [12] have proposed an interesting low power optimization for multiple instruction loops that has wide applicability in programmable DSPs. A small decoded instruction buffer (DIB) is provided that stores decoded instructions during the first iteration into the loop. Subsequent iterations do not engage the instruction memory and decode unit, but fetch the decoded instructions from the DIB. Case studies have indicated 40% power savings when a DIB is implemented in a DSP for certain multimedia applications.

Recently, the Berkeley Pleiades project [13] has introduced a 1-V heterogeneous reconfigurable DSP targeted to wireless baseband processing. The architecture consists of multiple “satellite” arithmetic processors, on-chip FPGA sections, on-chip memory banks, address generators, and an embedded ARM core. All these heterogeneous units are interconnected with a hierarchical reconfigurable network. The ARM core is responsible for the online reconfiguration through a dedicated bus. According to the Pleiades computation model, the embedded microprocessor core executes the high-level control and spawns arithmetic-intensive DSP kernels to the satellites. The flow of control is returned to the ARM core when all the satellite operations have completed. Run-time reconfiguration makes such an architecture very power-efficient compared to conventional programmable DSPs. A Pleiades silicon implementation is reported to implement baseband wireless functions at 10–100 MOPS/mW.

## Circuit Power Optimizations

Most of the DSPs available in the market today include some form of fine-grain, clock-gating mechanism for power reduction. DSPs are very well suited for clock-gating because of the regular datapath structure and the small control structures (which typically cannot employ fine-grain gated clocks). A typical datapath pipeline stage employing clock-gating is shown in Fig. 29.3. Signals EN0 and EN1 are the stage clock enables that are latched 180° ahead of time and computed by the control section. A master clock is distributed to the gating clock drivers, which are typically amortized across the entire datapath width of the pipeline. Clock-gating not only saves clock and flip-flop power, but also prevents the combinational logic between pipeline stages from switching. The main down side of clock-gating is that it can present some difficulties in static timing closure because of increased uncertainty during the calculation of setup and hold time constraints. Clock-gating reduces the switching activity factor  $a$  in Eq. (29.2).

On-chip memory blocks (SRAMs and ROMs) are typically optimized for low power: Memory blocks are partitioned in multiple banks so that a small fraction of the total memory array is activated during a memory access [6,8]. Moreover, address bits are typically allocated in such a fashion among row decoders and column decoders such that sequential memory accesses do not activate the row decoders during each cycle [8].

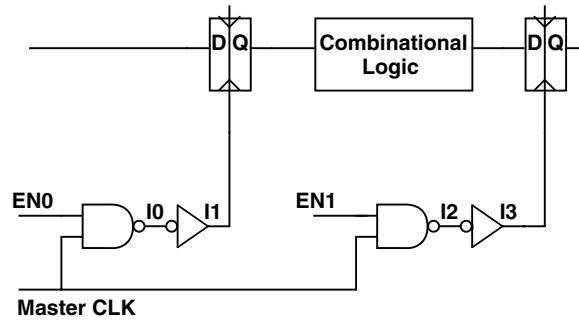

FIGURE 29.3 Clock-gating.

FIGURE 29.4 Adaptive supply voltage schemes.

## 29.4 Low-Power Design in Application-Specific DSPs

Low-power design approaches in application-specific DSPs exhibit more breadth and innovation due to the fact that such designs target a well defined problem as opposed to a wide range of possible applications. Classification of such design techniques can by no means be complete due to continuous novelties in circuit and system designs improving DSP system power performance. In this section, technology and low-level circuit issues are not addressed because they were briefly addressed earlier and are also relevant to general-purpose DSP systems. Instead, the focus is on unique application-specific power reduction techniques that have been reported in the literature during the last few years.

### Variable Supply Voltage Schemes

Embedded adaptive supply scaling has been the focus of multiple investigators due to the potential for substantial power savings in both fixed and variable throughput systems.

Nielsen et al. [14] have demonstrated a self-timed adaptive supply voltage system that takes advantage of variable computational loads (Fig. 29.4(a)). The self-timed system operates in a synchronous environment and is enclosed between rate-matching FIFO buffers. The state detecting circuit monitors the state of the input FIFO, which is an indicator of remaining workload. If the buffer is relatively full, the supply voltage is increased and the circuit operates faster to keep up with the load. If the FIFO is relatively empty the supply voltage is reduced because the circuit operates too fast. In this way, the supply voltage is optimally adjusted to the actual workloads maintaining the throughput requirements at all times. Wei and Horowitz [15] have investigated techniques for low-power switching supplies for similar applications.

Gutnik [16] has demonstrated a synchronous implementation of a variable supply voltage scheme that uses FIFO state to generate both a supply voltage and a corresponding variable clock using a closed-loop ring oscillator (Fig. 29.4(b)). As the FIFO fills up the clock speed increases to sustain the higher workload and as the FIFO empties the clock slows and the supply voltage decreases for quadratic power reduction.

Power savings are higher than simple clock gating mechanisms due to the square law dependence of power dissipation on supply voltage. Buffering and workload averaging makes this scheme applicable to fixed throughput but variable algorithmic load applications (i.e., video compression/decompression and digital communication applications).

Goodman and Dancy [17] have demonstrated a low power encryption processor with an embedded high-efficiency DC-DC converter that takes advantage of the time-varying data rates found in wireless encryption applications. Power reduction varying from 1× up to 5.33× has been reported depending on data throughput variations.

## Nonstandard Arithmetic Structures

Fixed-function DSP VLSI implementations (i.e., digital filters with constant coefficients, frequency domain data transformations such as FFT and DCT) can benefit a lot from hardwired arithmetic structures, different from standard multipliers and adders. One such important structure is the distributed arithmetic (DA) implementation, which has found many applications in past chips [18,19].

DA [20,21] is a bit-serial operation that computes the inner product of two vectors (one of which is a constant) in parallel. In the DSP domain, this operation finds applications in FIR computations, linear transform computation, and any other DSP kernel which involves dot products. Its main advantage is the efficiency of mechanization and the fact that no multiplications are necessary. DA has an inherent bit serial nature but this additional latency can be hidden if the number of bits in each variable vector element is equal or similar to the number of elements in each vector. In other words, DA is very efficient in computing long dot products of relatively low precision numbers.

As an example of DA mechanization let us consider the computation of the following inner product of  $M$ -dimensional vectors  $\mathbf{a}$  and  $\mathbf{x}$  where  $\mathbf{a}$  is a constant vector:

$$y = \sum_{k=0}^{M-1} a_k x_k \quad (29.4)$$

Let us further assume that each vector element  $x_k$  is an  $N$ -bit 2's complement binary number and can be represented as

$$x_k = -b_{k(N-1)}2^{N-1} + \sum_{n=0}^{N-2} b_{kn}2^n \quad (29.5)$$

where  $b_{ki} \in \{0, 1\}$  is the  $i$ th bit of vector element  $x_k$ . Note that  $b_{k0}$  is the least significant bit (LSB) of  $x_k$  and  $b_{k(N-1)}$  is the sign bit.

Substituting Eq. (29.5) in Eq. (29.4) yields (after interchanging the double summation order):

$$y = -\sum_{k=0}^{M-1} a_k b_{k(N-1)}2^{N-1} + \sum_{n=0}^{N-2} \left[ \sum_{k=0}^{M-1} a_k b_{kn} \right] 2^n \quad (29.6)$$

Let us consider the term in brackets:

$$q_n = \sum_{k=0}^{M-1} a_k b_{kn} \quad (29.7)$$

Because  $b_{kn} \in \{0, 1\}$ ,  $q_n$  has only  $2^M$  possible values. Such values can be precomputed and stored in a ROM of size  $2^M$ . The bit serial input data ( $\{b_{0p}, b_{1p}, \dots, b_{kp}\}$  for  $i = 0, 1, \dots, N-1$ ) is used to form the ROM address, and the ROM contents can be successively added in an accumulation structure to form the outer sum of Eq. (29.6). Successive scalings with powers of 2 can be achieved with an arithmetic shifter in the accumulator feedback path. Some additional control circuit is necessary to ensure that the partial sum is subtracted as opposed to being added to the total at sign bit time (negative term in Eq. (29.6)).

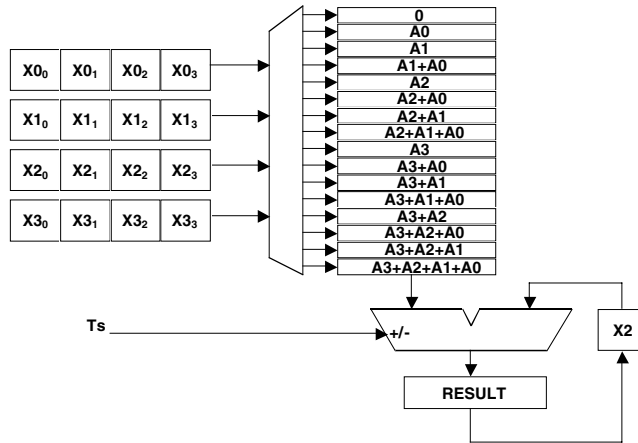

FIGURE 29.5 Distributed arithmetic ROM and accumulator (RAC) structure.

After  $N$  cycles (where  $N$  is the total bitwidth of the  $x_k$  vector elements) the final result  $y$  has converged to its final value in the accumulator.

Figure 29.5 shows a detailed example of a DA computation. The structure shown computes the dot product of a 4-element vector  $\mathbf{X}$  and a constant vector  $\mathbf{A}$ . All 16 possible linear combinations of the constant element vectors ( $\mathbf{A}_i$ ) are stored in a ROM. The variable vector  $\mathbf{X}$  is forming the ROM address, MSB-first. The figure assumes that the  $\mathbf{X}_i$  elements are 4-bit 2's complement integers (bit 3 is the sign bit.) Every clock cycle, the RESULT register adds  $2\times$  its previous value to the currently addressed ROM contents. In addition, the 4-shift registers that hold the variable vector  $\mathbf{X}$  are shifted to the right. The sign timing pulse  $T_s$  is activated when the ROM is addressed by the sign bit (bit 3) of the vector elements. In this case, the accumulator subtracts the addressed ROM contents to implement the first negative term of Eq. (29.6). After four cycles, the dot product has been produced within the RESULT register.

The power advantages of DA versus multiply-accumulate can be summarized as follows:

1. ROM accesses can be more energy efficient than multiplications.
2. A ROM and accumulator (RAC) structure can be much more area efficient than a multiplier and accumulator (MAC) structure. In such case, wires tend to be shorter and less capacitive.
3. If the number of elements in the vectors forming the dot product is greater than the bit precision of the variable vector, then DA structure can be clocked slower than the sample rate and take advantage of voltage scaling techniques. Essentially, such a configuration is an interesting form of parallelism.
4. A DA RAC structure is an ideal arithmetic unit for approximate processing (trading off power dissipation vs. output quality). This property will be expanded upon in the subsection on "Power vs. Quality and Precision Trade-offs."

## Algorithmic/Architectural Exploitation of Data Distribution Properties

Fixed-function DSP systems typically operate on data streams that exhibit common distribution properties. Some examples are:

1. Data streams related to human aural and visual perception (uncompressed audio and video samples): Such streams typically exhibit large spatial and temporal correlation and reduced dynamic range.
2. Data streams of compressed video or image data in the frequency domain: Typically, such streams contain large numbers of zero-valued coefficients indicating the lack of high spatial frequencies in natural images.

A priori knowledge of data stream distribution can be exploited at the algorithmic and architectural level for computation minimization and power reduction.

Nielsen and Sparso [22] observed that 16-bit sampled speech data samples exhibit significant correlation, in addition to a predominance of small signal values. As a result, they have proposed a sliced datapath for a digital hearing aid filter bank to exploit the small magnitude of the input samples. The arithmetic datapath has been partitioned in an MSB and an LSB slice. The MSB slice is only engaged when the input bitwidth requires it. Activation of the slices is performed by using special data tags that indicate the presence of sign extension bits in the MSB input slice. Additional circuit overhead is required for the computation and update of the tags. Dynamic bitwidth adaptation is coarse and can only be performed on a slice basis. This scheme results in data-dependent power reduction and processing time.

Xanthopoulos [23] has demonstrated a DA-based discrete cosine transform (DCT) [24] architecture that exploits correlation in the incoming image or video samples for computation minimization and power reduction. DCT is a frequency domain data transform widely used in video and still image compression standards such as MPEG [25] and JPEG [26]. The 8-point one-dimensional DCT transform is defined as follows:

$$X[u] = \frac{c[u]}{2} \sum_{i=0}^7 x[i] \cos\left(\frac{(2i+1)u\pi}{16}\right) \quad (29.8)$$

where  $c[u] = 1/\sqrt{2}$  if  $u = 0$  and 1 otherwise.

Image pixels are locally well correlated and exhibit a certain number of common most significant bits. These bits constitute a common-mode DC offset that only affects the computation of the DC DCT coefficient ( $X[0]$  in Eq. (29.8)) and is irrelevant for the computation of the higher spectral (AC) coefficients ( $X[1]\dots X[7]$  in Eq. (29.8)). The DCT chip in [23] includes adaptive-bitwidth DA computation units that reject common most significant bits for all AC coefficient computations resulting in arithmetic operations with reduced bitwidth operands, thus reducing switching activity. The bit-serial nature of the DA operation allows very fine grain (1-bit) adaptation to the input dynamic range as opposed to the coarse slice-level adaptation in [22].

An interesting algorithmic adaptation to data distribution properties has been demonstrated in [27]. The chip computes the inverse discrete cosine transform (IDCT) and is targeted to MPEG-compressed video data. The 8-point, one-dimensional IDCT is defined as follows:

$$x[i] = \sum_{u=0}^7 \frac{c[u]}{2} X[u] \cos\left(\frac{(2i+1)u\pi}{16}\right) \quad (29.9)$$

where  $c[u] = 1/\sqrt{2}$  if  $u = 0$  and 1 otherwise.

Numerous fast IDCT algorithms can minimize the number of multiplications and additions implied by Eq. (29.9) [28,29]. Yet, the statistical distribution of the input DCT coefficients possesses unique properties that can affect IDCT algorithmic design. Typically, 64-coefficient DCT blocks of MPEG-compressed video sequences have only 5–6 nonzero coefficients, mainly located in the low spatial frequency positions due to the low pass characteristics of frame sequences [27]. The histogram of Fig. 29.6 shows the frequency of 64-coefficient block occurrence plotted versus the number of nonzero coefficient content for a typical MPEG sequence. The mode of such distributions is invariably blocks with a single nonzero spectral coefficient (typically the DC).

Given such input data statistics, we observe that direct application of Eq. (29.9) will result in a small average number of operations since multiplication and accumulation with a zero-valued coefficient  $X[k]$  constitutes a NOP [30]. The chip in [27] uses such a direct coefficient-by-coefficient algorithm coupled with extensive clock-gating techniques to implement the implied NOPs. IDCT computation power of 4.5 mW for MPEG-2 sample rates has been reported.

FIGURE 29.6 Histogram of Nonzero DCT coefficients in sample MPEG stream.

### Power vs. Quality and Precision Trade-offs

In many DSP applications, lower quality in visual or audio output can be tolerated for reduced power dissipation. Recently, a number of researchers have resorted to approximate processing as a method for reducing average system power. Ludwig et al. [31] have demonstrated an approximate filtering technique, which dynamically reduces the filter order based on the input data characteristics. More specifically, the number of taps of a frequency-selective FIR filter is dynamically varied based on the estimated stopband energy of the input signal. The resulting stopband energy of the output signal is always kept under a predefined threshold. This technique results in power savings of a factor of 6 for speech inputs. Nikol et al. [32] have demonstrated an adaptive scheme for dynamically reducing the input amplitude of a Booth-encoded multiplier to the lowest acceptable precision level in an adaptive digital equalizer. Their scheme simply involves an arithmetic shift (multiplication/division by a power of 2) of the multiplier input depending on the value of the error at the equalizer output. They report power savings of 20%.

When the DA operation is performed MSB first (“Variable Supply Voltage Schemes” subsection), it exhibits stochastically monotonic successive approximation properties. In other words, each successive intermediate value is closer to the final value in a stochastic sense. An analytical derivation is presented in [33]. As an example, let us assume that we have a DA structure computing the dot product of two vectors. Each vector element is 8-bits 2’s complement integer. If we clock the DA structure of Fig. 29.5 for eight full cycles, the full precision value of the dot product will form into the RESULT register. If instead we clock the DA structure for four cycles and perform a 4-bit arithmetic left shift of the output in the RESULT register (multiplication by  $2^4$ ), we obtain an approximation of the actual dot product. If we clock the structure once more (total of five cycles) and then perform a 3-bit arithmetic left shift of the output (multiplication by  $2^3$ ), we obtain a better approximation. In this way, a DA structure can implement a fine-grain trade-off between power and precision.

Xanthopoulos [23] is extensively using this property for power reduction in a DCT application. In image and video compression applications not all spectral coefficients have the same visual significance. Typically, a large number of high spatial frequencies are quantized to zero in a lossy image/video compression environment (i.e., JPEG and MPEG) with no significant change in visual quality. The DCT processor in [23] exploits such different precision requirements on a coefficient basis by reducing the number of iterations of the DA units that compute the visually insignificant spectral coefficients in a user-programmable fashion. Figure 29.7 plots average power chip dissipation vs. compressed image quality in terms of the image peak SNR (PSNR), a widely used quality measure in image processing. The data points in the graph have been obtained by chip power measurements at different RAC maximum iteration settings. The data implies that the chip can produce on average 10 additional decibels of image quality per milliwatt of power dissipation. Figure 29.8 displays the actual compressed images for three (power, PSNR) data points of Fig. 29.7 for visual appreciation.

FIGURE 29.7 DCT Chip [my DCT] average power vs. compressed image quality.

FIGURE 29.8 Compressed image quality and power.

Amirtharajah et al. [34,36] use a similar DA-based approximate processing technique in a programmable ultra-low-power DSP targeted to physiological monitoring. Reduced RAC iterations reduce the signal to noise ratio of the input signal (effectively increasing the quantization noise) and result in less reliable heart beat detection. Yet, the reduced performance results in linear power savings, which may be desirable in certain situations.

## 29.5 Conclusion

This chapter has presented a collection of power reduction techniques that applied in DSP applications during the last few years. Although presented in a categorized form to provide structure in the exposition, the author does not believe that true low-power design involves a laundry list of power reduction techniques and blind application to the problem in question. Instead, low-power design involves a vertical design process and a global optimization across algorithmic, architectural, circuit, and physical design boundaries. A designer must have a deep understanding of the DSP application under power optimization. The best algorithm must be selected, which minimizes a weighted average of the number of arithmetic operations, memory accesses, on-chip communication, and silicon area. The right boundary must be achieved between programmability and predefined functionality. Architectural, circuit, and physical design techniques must then be applied that fully support the algorithmic selection but at the same time should be allowed to influence such selection in order to achieve optimum results.

The author concludes by enumerating a few case studies, which demonstrate concurrent optimization across all design phases and as a result have achieved impressive results in a few key DSP application areas. Chandrakasan et al. [35] have demonstrated a low-power chipset for a portable multimedia terminal. This work was power optimized from a system perspective and performed a number of functions such as protocol conversion, synchronization, and video decompression, among others, while consuming under 5 mW of power. Amirtharajah [36] has demonstrated an ultra-low-power programmable DSP for physiological monitoring (heartbeat detection and classification). His techniques involved algorithmic design,

a balanced hybrid architecture containing both customized and programmable units, and appropriate circuits supporting such architectural choices. The DSP consumes 220 nW at 1 V, 1.2 kHz and includes embedded support for harvesting energy from ambient sources. Simon [37] has demonstrated a low-power single chip video encoder with embedded dynamic memory. The compression is performed using wavelet filtering and a combination of zero-tree and arithmetic coding of filter coefficients. Hooks for motion estimation are also provided. The chip dissipates on the order of 0.5 mW while compressing an 8-bit gray scale 30 frames/sec,  $128 \times 128$  video stream. Goodman [38] built a programmable reconfigurable public key processor that demonstrated 2–3 orders of magnitude of power reduction compared to software and programmable-logic based implementations while providing similar flexibility and freedom in algorithm selection. Finally, Mosch et al. [39] have demonstrated a DSP for a hearing aid chipset featuring 77 MOPS/mW. Algorithmic and architectural optimizations were heavily employed to achieve such a result.

### 30.1 Architecture

---

The set of layers and the corresponding set of protocols are called the architecture of a network. In designing a layered architecture there are problems that must be solved in several layers. These problems include addressing and connection establishment, connection termination, nature of channel (e.g., full or half-duplex), error control and sequencing, flow control, and multiplexing.

#### OSI Reference Model

Open Systems Interconnect (OSI) Reference Model consists of seven layers: physical, data link, network, transport, session, presentation, and application.

The physical layer is responsible for transmitting bits over a communication channel.

The data link layer is responsible for providing an error-free line to the higher layers. It provides error and sequence checking, and implements a system of time-outs and acknowledgements that enables a transmitter to determine which frames need to be retransmitted due to error or drop out. In addition, flow control is provided in data link layer.

The network layer provides routing and congestion control services to higher layers. The network accounting function is obtained in this layer.

The transport layer accepts data in message form from the session layer above it, breaks it into smaller pieces, usually called packets, and passes the packets to the network layer. It must then ensure that the packets arrive correctly at the destination host. The transport layer is an end-to-end protocol, as opposed to layers below it, which are chained. The transport layer may multiplex several sessions over a single network connection, or it may utilize several connections to provide a high data rate for a session that requires it. The transport layer may provide either virtual circuit or datagram service to the session layer. In a virtual circuit, messages are delivered in the order in which they were sent, while in a datagram service there is no guarantee concerning order of delivery. The transport layer also has the responsibility

for establishing and terminating connections between hosts across the network and for providing host-to-host flow control.

The session layer is responsible for establishing and managing connections between two processes. Session establishment typically requires authentication, billing authorization, and agreement on a set of parameters that will be in effect for the session. The session layer is also responsible for recovery from a transport failure and for providing virtual circuit service if the transport layer does not do so.

The presentation layer performs services that are commonly requested by users, such as text compression, code conversion, file formatting, and encryption.

The application layer contains routines specific to a particular application.

## **Networks**

### **LAN**

Local area network (LAN) is a privately owned network of up to a few kilometers in size. LANs are used to connect computers, workstations, and file servers, and attach printers and other devices. The restricted size of LANs allows for prediction of transmission time, and simplifies network management. Traditional LANs run at speeds of 10–100 Mbps and have low delay of tens of milliseconds.

Broadcast topologies include bus and ring. In a bus network, at any instant one machine is the master and is allowed to transmit. At the same time, all other machines are required to refrain from sending. IEEE 802.3, which is the Ethernet, is a bus-based broadcast network with decentralized control operating at 10 or 100 Mbps. Computers on an Ethernet can transmit at any time. If two or more packets collide, each computer waits for a random time and tries again later.

In a ring network, each bit propagates around on its own, not waiting for the rest of the packet to which it belongs. IEEE 802.5, which is the IBM token ring, is a ring-based LAN operating at 4 and 16 Mbps.

### **WAN**

Wide area network (WAN) covers a large area, a country or a continent. The hosts in WAN are used to run application programs and are connected by a communication subnet, which consists of transmission lines and switching elements. A switching element, also called router, is used to forward packets to their destinations.

### **Cellular Network**

The most widely employed wireless network topology is the cellular network. This network architecture is used in cellular telephone networks, personal communication networks, mobile data networks, and wireless local area networks (WLAN). In this network configuration, a service area, usually over a wide geographic area, is partitioned into smaller areas called cells. Each cell, in effect, is a centralized network, with a base station (BS) controlling all the communications to and from each mobile user in the cell. Each cell is assigned a group of discrete channels from the available frequency spectrum (usually radio frequency). These channels are in turn assigned to each mobile user, when needed.

Typically, BSs are connected to their switching networks using landlines through switches. The BS is the termination point of the user-to-network interface of a wireless cellular network. In addition, the BS also provides call setups, cell handoffs and various network management tasks, depending on the type of network.

## **TCP/IP Protocol**

Transmission control protocol/Internet protocol (TCP/IP) suite is used in the network and transport layers. TCP/IP is a set of protocols allowing computers to share resources across the network. Although the protocol family is referred to as TCP/IP, user datagram protocol (UDP) is also a member of this protocol suite.

TCP/IP protocol suite used as network and transport layers has the following advantages:

1. It is not vendor-specific.
2. It has been implemented on most systems from personal computers to the largest supercomputers.
3. It is used for both LANs and WANs.

Using TCP/IP also makes the network system portable, and program portability is one of the system design goals.

The network layer uses Internet protocol (IP). IP is responsible for routing individual datagrams and getting datagrams to their destination. The IP layer provides a connectionless and unreliable delivery system. It is connectionless because it considers each IP datagram independent of all others and any association between datagrams must be provided by the upper layers. Every IP datagram contains the source address and the destination address so that each datagram can be delivered and routed independently. The IP layer is unreliable because it does not guarantee that IP datagrams ever get delivered or that they are delivered correctly. Reliability must be provided by the upper layers.

Transport layer uses UDP and transmission control protocol (TCP). TCP is a connection-oriented protocol that provides a reliable, full-duplex, byte stream for the multimedia communication process. TCP is responsible for breaking up the message into datagrams, reassembling them at the other end, resending anything that got lost, and putting everything back in the right order. TCP handles the establishment and termination of connections between processes, the sequencing of data that might be received out of order, the end-to-end reliability (checksums, positive acknowledgments, timeouts), and the end-to-end flow control.

UDP is a connectionless protocol for user processes. Unlike TCP, which is a reliable protocol, there is no guarantee that UDP datagrams ever reach their intended destination. UDP is less reliable than TCP but transfers data faster because they are not held up by earlier messages awaiting retransmission. TCP protocol is used for file transfer that requires reliable, sequenced delivery, where real-time delivery may not be of utmost importance.

## Mobile IP Protocols

In TCP/IP an application is connected with another application through a router. Each host in Internet has a unique address. An IP address is a 32-bit binary number that can also be used in a dotted notation. IP addresses contain two parts: network address which identifies the network to which the host is attached, and local address which identifies the host. Local address can be separated into two parts, subnet address and local address.

The hierarchical address makes routing simple. A host that wants to send packets to another host only needs to send packets to the network to which the target host is attached. The host does not need to know the inside of the network; however, a computer's IP address cannot be changed during connection and communication. If the user wants to move the computer to the other area while using it, this will be difficult because the physical IP address of the computer must be changed in a different subnet. To solve this problem, a number of protocols have been proposed: virtual IP (VIP), loose source routing IP (LSRIP), and Internet engineering task force mobile IP (IETF-MIP).

### VIP

VIP uses two, 32-bit IP-style addresses to identify mobile hosts: one is named virtual IP (VIP) address, the other is named temporary IP (TIP) address. VIP address is the IP address that mobile hosts get from their home network. Mobile hosts always use VIP as their source address inside IP packet. When mobile hosts move to another network, they get another IP address from the foreign network, it is a TIP address. Each VIP packet contains information to combine VIP and TIP, so the packet target to VIP can be routed through general Internet to its temporary network by reading its TIP. VIP uses additional space inside packet to carry this information: a new IP option to identify VIP while original address fields carry TIP.

When a mobile host moves to a foreign network, the information about mobile host's current location is sent to the mobile host's home network. During the transmission, each intermediate router that supports VIP protocol can receive this information and update this router's cache. This cache is a database that stores information about mobile hosts' current location.

If a host wants to send a packet to a mobile host, it only knows the VIP address of the mobile host and does not know its TIP, which is its current location. The packet will be sent to the mobile host's home area. If any intermediate router that supports VIP receives this packet, it will modify this packet

according to its cache so that the new packet will include information of TIP and can be routed to the mobile host's current location. If the packet does not reach any intermediate router that supports VIP and has cache information about the mobile host, the packet will be routed to mobile host's home network. The gateway in mobile host's home network can modify this packet according to this gateway's cache and route the packet to the mobile host's current network. This gateway always has the mobile host's current location, because each time when the mobile host moves to a new network, the mobile host notifies its home network about the mobile host's current location. The optimized path in VIP is mainly based on the number of intermediate VIP routers. If many intermediate routers support VIP, the optimized routing path should be obtained. The option VIP uses to carry information of VIP is an option of IP, and not all of the routers will support this option. Some computers even discard all of the options IP packets carry. VIP also needs many extra IP addresses for foreign network to assign to the mobile hosts.

## **LSRIP**

Loose source routing IP uses one of the IP options to cause the IP packets to be routed through a series of intermediate routers to the destination. This IP option is loose source and record route (LSRR). For example, if host A wants to send a packet to host C with LSRR option, the packet can reach host B through general IP routing. Then host B replaces the destination IP address in IP header with the first IP address C in LSRR option and routes the packet to a new destination C. Also host B puts the pointer to the second IP address in LSRR option. Host C can perform the same procedure: replace destination IP address with next IP address in LSRR option, increase pointer to next IP address in LSRR option, and reroute the packet to a new destination. Until the pointer points to the last IP address in LSRR option, the packet is sent to its destination address. LSRIP uses LSRR option to carry the information of a mobile host.

When a mobile host moves to a foreign network, the information about the mobile host's current location is sent to the mobile host's home network. During the transmission, each intermediate router that supports LSRIP protocol can receive this information and update this router's cache.

If a host wants to send a packet to a mobile host, which is not at its home area, the packet will be first sent to the mobile host's home network. During the path to the home network, if an intermediate router has the cache of the mobile host, this router can put the LSRIP option into the packet and cause it to be routed to the current network of the mobile host. The gateway of current network reads information from LSRIP option and can determine that the mobile host is the destination of this packet's destination. Thus, the gateway can route the packet to mobile host that is connected to current network.

If the packet does not reach any intermediate router that supports LSRIP and has cache information about the mobile host, the packet will be routed to mobile host's home network. The gateway in mobile host's home network can add the LSRIP option to this packet according to the gateway's cache and route the packet to the mobile host's current network. This gateway always has the mobile host's current location because each time when the mobile host moves to a new network, the mobile host notifies its home network about the mobile host's current location.

LSRIP needs more intermediate routers to achieve optimized routing path. Also, the option used by LSRIP is not compatible with current routers. This can be tested by sending a packet using traceroute, a tool to check the path one packet has passed. Traceroute uses LSRR option to record the path of the packet and the transmission time to each intermediate host. If any intermediate host does not support LSRR option, traceroute bypasses this host. After sending a packet, it can be found from the messages sent back that some sites are not displayed correctly, which means that these sites do not support LSRR option.

## **IETF-MIP**

IETF-MIP is the most usable protocol for mobile IP in the Internet. The basic idea is to use two agents to handle the job related to the mobile host. When the mobile host moves to the other networks, it will notify foreign network's agent, foreign agent, and its home agent about its current location. Then when the packet to mobile host is sent to home agent using general IP, the home agent will modify the header of IP packet: change the destination address to foreign agent's address and add some fields to the packet including the mobile host's permanent address. When the foreign agent receives this packet, it will know

this is for one mobile host which is now at its location, the foreign agent will modify this packet again and send it directly to the mobile host through the local network. In IETF-MIP, there are cache agents to optimize the performance. A cache agent is a host that can maintain a database that stores the mobile hosts current location. This database can be changed according to the location change of the mobile host.

In this protocol it is difficult to achieve the optimized routing path, especially in a WAN. For example, a user in London wants to send a packet to a mobile host in London, whose home network is in New York. This packet will be first sent to New York, then modified by the home agent, and then sent back. This takes about one half of the circle of the whole earth. The optimized path can only be about 100 ft. Thus, the only solution for IETF-MIP is to set up as many cache agents as possible in the entire Internet. When the cache agents receive a packet, they can modify the packet instead of sending it to the home agent of the mobile host.

Mobile IP should be compatible with current IPs, that means the current protocols and applications do not need to be changed. Mobile IP also needs to have optimized routing path, that means the protocol should be efficient in routing packets. VIP and LSRIP use the option of IP to carry the information of mobile hosts. But some of the current hosts do not support an IP option. When these hosts receive a packet that includes options, they discard the options of the IP packet. Meanwhile, IETF-MIP only uses basic IP header and packet, and does not use any IP option. From the compatibility point, IETF-MIP is the best out of those three protocols. From the point of optimized routing path, all three protocols depend on intermediate cache hosts. If enough intermediate cache hosts are inside the Internet, the three protocols can find optimized routing path. The IETF-MIP is the best out of the three mobile IPs considering both the compatibility and optimized routing path. IETF-MIP is also the mobile IP protocol that is used in the Internet.

## 30.2 Technology

---

### Broadband Networks

Broadband integrated services digital network (B-ISDN) based on asynchronous transfer mode (ATM) is used for transport of information from multimedia services and applications.

#### ATM

ATM is a cell-based, high-bandwidth, low-delay switching and multiplexing technology that is designed to deliver a variety of high-speed digital communication services. These services include LAN interconnection, imaging, and multimedia applications as well as video distribution, video telephony, and other video applications.

ATM standards define a fixed-size cell with a length of 53 bytes comprised of a 5-byte header and a 48-byte payload.

The virtual path identifiers (VPIs) and virtual channel identifiers (VCIs) are the labels to identify a particular virtual path (VP) and virtual channel (VC) on the link. The switching node uses these values to identify a particular connection and then uses the routing table established at connection set-up to route the cells to the appropriate output port. The switch changes the value of the VPI and VCI fields to the new values that are used on the output link.

#### SONET

Synchronous optical network (SONET) is used for framing and synchronization at the physical layer. The basic time unit of a SONET frame is 125  $\mu$ s. The basic building block of SONET is synchronous transport signal level 1 (STS-1) with a bit rate of 51.84 Mbps. Higher-rate SONET signals are obtained by byte-interleaving  $n$  frame-aligned STS-1s to form an STS- $n$  (e.g., STS-3 has a bit rate of 155.52 Mbps).

Due to physical layer framing overhead, the transfer capacity at the user-network interface (UNI) is 155.52 Mbps with a cell-fill capacity of 149.76 Mbps. Because the ATM cell has 5 bytes of overhead, the 48 bytes information field allows for a maximum of 135.631 Mbps of actual user information. A second

UNI interface is defined at 622.08 Mbps with the service bit rate of approximately 600 Mbps. Access at these rates requires a fiber-based loop.

### **ATM Services**

Users request services from the ATM switch in terms of destination(s), traffic type(s), bit rate(s), and Quality of Service (QoS). These requirements are usually grouped together and categorized in different ATM traffic classifications. The ATM services are categorized as follows:

- *Constant Bit Rate (CBR)*: Connection-oriented constant bit rate service such as digital voice and video traffic.
- *Real-Time Variable Bit Rate (rt-VBR)*: Intended for real-time traffic from bursty sources such as compressed voice or video transmission.
- *Non-Real-Time Variable Bit Rate (nrt-VBR)*: Intended for applications that have bursty traffic but do not require tight delay guarantee. This type of service is appropriate for connectionless data traffic.
- *Available Bit Rate (ABR)*: Intended for sources that accept time-varying available bandwidth. Users are only guaranteed a minimum cell rate (MCR). An example of such traffic is LAN emulation traffic.
- *Unspecified Bit Rate (UBR)*: Best effort service that is intended for noncritical applications. It does not provide traffic related service guarantees.

ATM networks are fixed (optical) point-to-point networks with high bandwidth and low error rates. These attributes are not associated with the limited bandwidth and error prone radio medium. While increasing the number of cables (copper or fiber optics) can increase the bandwidth of wired networks, wireless telecommunications networks experience a more difficult task. Due to limited usable radio frequency, a wireless channel is an expensive resource in terms of bandwidth. In order for wireless networks to support high-speed networks such as ATM, a multiple access approach is needed for sharing this limited medium in a manner different from the narrowband, along with the means of supporting mobility and maintaining QoS guarantees.

### **Wireless Networks**

Media access control (MAC) is a set of rules that attempt to efficiently share a communication channel among independent competing users. Each MAC uses a different media (or multiple) access scheme to allocate the limited bandwidth among multiple users. Many multiple access protocols have been designed and analyzed both for wired and wireless networks. Each has its advantages and limitations based on the network environment and traffic. These schemes can be classified into three categories: fixed assignments, random access, and demand assignment. The demand assignment scheme is the most efficient access protocol for traffic of varying bit rate in the wireless environment.

Due to the limited radio frequencies available for wireless communication, wireless networks have to maximize the overall capacity attainable within a given set of frequency channel. Spectral efficiency describes the maximum number of calls that can be served in a given service area. To achieve high spectral efficiency, cellular networks are designed with frequency reuse. If a channel with a specific frequency covers an area of a radius  $R$ , the same frequency can be reused to cover another area. A service area is divided into seven cell clusters. Each cell in the cluster, designated 1 through 7, uses a different set of frequencies. The same set of frequencies in each cell can be reused in the same service area if it is sufficiently apart from the current cell. Cells using the same frequency channels are called cocells. In principle, by using this layout scheme, the overall system capacity can be increased as large as desired by reducing the cell size, while controlling power levels to avoid co-channel interference. Co-channel interference is defined as the interference experienced by users operating in different cells using the same frequency channel. Smaller size cells called microcells are implemented to cover areas about the size of a city block. Research has been done on an even smaller cells called picocells.

## **TDMA**

Time-division multiple access (TDMA) and frequency-division multiple access (FDMA) are fixed assignment techniques that incorporate permanent subchannels assignments to each user. These traditional schemes perform well with stream-type traffic, such as voice, but are inappropriate for integrated multimedia traffic because of the radio channel spectrum utilization. In a fixed assignment environment, a subchannel is wasted whenever the user has nothing to transmit. It is widely accepted that most services in the broadband environment are VBR service (bursty traffic). Such traffic wastes a lot of bandwidth in a fixed assignment scheme.

## **ALOHA**

Typical random assignment protocols like ALOHA and carrier sense multiple access with collision detection (CSMA/CD) schemes are more efficient in servicing bursty traffic. These techniques allocate the full channel capacity to a user for short periods, on a random basis. These packet-oriented techniques dynamically allocate the channel to a user on a per-packet basis.

Although a few versions of the ALOHA protocol are used, in its simplest form it allows the users to transmit at will. Whenever two or more user transmissions overlap, a collision occurs and users have to retransmit after a random delay. The ALOHA protocol is inherently unstable due to the random delay, i.e., it is possible that a transmission may be delayed for an infinite time. Various collision resolution algorithms were designed to stabilize and reduce contention in this scheme.

Slotted ALOHA is a simple modification of the ALOHA protocol. After a collision, instead of retransmitting at a random time, slotted ALOHA retransmits at a random time slot. Transmission can only be made at the beginning of a time slot. Obviously, this protocol is implemented in time slotted systems. Slotted ALOHA is proven to be twice as efficient as a regular or pure ALOHA protocol.

## **CSMA/CD**

CSMA/CD, taking advantage of the short propagation delays between users in a typical LAN, provides a very high throughput protocol. In a plain CSMA protocol, users will not transmit unless it senses that the transmission channel is idle. In CSMA/CD, the user also detects any collision that happens during a transmission. The combination provides a protocol that has high throughput and low delay; however, carrier sensing is a major problem for radio networks. The signal from the local transmitter will overload the receiver, disabling any attempts to sense remote transmission efficiently. Despite some advances in this area, sensing still poses a problem due to severe channel fading in indoor environments. Similarly, collision detection proves to be a difficult task in wireless networks. Although it can be easily done on a wired network by measuring the voltage level on a cable, sophisticated devices are required in wireless networks. Radio signals are dominated by the terminal's own signal over all other signals in the vicinity preventing any efficient collision detection. To avoid this situation, a terminal transmitting antenna pattern has to be different from its receiving pattern. This requires sophisticated directional antennas and expensive amplifiers for both the BS and the mobile station (MS). Such requirements are not feasible for the low-powered mobile terminal end.

## **CDMA**

Code-division multiple access (CDMA) is a combination of both fixed and random assignment. CDMA has many advantages such as near zero channel access delay, bandwidth efficiency, and excellent statistical multiplexing, but it suffers from significant limitations such as limited transmission rate, complex BS, and problems related to the power of its transmission signal. The limitation in transmission rate is a significant drawback to using CDMA for integrated wireless networks.

## **Demand Assignment**

In demand assignment protocol, channel capacity is assigned to users on demand basis, as needed. Demand assignment protocols typically involve two stages: a reservation stage where the user requests access, and a transmission stage where the actual data is transmitted. A small portion of the transmission

channel, called the reservation subchannel, is used solely for users requesting permission to transmit data. Short reservation packets are sent to request channel time by using some simple multiple access schemes, typically, TDMA or slotted ALOHA. Once channel time is reserved, data can be transmitted through the second subchannel contention-free. Unlike a random access protocol where collisions occur in the data transmission channel, in demand assignment protocols, collisions occur only in the small-capacity reservation subchannel.

This reservation technique allows demand assignment protocols to avoid bandwidth waste due to collisions. In addition, unlike fixed assignment schemes no channels are wasted whenever a VBR user enters an idle period. The assigned bandwidth will simply be allocated to another user requesting access. Due to these features, protocols based on demand assignment techniques are most suitable for integrated wireless networks.

Demand assignment protocols can be classified into two categories based on the control scheme of the reservation and transmission stages. They can be either centralized or distributed. An example of a centralized controlled technique in demand assignment is polling. Each user is sequentially queried by the BS for transmission privileges. This scheme, however, relies heavily on the reliability of the centralized controller.

An alternative approach is to use distributed control, where MSs transmit based on information received from all the other MSs. Network information is transmitted through broadcast channels. Every user listens for reservation packets and performs the same distributed scheduling algorithm based on the information provided by the MS in the network. Requests for reservation are typically made using contention or fixed assignment schemes.

## 30.3 Routing

---

### Routing in Terrestrial Networks

Routing refers to the determination of a set of paths to be used for carrying messages from a source node to all destination nodes. It is important that the routes used for such communications consume a minimal amount of resources. In order to use network resources as little as possible while meeting the network service requirements, the most popular solution involves the generation of a tree spanning the source and destination nodes.

Routing algorithms for constructing trees have been developed with two optimization goals in mind. Two measures of the tree quality are in terms of the tree delay and tree cost, and are defined as follows:

1. The first measure of efficiency is in terms of the cost of the tree, which is the sum of the costs on the edges in the tree.
2. The second measure is the minimum average path delay, which is the average of minimum path delays from the source to each of the destinations in the group.

Optimization objectives are to minimize the cost and delay, however, the two measures are individually insufficient to characterize a good routing tree. For example, when the optimization objective is only to minimize the total cost of the tree, a minimum cost tree is built. Although total cost as a measure of bandwidth efficiency is certainly an important parameter, it is not sufficient to characterize the quality of the tree, because networks, especially those supporting real-time traffic, need to provide certain QoS guarantees in terms of the end-to-end delay along the individual paths from source to destination node. Therefore, both cost and delay optimization goal are important for the routing tree construction. The performance of such a route is determined by two factors:

1. Bounded delay along the path from source to destination
2. Minimum cost of the tree, for example, in terms of network bandwidth utilization

The goal of the routing algorithm is to construct a delay constrained minimum cost tree. In order to provide a certain quality of service to guarantee end-to-end delay along the path from source to destination node, the algorithm sets the delay constraint on the path, instead of trying to minimize the average

path delay. The two measures of the tree quality, the tree edge delay and tree edge cost, can be described by different functions. For example, edge cost can be a measure of the amount of buffer space or channel bandwidth, and edge delay can be a combination of propagation, transmission, and queuing delay.

The shortest path algorithm can be used to generate the shortest paths from the source to destination nodes; this provides the optimal solution for delay optimization. Routing algorithms that perform cost optimization have been based on computing the minimum Steiner tree, which is known to be an NP-complete problem.

## **DDBMA**

A heuristic algorithm called DDBMA (Dynamic Delay Bounded Multicasting Algorithm) is used for constructing minimum-cost multicast trees with delay constraints. The algorithm sets variable delay bounds on destinations and can be used to handle the network cost optimization goal: minimizing the total cost (total bandwidth utilization) of the tree. The algorithm can also be used to handle a dynamic delay-bounded minimum Steiner tree, which is accomplished by updating the existing multicast tree when destinations need to be added or deleted.

During the network connection establishment, DDBMA can be used to construct a feasible tree for a given destination set. For certain applications, however, nodes in the network may join or leave the initial multicast group during the lifetime of the multicast connection. Examples of these applications such as teleconferencing, mobile communication, etc., allow each user in the network to join or leave the connection at any time without disrupting network services to other users.

The DDBMA is based on a feasible search optimization method, which starts with the minimum delay tree and monotonically decreases the cost by iterative improvement of the delay-bounded tree. Then the algorithm starts to update the existing tree when nodes in the network request to join or leave. The algorithm will stay steady when there is no leaving or joining requests from nodes in the network.

Multimedia, multiparty communication services are supported by networks having the capability to setup/modify the following five basic types of connections: point-to-point, point-to-multipoint (also called multicast), multipoint-to-point (also called concast), multipoint-to-multipoint, and point-to-allpoint (also called broadcast).

Many types of communication require transmission of certain information from the source to a selected set of destinations. This could be the cast of multipoint video conference, the distribution of a document to a selected number of persons via a computer network or the request for certain information from a distributed database.

## **Routing in Wireless Networks**

Wireless personal communication networks use a general routing procedure, a rerouting procedure, and a handoff. Along with the features of wireless communication, the user mobility control function tracking locations of networks subscribers should be associated with routing schemes during communication connection. In wireless communications networks the network topology is established by virtual paths. Virtual paths are logical direct radio links between all switch nodes. The bandwidth of virtual path can consist of a number of virtual channels. Because of the features of wireless communications networks, the network topology is highly dynamic. The bandwidth of wireless communications networks is limited, the traffic increases quickly, and it is hard to schedule incoming traffic on time in the centralized approaches, which are not efficient when network size increases and the network services are enhanced.

The subscribers in wireless communications networks roam. To create connections between all communication parties to deliver incoming and outgoing calls, the first consideration is the current location of mobile users and hosts. In wireless communications networks, the key service for providing seamless connectivity to mobile hosts is creation and maintenance of a message forwarding path between two known locations of calling and called mobile hosts. A routing decision in wireless communications networks is made not only using the states of paths and internal switching nodes, but also using the location of available information.

Geographical area covered by wireless communication networks is partitioned into a set of cells. A routing path may be inefficient while a mobile host hands off to another cell coverage area. The connection paths need to be reestablished each time to continue communication. As a result, the network call processor can become involved many times during the lifetime of mobile connection. When wireless communications networks move toward smaller size cells to accommodate more mobile hosts or to provide higher capacity, the handoff becomes a more frequent part of communications. Conventional routing procedures for connecting mobile hosts fail due to frequent handoff when the network call processor becomes a bottleneck. Hence, routing efficiency in wireless communications networks depends critically on the propagation of location information into the network; however, excessive information propagation can waste network resources, while insufficient location information leads to inefficient routing.

Wireless communications networks can provide different personal communications services, which have different transmission time delay requirements. For cellular telephone communication, the shortest time delay or strict time delay to transmit voice message is required. In portable computer communications or other data communications, the requirements of transmitted time delay are not very strict. Transmitted data can be stored in buffers and be transmitted later when channels are available; however, in order to provide a high QoS, transmission time delay is an important factor in wireless communications networks. Routing procedure in wireless communications networks should depend on different requirements of transmission time delay, and on how to balance transmission load and find minimum cost transmission paths.

## 30.4 Applications Support

---

### Multimedia

Multimedia communications is the field referring to the representation, storage, retrieval, and dissemination of machine-processable information expressed in multimedia, such as voice, image, text, graphics, and video. With high-capacity storage devices, powerful and yet economical computer workstations, and high-speed integrated services digital networks, providing a variety of multimedia communication services is becoming not only technically but also economically feasible. Multimedia conference systems can help people to interact with each other from their homes or offices while they work as teams by exchanging information in several media, such as voice, text, graphics, and video. Multimedia conference system allows a group of users to conduct a meeting in real time. The participants can jointly view and edit relevant multimedia information, including text, graphics, and still images distributed throughout the LAN. Participants can also communicate simultaneously by voice to discuss the information they are sharing. This multimedia conference system can be used in a wide variety of cooperative work environment, such as distributed software development, joint authoring, and group decision support.

Multimedia is the integration of information that may be represented by several media types, such as audio, video, text, and still images. The diversity of media involved in a multimedia communication system impose strong requirements on the communication system. The media used in the multimedia communications can be classified into two categories: discrete media and continuous media.

Discrete media are those media that have time-independent values, such as text, graphics, or numerical data, bit mapped images, geometric drawings, or any other non-time-dependent data format. Capture, storage, transmission, and display of non-real-time media data does not require that it happen at some predictable and fixed time or within some fixed time period.

Continuous media data may include sound clips, video segments, animation, or timed events. Real-time data requires that any system that is recording or displaying be able to process the appropriate data within a predictable and specified time period. In addition, the display of real-time data may need to be synchronized with other data or some external (real-world ) event.

Multimedia data can be accessed by the user either locally or remotely during multimedia communication. Locally stored data typically resides in conventional mass storage systems such as hard disk, CD-ROMs, optical disk, or high-density magnetic tape. It can also be stored to and recalled from analog devices that

are under the control of the system, video tape disks, videodisk players, CD-audio disks, image scanners, and printers. In addition, media data can be synthesized locally by the systems or its peripherals. Multimedia data is typically recorded and edited on local systems for distribution on some physical media and is later played back using local devices.

Remotely stored multimedia data is accessed via a network connection to a remote system. The data is stored on that remote server and recalled over the network for viewing, editing, or storage on the user's system.

Multimedia communications cover a large set of domains including office, electronic publishing, medicine, and industry. Multimedia communication can be classified into real-time applications and non-real-time applications.

Multimedia conferencing represents a typical real-time multimedia communication. In general, high conductivity is needed for real-time multimedia communications. A guaranteed bandwidth is required to ensure real-time consistency, and to offer the throughput required by the different media. This bandwidth varies depending on the media involved in the application. There is also a need for synchronization between different users, and between different flows of data at a user workstation.

Non-real-time multimedia communications, such as multimedia mail are less demanding than real-time applications in terms of throughput and delay, but edition tools, exchange formats, and exchange protocols are essential. Multicast service and synchronization at presentation time has to be offered.

Local non-real-time multimedia characterizes most typical personal computer applications, such as word processing, and still image editing. Typical text-based telecommunications can be described as remote non-real-time. Database of text and still image may be interactively viewed and searched, and audio or video data (perhaps included in mail messages) can be downloaded for display locally.

Multimedia workstations are generally characterized by local real-time applications. Data from video and audio editing and annotations, interactive animated presentations, and music recording are stored on local devices and are distributed on physical media for use locally.

Networks that can provide real-time multimedia communication via a high-speed network connection enable the new generation of multimedia applications. Real-time remote workstation-based multimedia conferencing, video and audio remote database browsing, and viewing of movies or other video resources on demand are typical for these systems.

## **Mobile and Wireless**

The support for bandwidth intensive (multimedia) services in mobile cellular networks increases the network congestion and requires the use of micro/picocellular architectures in order to provide higher capacity in regard to radio spectrum. Micro/pico cellular architectures introduce the problem of frequent hand-offs and make resource allocation difficult. As a result, availability of wireless network resources at the connection setup time does not necessarily guarantee that wireless resources are available throughout the lifetime of a connection. Multimedia traffic imposes the need to guarantee a predefined QoS to all calls serviced by the network.

In microcellular networks supporting multimedia traffic, the resource allocation schemes have to be designed such that a call can be assured a certain QoS once it is accepted into the network. The resource allocation for multimedia traffic becomes quite complex for different classes of traffic comprising multimedia traffic. These classes of traffic have different delay and error rate requirements. Resource allocation schemes must be sensitive to traffic characteristics and adapt to rapidly changing load conditions. From a service point of view, multimedia traffic can be categorized into two main categories: real-time traffic with stringent time delays and relaxed error rates, and non-real-time traffic with relaxed time delays and stringent error rates.

It is important to note that provisioning of QoS to different classes of traffic necessitates a highly reliable radio link between the mobile terminal and its access point. This requires efficient communication techniques to mitigate the problems of delay sensitivity, multipath fading, shadow fading, and cochannel interference. Some methods such as array antennas and optimal combining can be used to combat these problems.

## **CAC**

Schemes have been proposed to address the problem of resource allocation for multimedia traffic support in microcellular networks. In these schemes, real-time traffic being more delay sensitive, is given priority over non-real-time traffic.

In these schemes, the central approach used is call admission control (CAC). CAC imposes a limit on the number of calls accepted into the network. Each cell site only supports a predetermined number of call connections. This call threshold is periodically calculated depending on the number of existing calls in the cell in which the call arrives and its adjoining cells and the resources utilized by all calls in the cell. Once the threshold is reached, all subsequent requests for new call connections are refused.

## **AT**

In an admission threshold (AT)-based scheme, resource management is done by periodically calculating the admission threshold and by blocking all new call connection requests once the threshold is reached. The call admission decision is made in a distributed manner whereby each cell site makes a decision by exchanging state information with adjoining cells periodically. A cell with a base station and a control unit is referred to as cell site.

## **RS**

In a resource sharing (RS)-based scheme to support traffic classes with different delay and error requirements, resource sharing provides a mechanism to ensure a different grade of service to each class of traffic. This scheme employs a resource sharing mechanism that reacts to rapidly changing traffic conditions in a cell. An adaptive call admission control policy that reacts to changing new call arrival rates can be used to keep the handoff dropping rate and forced call termination rate acceptably low.

The call admission control scheme differentiates the new call on the basis of its traffic class and a decision is based on traffic class of the new call connection request and number of call connections of each class already being serviced in the cell cluster.

For real-time call connections, a new call is blocked if no bandwidth is available to service the request. A similar algorithm is used to service a handoff request. The QoS metrics for real time calls are handoff dropping probability and forced call termination probability. For non-real-time calls, the available bandwidth is shared equally among all non-real-time call connections in the cell. Handoff queuing or delaying is not used in this scheme. CAC keeps the probability of a call being terminated before its lifetime acceptably low. Resource sharing algorithms provide better performance for a particular class of traffic.

## **RRN**

Resource reservation and renegotiation (RRN) scheme provides QoS guarantee to real-time traffic and at the same time guarantees a better performance to non-real-time traffic. The resource allocation scheme uses resource reservation in surrounding cells for real-time calls and renegotiation of bandwidth assigned to non-real-time calls. The resource allocation scheme is simple enough and can be implemented in a distributed manner to ensure fast decision making.

In RRN scheme, for service applications requiring smaller bandwidths, a shared pool of bandwidth is used for reservation. For applications requiring greater bandwidth, the largest of requested bandwidth is reserved. This helps in keeping the call blocking rate low and does not affect the handoff dropping rate.

In microcellular networks, calls require handoffs at much faster rates in comparison to networks with larger cells. On the other hand, microcellular networks provide a higher system capacity. The RRN scheme supports real-time calls and non-real-time calls along with a variety of service type for each class. Real-time calls are delay sensitive and hence cannot be queued or delayed. Resources must be available when a handoff is requested. In order to guarantee that real-time calls are not forced to terminate at the time of handoff, a resource reservation mechanism is used. Resource reservation guarantees acceptably low handoff dropping rate and forced call termination rate for real-time traffic.

For a real-time call, bandwidth is reserved in all cells adjacent to the cell in which the call arrives. When a call hands-off to another cell, if enough bandwidth is not available to service the handoff, it uses

the bandwidth reserved in the target cell and thus the likelihood that a call will be dropped is reduced. When a call is successfully handed off to another cell, the bandwidth of old cell is released and reserved in the cell cluster of new cell.

Non-real-time calls are more tolerant to delay as compared to real-time calls. Delay tolerance is equivalent to accepting variable service rate. This property of data traffic makes resource renegotiation possible in microcellular networks. Non-real-time calls receive higher service rates under low traffic conditions while, under heavy traffic conditions, the service rate available to them is kept at a minimum. Thus, the resource renegotiation scheme adapts to changing traffic conditions in the network.

The speed of off-chip I/O circuits plays a significant role in the overall performance of a computer system. To keep up with the increasing clock rates in processors, designers target I/O data rates that are exceeding gigabits per second per pin for memory busses [26], peripheral connections [29], and multiprocessor interconnection networks [17]. This chapter examines the issues and challenges in the design of these high-performance I/O subsystems.

As illustrated in [Fig. 31.1](#), an I/O subsystem consists of four components: a transmitter, a transmission medium, a receiver, and a timing-recovery circuit. A transmitter converts the binary sequential bit stream into a stream of analog voltages properly sequenced in time. The medium such as a cable or PCB trace delays and filters the voltage waveform. The receiver recovers the binary values from the output of the medium. As part of the receiver, a clock samples the data to recover the bit sequence compensating for the arbitrary delay of the medium.

This chapter focuses on the transmission over an electrical medium<sup>1</sup> and begins by reviewing the electrical characteristics of transmission lines. The design issues and design techniques for each link component will be described, beginning with the transmitter (section 31.2) continuing with the receiver (section 31.3), and ending with the timing-recovery circuits (section 31.4).

### 31.1 Transmission Lines

---

A transmission medium confines the energy of a signal and propagates it [33]. The energy is stored as the electric and magnetic field between two conductors, the transmission line. The geometric configuration of the conductors for a segment of the transmission line determines the voltage and current

---

<sup>1</sup>Optical local interconnects are emerging as an alternative for short haul systems.

FIGURE 31.1 Components of an I/O subsystem.

FIGURE 31.2 Cross-sectional view of transmission line: (a) coaxial, (b) microstrip (PCB), and (c) LC model of a transmission line.

relationship in that segment defining an effective impedance ( $Z_o = VI$ ). A signal source driving the segment only sees this impedance as a sink of the signal energy and has no immediate knowledge of other parts of the line.

The two conductors can be either two signal wires driven differentially or a single signal wire over a reference plane where an image current<sup>2</sup> flows in the plane coupled to the signal. A coaxial cable has a center conductor for the signal and the outer shield as the reference (Fig. 31.2(a)). Similarly a PCB trace forms a microstrip line with a ground plane as the reference (Fig. 31.2(b)).

An effective way to model a transmission line is to use capacitances and inductances to represent the electrical and magnetic energy storage and propagation. The entire line is modeled using multiple LC segments as illustrated in Fig. 31.2(c).<sup>3</sup> The impedance of the line and the propagation velocity can be represented as  $Z = \sqrt{L/C}$  and  $v = 1/(\sqrt{LC})$ . An ideal transmission line propagates a signal with no added noise or attenuation. Imperfections in the construction of the line such as varying impedance or neglecting the image current path cause noise in the signal transmission.

## Reflections, Termination, and Crosstalk

When a signal wave encounters a segment with a different impedance, a portion of the signal power reflects back to the transmitter and can interfere with future transmitted signals. The reflection occurs because the boundary condition at a junction of two impedances must be preserved such that (1) the voltage is the same on both sides of the junction and (2) the signal energy into and out of the junction is conserved. For instance, if a lower impedance is seen by a signal, a lower voltage must be propagated along the new segment so that the propagated power is less than the original power. The lower voltage at the junction implies that a negative voltage wave is propagated in the reverse direction. Similarly, at the end of a transmission line, the receiver appears as an open circuit (high impedance) and would cause

<sup>2</sup>Image current, also called return current, is equal to the signal current.

<sup>3</sup>The  $L$ 's and  $C$ 's are per unit length.

**FIGURE 31.3** Frequency (a) and time (b) domain of an RG-55U cable illustrating filtering and ISI.

a positive reflection of the entire signal energy. The equation

$$V_{\text{reflect}} = \Gamma V_{\text{in}} = \frac{Z_{\text{out}} - Z_{\text{in}}}{Z_{\text{out}} + Z_{\text{in}}} V_{\text{in}}$$

represents the reflected wave, where  $\Gamma$  is the reflection coefficient.

Using a termination resistance at the end of the line that is equal to that of the transmission line impedance eliminates the reflection by dissipating the signal power. A reflection only poses a problem if the transmitter reflects the wave again causing the old signal energy from a previous bit to add to the signal of a newly transmitted data bit.<sup>4</sup> Allowing the entire signal to reflect at the receiver is acceptable as long as the line is properly terminated at the transmitter. So proper termination of a transmission line includes matching the resistance either at the receiver (end termination) or at the transmitter (source termination). Noise in the signal results either from imperfect termination at the ends of the line or from variations in the impedance along the line.<sup>5</sup>

A second source of noise is due to the leakage of signal energy from other transmission lines (aggressors) known as crosstalk. Improper design of transmission line often neglects the image current path. Image current can flow on closely routed signal traces on a PCB or nearby signal pins on a connector instead of the reference plane. The coupling appears as noise when the nearby signal transitions. The worst often occurs in the chip carrier where a reference plane is not readily available.

The noise source is modeled as either mutual inductance or capacitance in the LC model. The amount of noise is proportional to the aggressor's signal amplitude. Because the coupling is reactive, the noise is proportional to the frequency of the aggressor signal. This motivates the design of transmitters and receivers to filter frequencies above the data bandwidth, as will be discussed.

## Frequency Response and ISI

An ideal transmission-line segment delays a signal perfectly; however, real transmission media attenuate the signal because of the line conductor's resistance and the loss in the dielectric between the conductors. Both loss mechanisms of wires increase at higher signal frequencies. Hence, a wire low-pass filters and the filtering increases with distance. The transfer function of a 6-m and 12-m cable, shown in Fig. 31.3(a), illustrates increasing attenuation with frequency and distance. Figure 31.3(b) illustrates the effects of that frequency-dependent attenuation in the time-domain. The signal amplitudes are reduced and the energy of each bit is spread in time. If the bit time is short, the spreading causes interference between subsequent

<sup>4</sup>This noise can be compensated if the length of the delay and amount of reflection can be measured, but it adds significant complexity to the system.

<sup>5</sup>Impedance variations can be due to vias, changing of reference plane, connectors, etc.

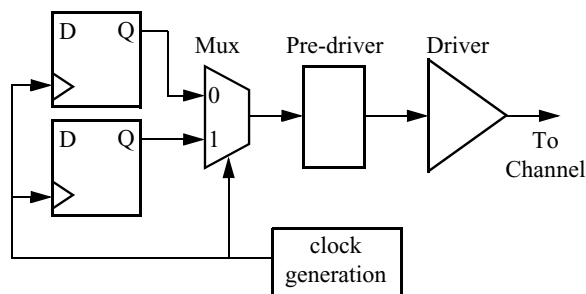

FIGURE 31.4 Transmitter components.

bits known as inter-symbol interference (ISI). As data rates increase beyond gigabits per second, the design of transmitters and receivers must incorporate additional filtering to compensate for this low-pass filtering.

## Methods of Signaling

The characteristics of the transmission medium influence the trade-off between various signaling methods. In DRAM or backplane applications where a data word connects between multiple chips, multi-drop busses save considerable pins over point-to-point connections; however, each drop of a bus structure introduces a splitting of a transmission line that causes reflections and increases noise. A similar trade-off exists with differential and single-ended signaling. Differential signaling is more robust to common-mode noise by using the second wire as the explicit image current path. A third trade-off involves whether or not signaling occurs in both directions on a pin simultaneously (full-duplex). Typically, an I/O link contains both a transmitter and a receiver on each end. Only one pair is operating at one time (half-duplex). Operating full-duplex halves the number of pins but degrades the signal amplitude and increases noise because the receiver must now compensate for the transmitted values. All three of these common choices are trading between the number of I/O pins and the signal-to-noise ratio (SNR). For high performance, system designers often opt for the more expensive options of point-to-point and differential links that are half-duplex. Some designers use single-ended signaling that has an explicit and dedicated ground pin for a signal's image current since perfectly differential structures are difficult to maintain in a PCB environment.

The following sections focus on the design of high-performance link circuitry in a high-performance system of point-to-point links. Many of the design techniques are applicable to busses and bidirectional links as well.

## 31.2 Transmitters

Transmitters convert the digital bits into analog voltages. Figure 31.4 illustrates the major pieces of a transmitter. Prior to the conversion by the output driver, transmitters commonly synchronize the data to that of a stable, noise-free clock so the resulting waveform has well-defined timing. Because I/Os often operate at a higher rate than the on-chip clock, the synchronization also multiplexes the data. The simplest and most commonly used is 2:1 multiplexing, using each half-cycle of the clock to transmit a data bit.<sup>6</sup> A pre-driver follows the multiplexing and provides any pre-conditioning of the data signal.

The output voltage range depends on the signaling specification. If the voltage range nears or exceeds that of the on-chip supply voltage, the design must convert the voltage and ensure the reliability to the over-voltage. In addition to protection against electrostatic discharge (ESD), transistors that are not built

<sup>6</sup>For memories, the 2:1 multiplexing is known as double-data rate (DDR). The duty cycle of the clock is critical in guaranteeing a constant width of each bit. Even higher multiplexing has been demonstrated using multiple clock phases [52].

FIGURE 31.5 Push-pull I/O driver with level shifting pre-drivers.

to handle large voltages across the gate oxide or source/drain junction must be appropriately protected by cascoding and well-biasing. This section begins with discussing these large output-swing transmitters. The section follows with low-swing transmitters, which are more common for high-performance designs.

Noise is the primary challenge. Techniques that reduce noise such as impedance matching, swing control, and slew-rate control are described next. The last part addresses techniques that can be used to reduce intersymbol interference due to a band-limiting transmission channel.

## Large-Swing Output Drivers

A simple push-pull architecture, as shown in Fig. 31.5, can drive a signal as large as the voltage provided for the I/O,  $V_s$ . When driving a transmission line, the initial output voltage is the result of a voltage division

$$V_o = V_s \left( \frac{R_o}{R_{drv} + R_o} \right)$$

where  $R_{drv}$  is the on-resistance of the driving device. The initial voltage is also the final voltage if the line is terminated appropriately at the receiver. In which case, the driver draws continuous current even with the absence of signal transitions. With only source termination ( $R_{drv}$  equal to  $R_o$ ), the line voltage settles to  $V_s$ . The power dissipation is less since no current flows when the signal is constant. If the line is unterminated on either end, the signal will reflect several times before settling to  $V_s$ . Because the bit period must be long enough for the signal to settle, high-performance links avoid this penalty.

Impedance matching at the transmitter is challenging because (1) process, voltage, and temperature (PVT) varies, and (2) the impedance changes significantly as the device is switched from *on* to *off*. To minimize the net variation, designers over-design the size of the device for an impedance much lower than  $R_o$ . And then, by adding an external but constant resistance  $R_{ext} = R_o - R_{drv}$ , the net impedance varies within an acceptable tolerance.

Many chips are required to interface with chips that operate at different power supply voltages. As on-chip supplies lower with CMOS technology scaling, the disparity between on-chip and off-chip voltages increases. Unfortunately, for high reliability, the on-chip devices cannot tolerate excessive over-voltage. Catastrophic breakdown of gate oxide occurs at 12 MV/cm of oxide thickness.

Device technologists address the issue by providing transistors that are slower but high-voltage tolerant. One of the tasks of the pre-driver is to shift the level of the input so that the output-driver devices are fully turned *off*. Figure 31.5 illustrates an example of level-shifting using cross-coupled PMOS devices in the pre-driver.

To avoid over-voltage, circuit designers add a cascode transistor in series with the output switch to reduce the voltage drop [39]. Figure 31.6(a) shows a bottom device that switches with the data. The upper cascoding device uses a constant *high* gate voltage that is commonly the core  $V_{dd}$ . As long as the output voltage does not exceed  $V_{dd} + V_{oxide(max)}$ , the gate oxide is preserved.  $V_x$  remains below  $V_{dd} - V_{T(eff)}$

FIGURE 31.6 Cascoding (a) and well-biasing (b) to protect driving devices.

FIGURE 31.7 Low-swing, push-pull driver with supply bypassing.

hence avoiding source/drain punchthrough of  $N_1$ .<sup>7</sup> To avoid a source/drain punchthrough of  $N_2$  during an output *high-low* transition, the size of the cascode device needs to be large enough so that  $V_x$  does not fall too quickly.<sup>8</sup>

PMOS devices for the pull-up pose an additional challenge. In a half-duplex configuration, the system tri-states the transmitter by pulling the gate of the driving device to the I/O supply voltage,  $V_s$ ; however, with reflections and inductive ringing, line voltages can exceed  $V_s$ . To avoid forward biasing the drain–well junction, designers leave the well floating, as shown in Fig. 31.6(b) [8]. Transistors  $P_1$  and  $P_2$  allow the well to be charged up to either the pad voltage or  $V_s$  depending on which is higher. To avoid conduction of the driving device when pad voltage is *high*,  $P_{drv}$ , transistor  $P_3$  pulls the gate input to the pad voltage.

## Small-Swing Output Drivers

I/O standards are migrating toward smaller output voltage swings due to several advantages. There is less concern regarding over-voltages on I/O devices. Using smaller devices and fewer over-voltage protection devices reduces output capacitance and improves bandwidth. The device stays in a single region of operation (either in triode or saturation) reducing impedance mismatches. The transmitter also dissipates less power because of the lower-swing and smaller drive devices; however, reducing signal swing directly reduces the SNR making the designs more sensitive to noise.<sup>9</sup> The following describes two commonly used driver architectures: low-impedance and high-impedance drivers.

A simple extension of the large-swing push-pull driver to low-swing is shown in Fig. 31.7, where  $V_s$  is a low voltage that determines the signal swing. The transistors operate in the linear region of their I-V curve appearing as a low-impedance signal source. With signal swings under 1 V, a smaller NMOS device can have the same pull-up resistance as PMOS devices. The impedance matching is better than the large signal driver because the device impedance varies less with  $V_{ds}$  [19].

However, with low-impedance drivers, power-supply noise appears directly on the signal. By connecting the power supply as the signal's return connection, the noise would appear as common-mode. Unfortunately,

<sup>7</sup>Feedthrough from output to the  $V_{gate}$  of  $N_2$  can dynamically elevate  $V_x$  so  $N_2$  cannot be excessively large.

<sup>8</sup> $N_2$  can often be a size 4× larger than  $N_1$ .

<sup>9</sup>Fortunately, many noise sources are proportional to the signal swing, so the SNR degradation is not overly severe.

FIGURE 31.8 High-impedance drivers: PECL (a) and open-drain (b).

the connection is difficult because multiple I/Os (and sometimes the core logic) share the ground to minimize cost. Furthermore, signal current flows through two supplies. To reduce noise, designers trade-off area and pin by (1) bypassing  $V_s$  to ground with a large capacitance, (2) limiting the number of I/Os sharing a single ground, and (3) carefully minimizing the inductive loop formed by the current return path (ground connection).

A second style of drivers, high-impedance drivers, switch currents instead of voltages. By keeping transistors in the saturated-current region, the devices appear as current sources. The current can be switched either differentially in PECL type drivers (Fig. 31.8(a)) or single-ended in open-drain type drivers (Fig. 31.8(b)). To provide source termination, a resistor ( $R_o$ ) can be placed in parallel with the output. These drivers have several advantages over their low-impedance counterparts. The outputs have less noise because the high-impedance isolates the output from one of the power supplies, but it is critical for the current to remain constant. The output bandwidth is higher because the saturated device (with a higher  $V_{ds}$ ) is smaller in size, for a given current than a triode device (with low  $V_{ds}$ ); however, because of the higher  $V_{ds}$ , these drivers dissipate more power,  $I \cdot V_s$ .

For both high- and low-impedance drivers, switching currents inject noise onto the supply via  $di/dt$ . Instead of using purely single-ended drivers, complementary single-ended drivers approximates a constant current and reduces the noise. Differential drivers such as PECL force a constant current over time and eliminate the problem.<sup>10</sup>

## Impedance, Current, and Slew-Rate Control

Process, voltage, and temperature (PVT) variations can cause drive resistance (of low-impedance drivers) and currents (of high-impedance drivers) to deviate from the design target causing offsets and noise. For robust operation, control loops are often used to dynamically maintain the proper impedance or current. To minimize coupled and reflected noise, designers also limit the high-frequency spectral content of the output signal. This section describes these noise reduction methods.

Figure 31.9 illustrates the block diagram of a loop that controls the current of a high-impedance driver [28]. The output driver device is divided into binary-weighted segments. A digital control word, stored in a register, sets the number of transistors used by the driver. A replica driver determines the control word. The replica drives half the output impedance. A comparator compares the output voltage with a reference voltage set at  $V_s - V_{sw}/2$ , where  $V_{sw}$  is the desired voltage swing of the output. The comparison result increments or decrements the control word until reaching the desired output current. A similar loop can control the output impedance by adjusting the resistance of driving devices using binary-weighted segments [7].

As mentioned earlier, filtering the high-frequency spectral content of the output signal reduces coupling noise. This is equivalent to limiting the output slew rate, but an excessively low slew rate may filter the signal's desired spectral frequencies and cause ISI. The difficulty arises when the slew rate is designed for

<sup>10</sup>The drawback is that differential drivers have slightly larger output capacitance because the differential input devices have smaller  $V_{gs}$  and need to be larger to switch the output current.

### Setting the control register

**FIGURE 31.9** Current-control feedback loop.

**FIGURE 31.10** Slew-rate control using resistors (a) and controlled pre-driver (b).

the fastest operating condition. The slowest operating condition would cause excessive ISI. Early designs of drivers use devices that correlate inversely with transistor speed. In the example shown in Fig. 31.10(a), an output device can be broken into segments and each segment turns on sequentially [41]. The delay can be introduced using polysilicon resistors, which are not very sensitive to PVT. More recent methods (Fig. 31.10(b)) control the rate at which the pre-driver turns on the output device. By using a control voltage that tracks PVT,<sup>11</sup> the pre-driver resistance or current stays constant and consequently the slew-rate.

## Transmitter Pre-Emphasis

When the data rate exceeds the channel bandwidth, designers compensate for the filtering by equalization. Because of the ease of implementation, many high-speed links equalize at the transmitter by pre-distorting the signal to emphasize higher frequencies [6, 14, 50]. Early pre-emphasis designs were known as advanced pull up/down (APU/D) [12], which were applied to driving large capacitances. The technique turns on

<sup>11</sup>The control voltage can be the voltage of a VCO whose frequency is locked to an external reference clock via a PLL [49].

FIGURE 31.11 Transmitter pre-distorted waveform (a) and implementation (b).

the driver more strongly for a period immediately after a data transition so that the transmitter drives higher frequency components with more signal power. For more complex channel responses, a programmable filter precedes the actual line driver and inverts the effect of the channel. Figure 31.11(a) illustrates an example of an analog filter. The length of the optimal filter depends on the tail of the pulse response. For many cables (less than 10 m) one or two taps is sufficient [6,13,14]. Figure 31.11(b) shows the effect of transmitter equalization. The small, negative pulses before and after the original pulse eliminates the tails of the pulse response.

A digital-FIR filter would output a quantized word that represents the output voltage. Instead of transmitting two levels, the driver is a high-speed D/A converter. Because current or impedance control uses binary-weighted driver segments, designs for a D/A converter are not significantly different; however, a design with linearity of  $>6$  bits at multi-GSamples/sec faces challenging issues: device mismatches limit linearity, transmit clock jitter limits the SNR, and the switching of output transitions induce glitches. Thermal noise for a 50- $\Omega$  environment is approximately  $1\text{ nV}/\sqrt{\text{Hz}}$  and only limits resolution at very high resolution. Recent research has demonstrated this potential with  $<6$ -bit D/A converters [10,13].

Two system issues must be considered when implementing transmitter pre-distortion. First, transmit power is limited, so the low-frequency signal energy must be attenuated to that of the worst-case attenuation of the channel. This leads to significant loss of SNR. Second, the channel characteristic is not known to the transmitter. Accurate filter coefficients are dynamically trained with loopback information sent from the receiver, which adds complexity to the system.

### 31.3 Receivers

The task of the receiver is to convert the analog waveform from the channel into a sequence of binary data. Figure 31.12 illustrates the common components of a receiver. First, an input amplifier conditions the signal. A sampling circuit follows and captures the analog value of each bit. A comparator amplifies the sampled value to digital values. Similar to the transmitter, the sampling block often demultiplexes the data so that the on-chip clock rate can be slower than the off-chip data rate. The most simple and common design uses two samplers operating on opposite edges of a digital clock for 2:1 demultiplexing.

The primary difficulty in high-performance receiver design is maintaining low noise, both static and dynamic. The noise of a signal at the receiver can be illustrated by an eye diagram (Fig. 31.13), which overlays the waveform of each bit of a random sequence. The transmitter design and the channel contributes the majority of the signal's amplitude and timing noise. The receiver should compare the signal with a proper reference voltage. Static offsets reduce the effective signal amplitude reducing the SNR. To minimize dynamic noise, the receiver should reject supply and common-mode noise, filter high-frequency input noise, and avoid any bandwidth limitation and ISI. Sampling the data at the optimal point will be addressed in the timing-recovery section. This section describes several examples of high-performance receiver designs. Then techniques to reduce noise and ISI are addressed.

FIGURE 31.12 Receiver components.

FIGURE 31.13 Eye diagram at the receiver.

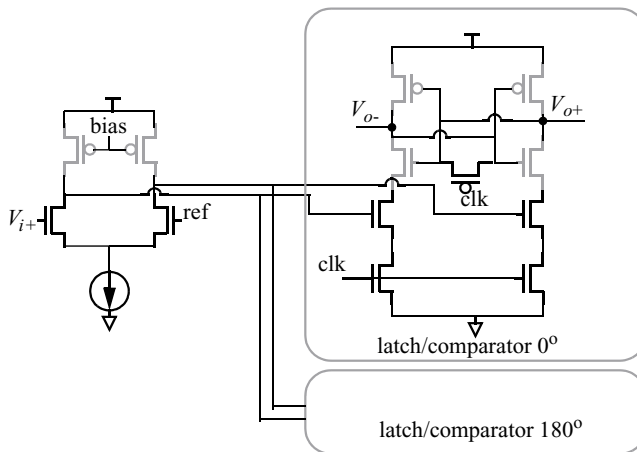

FIGURE 31.14 Receiver design with receiving amplifier.

## Receiver Designs

Figure 31.14 illustrates an example of a receiver design. The first stage performs several tasks: (1) filtering the noise, (2) level-shifting the output, and (3) amplifying the signal. An amplifier with appropriate bandwidth can filter input noise frequencies above the data bandwidth. Furthermore, using a differential structure improves the common-mode and supply noise rejection even though the input may be single-ended. The outputs of the first stage [5,9] are differential for good supply noise sensitivity and are

FIGURE 31.15 Receiver design using clocked amplifier/sampler as first stage.

level-shifted<sup>12</sup> to accommodate the clocked comparator that follows [34]. A *high* clock level resets the comparator shown in Fig. 31.14. The negative clock edge samples the data and starts a positive feedback that regeneratively amplifies the sampled value to digital values during the *low* clock phase. To demultiplex the data, the comparators operate on different clock phases. The amplification is exponentially dependent on the duration of the *low* phase. Because the comparator has high gain, the first stage does not need significant gain. Some gain reduces the effective input offset voltage since the contribution of the comparator's offset is divided by the gain. Mismatch in the feedback devices and clock coupling of the comparators can introduce significant offsets. For very high data rates, the drawback of the design is that the first stage must have sufficient bandwidth to minimize ISI. Furthermore, delay variation of the first stage can add timing noise.

A simple design can avoid ISI by eliminating the first stage and sampling/demultiplexing the input with comparators directly [24,52]. Because the comparators are reset before each sample, no signal energy from previous bits remains hence removing ISI; however, direct sampling is noisier and has larger static offsets. Figure 31.15 illustrates an alternate design that clocks the first stage to remove ISI but still conditions the signal [26,43]. During the low phase of the clock, the amplifier output is reset. During the high phase of the clock, the amplifier conditions the data. For demultiplexing, two clocked amplifiers loads the input. A comparator samples the amplifier output to further amplify to digital levels. The clock used for the clocked amplifier must be timed with the arriving signal to amplify the proper bit. The timing issue will be discussed in section 31.4.

## dc Offsets

Random dc offsets limit the voltage resolution of the receiver. These offset are due to random mismatches in the devices and scales inversely with the size of the device [35]. Because minimum size devices are often used to minimize pin capacitance and power dissipation, input-referred offset of amplifiers and comparators can be tens of millivolts.

To compensate for the error, devices are added that can create an offset in either the first amplifier or the comparator. The control can be open-loop where the compensation value is determined with an initial calibration [10]. Figure 31.16(a) shows a comparator with digitally controllable switches that differentially inject an error current. The open-loop compensation is commonly digital so the value does not drift in time. Alternatively, the control can be continuously operating and closed-loop [51]. As shown in Figure 31.16(b), a third nonoverlapping clock phase,  $clk_1$ , is added to the reset and amplify ( $clk_0$ ) phases of operation.  $Clk_1$  reconfigures the amplifier to short the inputs and to store the value of the offset on

<sup>12</sup>The input common-mode voltage depends on the transmitter and the I/O specification.

FIGURE 31.16 Offset cancellation using digital controllable switches (a) and using feedback control (b).

capacitors,  $C_{os}$ . If data is encoded so that averaged dc is a constant (dc-balanced), a similar technique finds the offset by averaging of the received data [22] instead of wasting a phase to short the inputs.

## Noise

The main sources of noise for a receiver are mutual coupling between I/O signals and differences between chip ground and board ground. Large image currents that flow through the supply pins to support the output drivers cause significant voltage differences.<sup>13</sup> Some of the supply noise inevitably appears at the input to the receiver. Signaling differentially and carefully routing the two signals together can effectively reduce noise to the order of tens of millivolts. Supply noise couple capacitively as common-mode noise. Furthermore, mutual coupling from other signals is at least partially compensated by coupling from its complement.

Single-ended signaling can achieve nearly the same performance if the return current supply connection is brought on-chip, tightly coupled to the signal through a separate pin. The receiver's reference can be derived from the return connection, but this requires the same number of pins as differential signaling. To save pins, most single-ended systems use the chip supplies ( $V_{dd}$  and ground) to derive the reference. Or, several receivers share a single return current connection. Unfortunately, since the reference signal is shared, the capacitance between the supplies to the input pad and to the reference voltage differ. The larger capacitance to the reference couples more high-frequency supply noise [26,42,46]. Single-ended systems typically require larger input swings than differential systems for the same performance.

A band-limited receiving amplifier can filter some of the noise. One approach to control the bandwidth is to bias the effective load transistors with a control signal that tracks the bit time.<sup>14</sup> To maintain constant output swing, the bias current of the differential amplifier must also track. An ideal filter for square-wave inputs averages the input signal over the bit time with an integrator<sup>15</sup> [43]. An integrating receiver replaces the load elements with capacitors. The capacitors integrate the current that is switched by the input value. At the end of the bit time, a comparator samples and compares the values on the capacitors before the integrator is reset.

## Receiver Equalization

With data rates above the bandwidth of the channel, an alternative to transmitter pre-emphasis is to build the inverse channel filter at the receiver. Designers can increase the gain of the first amplifier at high-frequencies to flatten the system response [45]. The required high-pass filter can also be implemented

<sup>13</sup>On-chip bypass capacitance only reduces chip  $V_{DD}$  to chip ground noise, and has no effect on the noise between chip ground and board ground.

<sup>14</sup>Similar to transmitter slew-rate control, one can leverage the fact that buffers in the clock generator have been adjusted to have a bandwidth related to the bit rate [49].

<sup>15</sup>Most signals are not perfect square waves. In addition to finite signal slew rate, bit boundaries contain timing uncertainty. Integrating over a portion of the bit-time ("window") can reduce noise.

digitally by first feeding the input to an analog-to-digital converter (ADC) and digitally post-processing the ADC's output. An ADC is commonly used in disk-drive read channels since it also allows one to implement more complex nonlinear receive filters. Although this approach works well at frequencies lower than 1 GHz, it is very challenging with gigahertz signals because of the required GSamples/sec converters. Recent research demonstrated a multi-GSamples/sec 4-bit ADC [10] (1 W of power), which indicates the potential of high data rate conversion albeit with high power dissipation. Instead of a digital implementation, for less area and power overhead at these high bit rates, a simple 1-tap FIR filter  $(1 - \alpha D)$  has been implemented as a switched-current filter [13] or a switched capacitor filter [47].

## 31.4 Timing Generation and Recovery

---

The task of timing recovery essentially determines the timing relationship between the transmitter and the receiver so that the data can be received with minimal error. Typically, the burden of adjusting the timing relationship falls on the receiver. Transmitter clocking is much easier where one primarily needs a low-jitter clock source.<sup>16</sup> The receiver has a more difficult task of recovering the timing from the received signals.

The prior receiver discussion does not address how to generate the clock for the amplifiers and samplers. Recovering a clock signal with low timing noise (jitter) and with accurate phase position is the most difficult challenge for high data rates. The same eye diagram in Fig. 31.13 illustrates the timing margin of a receiver. To maximize the timing margin, the receiver should sample the data in the middle of the data-eye.<sup>17</sup> If clocked amplifiers are used, the clock should be in-phase with the data to maximize the settling time of the amplifier. Furthermore, designs should minimize the jitter of both the sampling clock and the clock used at the transmitter. Almost all clock recovery circuits use a feedback loop known as a phase-locked loop (PLL) to adjust the clock phase position and minimize jitter. This section discusses different PLL architectures and methods to reduce offsets from the ideal sampling position (static phase offsets) and jitter.

### Architectures

A PLL is often used to synchronize the transmitter clock's phase and frequency<sup>18</sup> to that of a system clock. In order to transmit phase information along with the data, two methods are commonly used. For short distances of a wide data bus, source synchronous clocking is a method that transmits a clock in-phase with the data. Otherwise, prior to transmission, data is encoded to contain periodic data transitions that can be used to align the receive clock [13,15]. In some systems, the receiver and the transmitter use clocks with slightly different frequencies. Then the timing recovery PLL has the additional task of recovering the frequency from the data transitions.

Figure 31.17 shows the architecture of a PLL. Two basic approaches are used: oscillator-based PLLs, and delay-line-based PLLs or delay-locked loops (DLLs). Both systems are similar feedback loops where a control voltage ( $V_{ctl}$ ) adjust the phase of the periodic output signal ( $clk_{int}$ ) to have a fixed phase relationship with the input signal ( $inp_{ref}$ ). To distribute the clock to many receivers, a buffer chain drives the clock line,  $clk_{samp}$ .

DLLs control the output phase by directly adjusting the delay of a voltage-controlled delay line (VCDL) [25]. The control loop integrates the control voltage to drive the phase error to zero. This feedback loop is a first-order loop and is guaranteed stability, but it is constrained in that the frequency of the input clock ( $clk_{ext}$  or  $inp_{ref}$ ) determines the frequency of the output signal. Furthermore, the delay elements limit the maximum and minimum delay of the line. Designing the range to be large enough for all PVT and starting the loop at the correct delay often require auxiliary circuits. Using an oscillator-based PLL

---

<sup>16</sup>If data is multiplexed, clock phases must be properly positioned. For 2:1 multiplexing, the duty cycle needs to be 50%.

<sup>17</sup>The eye may not be symmetric. Off-center sampling may increase the amplitude of the sampled signal.

<sup>18</sup>PLLs are often used to generate a multiplied frequency.

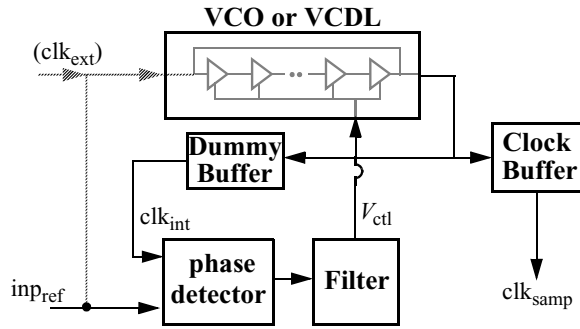

FIGURE 31.17 Phase-locked loop architecture using oscillator (a) and delay-line (b).

FIGURE 31.18 Phase-detection using SR-latch (a) or XOR (b) to detect data transition.

provides more flexible in frequency and phase. The oscillator is often implemented using a ring of controllable delay elements,<sup>19</sup> but an oscillator-based system is more complex to design. The phase of the output signal is adjusted by integrating the change in frequency of the oscillator. Thus, an oscillator-based PLL is a higher-order control system that has stability constraints [3,38].

Phase detector designs vary depending on whether the input reference is a clock or a data sequence. Recovering the phase from an input clock is easier because a transition is guaranteed every cycle. An example shown in Fig. 31.18(a) is an SR-latch where the  $Q$  and  $\bar{Q}$  outputs have equal pulse widths when the input clocks are spaced  $180^\circ$  apart [44]. When the phases deviate from  $180^\circ$ , the difference in pulse width indicates the phase difference. For data input, the added difficulty is recovering the transitions. A common design technique shown in Fig. 31.18(b) uses XORs to compare consecutive bits [20]. When the XOR output is *high*, a phase difference is present.  $PD_1$  is high starting on a transition of the input to the rising edge of the clock.  $PD_2$  is high for half the clock period whenever data transitions. The phase difference is the difference between the pulse width of  $PD_1$  and  $PD_2$ .<sup>20</sup>

<sup>19</sup>With the availability of on-chip inductors, LC-type oscillators often used in RF applications are being considered in large digital ICs.

<sup>20</sup>In order to recover frequency where the input data frequency is significantly different from the oscillator natural frequency, phase detection alone is often not sufficient. An entire class of circuits aids frequency acquisition [13,36,40].

FIGURE 31.19 90° locking using XOR (a) and ring-oscillator (b).

## Minimizing Jitter

Jitter in the sampling clock is primarily due to the sensitivity of the loop elements to supply noise. Although the feedback system can correct for noise with frequencies below the bandwidth of the loop, high-frequency noise can appear as jitter on the output clocks. Loop elements, especially oscillator or delay-line buffer elements, are often differential and have high common-mode and supply rejection to minimize the noise. Oscillators in particular are carefully designed because noise causes errors in frequency [32]. Phase error accumulates because it is the integral of the frequency error.

Many clocks drive large capacitances. Clock buffers are typically CMOS inverters for power efficiency, but they have much higher supply sensitivity than the delay buffers<sup>21</sup> and cause over half of the total jitter of the output clock. Dummy clock buffers are often included in the feedback of the PLL (Fig. 31.17) to use the feedback loop to track out the low frequency portion of the noise [1,21]. A well-designed loop in a system with 5% supply noise will often have a jitter roughly 0.5 of the delay of a FO-4 inverter<sup>22</sup> of the clock period. Intrinsic jitter without supply noise can be more than three times less.

## Phase Detection and Static Phase Offsets

In addition to the jitter, dc phase offsets are equally important in maximizing the timing margin. Using a loop that integrates the phase error helps reduce any inherent offsets. The offset primarily depends on any errors in the time spacing between sampling clocks when demultiplexing, and the mismatch between the phase detector and the receiver.

In a 1:2 demultiplexing receiver, the clock (0°) and its complement (180°) are used. Duty cycle errors can cause one receiver to not sample at its optimal location. Typically, a correction loop is added to the PLL output to guarantee 50% duty cycle<sup>23</sup> [31]. The loop averages a clock waveform to determine the duty cycle. Using the information, the duty cycle can be adjusted by changing the logical threshold of a clock buffer.

To sample at the middle of a data bit, a clock must be 90° shifted with respect to the data. This shift can be achieved by either (1) using a phase detector that indicates zero error when the difference is 90° [42], or (2) locking to 0° and shifting the clock by 90°. The first method employs XORs in the design of the phase detector. Figure 31.19(a) illustrates a simple case, when the reference input and loop output are two clock waveforms. The XOR output has equal high and low durations when the clocks are 90° apart. In the second method shown in Fig. 31.19(b), reference and loop output are locked in-phase. Using a ring-oscillator with even number of stages, an internal clock phase in the ring can be tapped for the 90° clock [27,49].

A common error in phase locking is that the receiving comparator has a nonzero setup time. To optimally sample the data, the clock position should be adjusted for the setup time.<sup>24</sup> An additional delay

<sup>21</sup>A 1% change in supply yields roughly a 1% change in delay, which can be 10× that of delay buffers.

<sup>22</sup>For a figure relatively insensitive to PVT, the time can be normalized relative to the delay of a FO-4 inverter.

<sup>23</sup>A higher degree of demultiplexing requires multiple phases to be generated and tuning of each phase position [52].

<sup>24</sup>An error that is not easily dealt with is any data dependent setup time variations. This can be minimized by designing the receiver for low input-offset voltage and hysteresis.

FIGURE 31.20 Scaling of link performance with process technology.

at the input of the phase detector can compensate for the setup delay. The most accurate compensation is to use a replica of the receiver as the phase detector since the setup time is inherent to the receiver; however, this poses challenge because a receiver does not give phase information proportional to the phase difference. The output only indicates that the loop clock is either earlier or later than an reference clock transition. An oscillator-based loop is not stable with this type of bang-bang control so only DLLs can be built. In order to also lock to the input frequency, a clever design uses a dual-loop architecture that locks to the input frequency using a core loop [21,27,44]. Coarsely-spaced clock phases from the core loop are interpolated<sup>25</sup> to generate a clock phase that can be finely controlled. This loop clock is locked to the input phase using a receiver replica phase detector. Using these techniques, phase offsets can be smaller than 2% of the bit time.

## 31.5 Conclusion

This chapter has described the design goals and challenges for high-performance I/O. Performance using 2:1 multiplexing of greater than 5 Gb/s has been demonstrated using a 0.18-μm CMOS technology [16,18,40]. Higher bit-rates have been shown using higher degree of multiplexing and demultiplexing. Because transistor speeds will scale with technology, link speeds are expected to scale as well. Unfortunately, noise coupling due to parasitic capacitances and inductances increases with frequency requiring designs to be even more robust to noise. Designs employ many of the noise reductions techniques described in this chapter and have continued to scale. Figure 31.20 illustrates the scaling so far. Future designs will need to improve these noise reducing and filtering techniques. Furthermore, wire bandwidth does not scale with technology scaling so the compensating for the low-pass filtering will be even more important.

Methods are being researched that can squeeze more bits into existing bandwidth. Given an SNR, Shannon's limit shows the maximum channel capacity to be  $\text{Capacity}/f_{bw} = \log(1 + \text{SNR})$ . Researchers are beginning to show that multilevel (4 + PAM) can be encoded in each bit period at the gigabits per second broadband data rate [10,13]. This and many techniques [37] that have been demonstrated in phone modems [4,23] can dramatically increase capacity to 10 bits/Hz in extremely noisy conditions, but all require accurate A/D and D/A converters. Research has shown that they are feasible but require extremely accurate timing. Low-jitter PLLs that lock accurately to the data phase are critical in maintaining the resolution at the gigahertz sampling rates.

<sup>25</sup>Interpolation takes two clock phases and performs a weighted average to generate an intermediate clock phase [32,52].

Power of these links is becoming an important issue. For many digital systems, the aggregate off-chip bandwidth is expected to exceed terabits per second in 2010. The data rate is not expected of a single link but over hundreds of I/Os. Each I/O cannot afford power more than a few tens of milliwatts.

These issues challenge the next generation of higher-performance link designs. The availability of faster and more abundant transistor as CMOS technology scales will help designers face the challenges.

### 32.1 Introduction

---

In large applications, data sets are often too massive to fit completely inside the computer's internal memory. The resulting input/output (or I/O) communication between fast internal memory and slower external memory (such as disks) can be a major performance bottleneck. For example, loading a register takes on the order of a nanosecond ( $10^{-9}$  s), and accessing internal memory takes tens of nanoseconds, but the latency of accessing data from a disk is several milliseconds ( $10^{-3}$  s), which is about one million times slower.

Many computer programs exhibit some degree of *locality* in their pattern of memory references: Certain data are referenced repeatedly for a while, and then the program shifts attention to other sets of data. Substantial gains in performance may be possible by incorporating locality *directly* into the algorithm design and by explicit management of the contents of each level of the memory hierarchy, thereby bypassing the virtual memory system.

## Overview of the Chapter

This chapter on the I/O communication between the random access internal memory and the magnetic disk external memory, where the relative difference in access speeds is most apparent. It surveys several paradigms for how to exploit locality and thereby reduce I/O costs when solving problems in external memory. The problems that are considered fall into two general categories:

1. *Batched problems*: No preprocessing is done and the entire file of data items must be processed, often by streaming the data through the internal memory in one or more passes.
2. *Online problems*: Computation is done in response to a continuous series of query operations and updates.

The approach is based upon the parallel disk model (PDM), which provides an elegant model for analyzing the relative performance of external memory (EM) algorithms and data structures. The three main performance measures of PDM are *the number of I/O operations*, *the disk space usage*, and *the CPU time*. For reasons of brevity, we focus on the first two measures. Most of the algorithms we consider are also efficient in terms of CPU time. In Section 32.4 we list four fundamental I/O bounds that pertain to most of the problems considered in this chapter. In Section 32.5 we discuss an automatic load balancing technique called disk striping for using multiple disks in parallel.

Section 32.6 examines canonical batched EM problem of external sorting and the related problems of permuting and fast Fourier transform. In Section 32.7, we discuss grid and linear algebra batched computations.

For most problems, parallel disks can be utilized effectively by means of disk striping or the parallel disk techniques of Section 32.6, and hence we restrict ourselves starting in Section 32.8 to the conceptually simpler single-disk case. In Section 32.8 we mention several effective paradigms for batched EM problems in computational geometry. In Section 32.9 we look at EM algorithms for combinatorial problems on graphs, such as list ranking, connected components, topological sorting, and finding shortest paths.

In Sections 32.10–32.12 we consider data structures based on hash tables and search trees in the online setting. We discuss some additional EM approaches useful for dynamic data structures, and we also consider kinetic data structures, in which the data items are moving. Section 32.13 deals with EM data structures for manipulating and searching text strings. In Section 32.14 we list several programming environments and tools that facilitate high-level development of efficient EM algorithms. In Section 32.15 we discuss EM algorithms that adapt optimally to dynamically changing internal memory allocations.

## 32.2 Parallel Disk Model (PDM)

---

EM algorithms explicitly control data placement and movement, and thus it is important for algorithm designers to have a simple but reasonably accurate model of the memory system's characteristics. Magnetic disks consist of one or more rotating platters and one read/write head per platter surface. The data are stored on the platters in concentric circles called *tracks*. To read or write a data item at a certain address on disk, the read/write head must mechanically *seek* to the correct track and then wait for the desired address to pass by. The seek time to move from one random track to another is often on the order of 3–10 ms, and the average rotational latency, which is the time for half a revolution, has the same order of magnitude. In order to amortize this delay, it pays to transfer a large contiguous group of data items, called a *block*. Similar considerations apply to all levels of the memory hierarchy.

Even if an application can structure its pattern of memory accesses to exploit locality and take full advantage of disk block transfer, there is still a substantial *access gap* between internal memory performance and external memory performance. In fact, the access gap is growing, because the latency and bandwidth of memory chips are improving more quickly than those of disks. Use of parallel processors further widens the gap. Storage systems such as RAID deploy multiple disks in order to get additional bandwidth [53,105].

The main properties of magnetic disks and multiple disk systems can be captured by the commonly used PDM introduced by Vitter and Shriver [202]:

- $N$  = problem size (in units of data items)
- $M$  = internal memory size (in units of data items)
- $B$  = block transfer size (in units of data items)
- $D$  = number of independent disk drives
- $P$  = number of CPUs

where  $M < N$ , and  $1 \leq DB \leq M/2$ . The data items are assumed to be of fixed length. In a single I/O, each of the  $D$  disks can simultaneously transfer a block of  $B$  contiguous data items. When the problem involves queries, two more performance parameters are needed:

- $Q$  = number of input queries (for a batched problem)
- $Z$  = query output size (in units of data items)

It is convenient to refer to some of the above PDM parameters in units of disk blocks rather than in units of data items:

$$n = \frac{N}{B}, \quad m = \frac{M}{B}, \quad q = \frac{Q}{B}, \quad z = \frac{Z}{B} \tag{32.1}$$

It is assumed that the input data are initially “striped” across the  $D$  disks, in units of blocks, as illustrated in Fig. 32.1, and we require the output data to be similarly striped. Striped format allows a file of  $N$  data items to be read or written in  $O(N/DB) = O(n/D)$  I/Os, which is optimal.

The three primary measures of performance in PDM are

1. the number of I/O operations performed,
2. the amount of disk space used,
3. the internal (sequential or parallel) computation time.

For reasons of brevity, this chapter focuses on only the first two measures. The reader can refer to [199] for discussion and references on more complex and precise disk models.

	$\mathcal{D}_0$	$\mathcal{D}_1$	$\mathcal{D}_2$	$\mathcal{D}_3$	$\mathcal{D}_4$
stripe 0	0 1	2 3	4 5	6 7	8 9
stripe 1	10 11	12 13	14 15	16 17	18 19
stripe 2	20 21	22 23	24 25	26 27	28 29
stripe 3	30 31	32 33	34 35	36 37	38 39

**FIGURE 32.1** Initial data layout on the disks, for  $D = 5$  disks and block size  $B = 2$ . The input data items are initially striped block-by-block across the disks. For example, data items 16 and 17 are stored in the second block (i.e., in stripe 1) of disk  $\mathcal{D}_3$ .

## 32.3 Related Memory Models, Hierarchical Memory, and Caching

---

The study of problem complexity and algorithm analysis when using EM devices began more than 40 years ago with Demuth's Ph.D. thesis on sorting [71,124]. In the early 1970s, Knuth [124] did an extensive study of sorting using magnetic tapes and (to a lesser extent) magnetic disks. At about the same time, Floyd [87,124] considered a disk model akin to PDM for  $D = 1$ ,  $P = 1$ ,  $B = M/2 = \Theta(N^c)$ , for constant  $c > 0$ , and developed optimal upper and lower I/O bounds for sorting and matrix transposition. Hong and Kung [108] developed a pebbling model of I/O for straightline computations, and Savage and Vitter [177] extended the model to deal with block transfer. Aggarwal and Vitter [15] generalized Floyd's I/O model to allow  $D$  simultaneous block transfers, but the model was unrealistic in that the  $D$  simultaneous transfers were allowed to take place on a single disk. They developed matching upper and lower I/O bounds for all parameter values for a host of problems. Because the PDM model can be thought of as a more restrictive (and more realistic) version of Aggarwal and Vitter's model, their lower bounds apply as well to PDM. The section on "A General Simulation" discusses a recent simulation technique due to Sanders et al. [176]; the Aggarwal–Vitter model can be simulated probabilistically by PDM with only a constant factor more I/Os, thus making the two models theoretically equivalent in the randomized sense. Deterministic simulations on the other hand require a factor of  $\log(N/D)/\log[\log(N/D)]$  more I/Os [29].

Surveys of I/O models, algorithms, and challenges appear in [19,94,181,199]. Several versions of PDM have been developed for parallel computation [70,135,185]. Models of "active disks" augmented with processing capabilities to reduce data traffic to the host, especially during streaming applications, are given in [3,167]. Models of microelectromechanical systems (MEMS) for mass storage appear in [100].

Some authors have studied problems that can be solved efficiently by making only one pass (or a small number of passes) over the data [81,106]. One approach to reduce the internal memory requirements is to require only an approximate answer to the problem; the more memory available, the better the approximation. A related approach to reducing I/O costs for a given problem is to use random sampling or data compression in order to construct a smaller version of the problem whose solution approximates the original. These approaches are highly problem-dependent and somewhat orthogonal to our focus in this chapter.

The same type of bottleneck that occurs between internal memory (DRAM) and external disk storage can also occur at other levels of the memory hierarchy, such as between registers and level 1 cache, between level 1 and level 2 cache, between level 2 cache and DRAM, and between disk storage and tertiary devices. The PDM model can be generalized to model the hierarchy of memories ranging from registers at the small end to tertiary storage at the large end. Optimal algorithms for PDM often generalize in a recursive fashion to yield optimal algorithms in the hierarchical memory models [12,13,201,203]. Conversely, the algorithms for hierarchical models can be run in the PDM setting, and in that setting many have the interesting property that they use no explicit knowledge of the PDM parameters like  $M$  and  $B$ . Frigo et al. [89] and Bender et al. [43] develop cache-oblivious algorithms and data structures that require no knowledge of the storage parameters.

However, the match between theory and practice is harder to establish for hierarchical models and caches than for disks. For reasons of focus, such hierarchical models and caching issues are not considered in this chapter. The reader is referred to the discussion and references in [199].

## 32.4 Fundamental I/O Operations and Bounds

---

The I/O performance of many algorithms and data structures can be expressed in terms of the bounds for the following four fundamental operations:

1. *Scanning* (a.k.a. *streaming* or *touching*) a file of  $N$  data items, which involves the sequential reading or writing of the items in the file
2. *Sorting* a file of  $N$  data items, which puts the items into sorted order

**TABLE 32.1** I/O Bounds for the Four Fundamental Operations

Operation	I/O bound, $D = 1$	I/O bound, general $D \geq 1$
Scan ( $N$ )	$\Theta\left(\frac{N}{B}\right) = \Theta(n)$	$\Theta\left(\frac{N}{DB}\right) = \Theta\left(\frac{n}{D}\right)$
Sort ( $N$ )	$\Theta\left(\frac{N}{B} \log_{M/B} \frac{N}{B}\right) = \Theta(n \log_m n)$	$\Theta\left(\frac{N}{DB} \log_{M/B} \frac{N}{B}\right) = \Theta\left(\frac{n}{D} \log_m n\right)$
Search ( $N$ )	$\Theta(\log_B N)$	$\Theta(\log_{DB} N)$
Output ( $Z$ )	$\Theta\left(\max\left\{1, \frac{Z}{B}\right\}\right) = \Theta(\max\{1, z\})$	$\Theta\left(\max\left\{1, \frac{Z}{DB}\right\}\right) = \Theta\left(\max\left\{1, \frac{z}{D}\right\}\right)$

Note: The PDM parameters are defined in Section 32.2.

3. Searching online through  $N$  sorted data items
4. Outputting the  $Z$  answers to a query in a blocked “output-sensitive” fashion

The I/O bounds for these four operations are given in Table 32.1. The special case of a single disk ( $D = 1$ ) is emphasized, because the formulas are simpler and many of the discussions in this chapter will be restricted to the single-disk case.

## 32.5 Disk Striping for Multiple Disks

It is conceptually much simpler to program for the single-disk case ( $D = 1$ ) than for the multiple-disk case ( $D \geq 1$ ). *Disk striping* [122,169] is a practical paradigm that can ease the programming task with multiple disks: I/Os are permitted only on entire stripes, one stripe at a time. For example, in the data layout in Fig. 32.1, data items 20–29 can be accessed in a single I/O step because their blocks are grouped into the same stripe. The net effect of striping is that the  $D$  disks behave as a single logical disk, but with a larger logical block size  $DB$ .

Therefore, the paradigm of disk striping can be applied to automatically convert an algorithm designed to use a single disk with block size  $DB$  into an algorithm for use on  $D$  disks each with block size  $B$ : In the single-disk algorithm, each I/O step transmits one block of size  $DB$ ; in the  $D$ -disk algorithm, each I/O step consists of  $D$  simultaneous block transfers of size  $B$  each. The number of I/O steps in both algorithms is the same; in each I/O step, the  $DB$  items transferred by the two algorithms are identical. Of course, in terms of wall clock time, the I/O step in the multiple-disk algorithm will be  $\Theta(D)$  times faster than in the single-disk algorithm because of parallelism.

Disk striping can be used to get optimal multiple-disk algorithms for three of the four fundamental operations of Section 32.4—streaming, online search, and output reporting—but it is nonoptimal for sorting. If  $D$  is replaced by 1 and then  $B$  by  $DB$  in the sorting bound  $Sort(N)$  given in Section 32.4, an expression is obtained that is larger than  $Sort(N)$  by a multiplicative factor of

$$\frac{\log(n/D)}{\log n} \frac{\log m}{\log(m/D)} \approx \frac{\log m}{\log(m/D)} \quad (32.2)$$

When  $D$  is on the order of  $m$ , the  $\log(m/D)$  term in the denominator is small, and the resulting value of (32.2) is in the order of  $\log m$ , which can be significant in practice.

It follows that the only way theoretically to attain the optimal sorting bound  $Sort(N)$  is to forsake disk striping and to allow the disks to be controlled *independently*, so that each disk can access a different stripe in the same I/O step. In the next section, algorithms for sorting with multiple independent disks are discussed. The techniques that arise can be applied to many of the batched problems addressed later in the paper. Two such sorting algorithms—distribution sort with randomized cycling and simple randomized mergesort—have relatively low overhead and will outperform disk-striped approaches.

## 32.6 External Sorting and Related Problems

The problem of *external sorting* (or sorting in external memory) is a central problem in the field of EM algorithms, partly because sorting and sorting-like operations account for a significant percentage of computer use [124], and also because sorting is an important paradigm in the design of efficient EM algorithms, as shown in Section 32.9. With some technical qualifications, many problems that can be solved easily in linear time in internal memory, such as permuting, list ranking, expression tree evaluation, and finding connected components in a sparse graph, require the same number of I/Os in PDM as does sorting.

**Theorem 32.6.1** [15,157] *The average-case and worst-case number of I/Os required for sorting  $N = nB$  data items using  $D$  disks is*

$$\text{Sort}(N) = \Theta\left(\frac{n}{D} \log_m n\right) \quad (32.3)$$

From Section 32.5, efficient sorting algorithms can be constructed for multiple disks by applying the disk striping paradigm to an efficient single-disk algorithm. But in the case of sorting, the resulting multiple-disk algorithm does not meet the optimal  $\text{Sort}(N)$  bound of Theorem 32.6.1. In the “Sorting by Distribution” and “Sorting by Merging” sections, some recently developed external sorting algorithms that use disks independently are discussed. The algorithms are based upon the important *distribution* and *merge* paradigms, which are two generic approaches to sorting.

### Sorting by Distribution

*Distribution sort* [124] is a recursive process in which we use a set of  $S - 1$  partitioning elements to partition the items into  $S$  disjoint buckets. All the items in one bucket precede all the items in the next bucket. We complete the sort by recursively sorting the individual buckets and concatenating them together to form a single fully sorted list.

One requirement is that we choose the  $S - 1$  partitioning elements so that the buckets are of roughly equal size. When that is the case, the bucket sizes decrease from one level of recursion to the next by a relative factor of  $\Theta(S)$ , and thus there are  $O(\log_S n)$  levels of recursion. During each level of recursion, we scan the data. As the items stream through internal memory, they are partitioned into  $S$  buckets in an online manner. When a buffer of size  $B$  fills for one of the buckets, its block is written to the disks in the next I/O, and another buffer is used to store the next set of incoming items for the bucket. Therefore, the maximum number of buckets (and partitioning elements) is  $S = \Theta(M/B) = \Theta(m)$ , and the resulting number of levels of recursion is  $\Theta(\log_m n)$ .

It seems difficult to find  $S = \Theta(m)$  partitioning elements using  $\Theta(n/D)$  I/Os and guarantee that the bucket sizes are within a constant factor of one another. Efficient deterministic methods exist for choosing  $S = \sqrt{m}$  partitioning elements [15,156,202], which has the effect of doubling the number of levels of recursion. Probabilistic methods based upon random sampling can be found in [82]. A deterministic algorithm for the related problem of (exact) selection (i.e., given  $k$ , find the  $k$ th item in the file in sorted order) appears in [184].

In order to meet the sorting bound (3), the buckets at each level of recursion must be formed using  $\Theta(n/D)$  I/Os, which is easy to do for the single-disk case. In the more general multiple-disk case, each read step and each write step during the bucket formation must involve on the average  $\Theta(D)$  blocks. The file of items being partitioned was itself one of the buckets formed in the previous level of recursion. In order to read that file efficiently, its blocks must be spread uniformly among the disks, so that no one disk is a bottleneck. The challenge in distribution sort is to write the blocks of the buckets to the disks in an online manner and achieve a global load balance by the end of the partitioning, so that the bucket can be read efficiently during the next level of the recursion.

Vitter and Shriver [202] develop two complementary randomized online techniques for the partitioning so that with high probability each bucket will be well balanced across the  $D$  disks. Putting the methods together, they got the first provably optimal randomized method for sorting with parallel disks.

DeWitt et al. [72] present a randomized distribution sort algorithm in a similar model to handle the case when sorting can be done in two passes. They use a sampling technique to find the partitioning elements and route the items in each bucket to a particular processor. The buckets are sorted individually in the second pass.

An even better way to do distribution sort, and deterministically at that, is the BalanceSort method developed by Nodine and Vitter [156]. During the partitioning process, the algorithm keeps track of how evenly each bucket has been distributed so far among the disks. It maintains an invariant that guarantees good distribution across the disks for each bucket.

The distribution sort methods that we mentioned above for parallel disks perform write operations in complete stripes, which makes it easy to write parity information for use in error correction and recovery. But since the blocks written in each stripe typically belong to multiple buckets, the buckets themselves will not be striped on the disks, and we must use the disks independently during read operations. In the write phase, each bucket must therefore keep track of the last block written to each disk so that the blocks for the bucket can be linked together.

An orthogonal approach is to stripe the contents of each bucket across the disks so that read operations can be done in a striped manner. As a result, the write operations must use disks independently, since during each write, multiple buckets will be writing to multiple stripes. Error correction and recovery can still be handled efficiently by devoting to each bucket one block-sized buffer in internal memory. The buffer is continuously updated to contain the exclusive-or (parity) of the blocks written to the current stripe, and after  $D - 1$  blocks have been written, the parity information in the buffer can be written to the final ( $D$ th) block in the stripe.

Under this new scenario, the basic loop of the distribution sort algorithm is, as before, to read one memoryload at a time and partition the items into  $S$  buckets; however, unlike before, the blocks for each individual bucket will reside on the disks in contiguous stripes. Each block therefore has a predefined place where it must be written. If we choose the normal round-robin ordering for the stripes (namely,  $\dots, 1, 2, 3, \dots, D, 1, 2, 3, \dots, D, \dots$ ), the blocks of different buckets may “collide,” meaning that they need to be written to the same disk, and subsequent blocks in those same buckets will also tend to collide. Vitter and Hutchinson [200] solve this problem by the technique of *randomized cycling*. For each of the  $S$  buckets, they determine the ordering of the disks in the stripe for that bucket via a random permutation of  $\{1, 2, \dots, D\}$ . The  $S$  random permutations are chosen independently. If two blocks (from different buckets) happen to collide during a write to the same disk, one block is written to the disk and the other is kept on a write queue. With high probability, subsequent blocks in those two buckets will be written to different disks and thus will not collide. As long as there is a small pool of available buffer space to temporarily cache the blocks in the write queues, Vitter and Hutchinson show that with high probability the writing proceeds optimally.

The randomized cycling method or the related merge sort methods discussed at the end of the subsection on “Sorting by Merging” will be the methods of choice for sorting with parallel disks. Experiments are underway to evaluate their relative performance. Distribution sort algorithms may have an advantage over the merge approaches in that they typically make better use of lower levels of cache in the memory hierarchy of real systems, based upon analysis of distribution sort and merge sort algorithms on models of hierarchical memory, such as the RUMH model of Vitter and Nodine [201].

## Sorting by Merging

The *merge* paradigm is somewhat orthogonal to the distribution paradigm of the previous section. A typical merge sort algorithm works as follows [124]: In the “run formation” phase, the  $n$  blocks of data are scanned, one memoryload at a time; each memoryload is sorted into a single “run,” which is then output onto a series of stripes on the disks. At the end of the run formation phase, there are  $N/M = n/m$  (sorted)

runs, each striped across the disks. (In actual implementations, we can use the “replacement-selection” technique to get runs of  $2M$  data items, on the average, when  $M \gg B$  [124].) After the initial runs are formed, the merging phase begins. In each pass of the merging phase, we merge together groups of  $R$  runs. For each merge, we scan the  $R$  runs and merge the items in an online manner as they stream through internal memory. Double buffering is used to overlap I/O and computation. At most  $R = \Theta(m)$  runs can be merged at a time, and resulting number of passes is  $O(\log_m n)$ .

To achieve the optimal sorting bound (32.3), each merging pass must be performed in  $O(n/D)$  I/Os, which is easy to do for the single-disk case. In the more general multiple-disk case, each parallel read operation during the merging must on an average bring in the next  $\Theta(D)$  blocks needed for the merging. The challenge is to ensure that those blocks reside on different disks so that they can be read in a single I/O (or a small constant number of I/Os). The difficulty lies in the fact that the runs being merged were themselves formed during the previous merge pass. Their blocks were written to the disks in the previous pass without knowledge of how they would interact with other runs in later merges.

For the binary merging case  $R = 2$ , can be devised a perfect solution, in which the next  $D$  blocks needed for the merge are guaranteed to be on distinct disks, based upon the Gilbreath principle [92,124]: The first run is striped into ascending order by disk number, and the other run is striped into descending order. Regardless of how the items in the two runs interleave during the merge, it is always the case that we can access the next  $D$  blocks needed for the output via a single I/O operation, and thus the amount of internal memory buffer space needed for binary merging is minimized. Unfortunately there is no analog to the Gilbreath principle for  $R > 2$ , and as we have seen above, we need the value of  $R$  to be large in order to get an optimal sorting algorithm.

The Greed Sort method of Nodine and Vitter [157] was the first optimal deterministic EM algorithm for sorting with multiple disks. Each merge is done “approximately” so that items go relatively closely to their final destinations. A final application of Columnsort [133], using  $O(n)$  extra I/Os, completes the merge.

Aggarwal and Plaxton [14] developed an optimal deterministic merge sort based upon the Sharesort hypercube parallel sorting algorithm [67]. To guarantee even distribution during the merging, it employs two high-level merging schemes in which the scheduling is almost oblivious. Similar to Greed Sort, the Sharesort algorithm is theoretically optimal (i.e., within a constant factor of optimal), but the constant factor is larger than the distribution sort methods.

One of the most practical methods for sorting is based upon the simple randomized merge sort (SRM) algorithm of Barve et al. [34,36], referred to as “randomized striping” by Knuth [124]. Each run is striped across the disks, but with a random starting point (the only place in the algorithm where randomness is utilized). During the merging process, the next block needed from each disk is read into memory, and if there is not enough room, the least needed blocks are “flushed” (without any I/Os required) to free up space. Barve et al. [34] derive an asymptotic upper bound on the expected I/O performance, with no assumptions on the input distribution. A more precise analysis, which is related to the so-called *cyclic occupancy problem*, is an interesting open problem. The expected performance of SRM is not optimal for some parameter values, but it significantly outperforms the use of disk striping for reasonable values of the parameters, as shown in Table 32.2. Experimental confirmation of the speedup was obtained on a 500-MHz CPU with six fast disk drives, as reported by Barve and Vitter [36].

**TABLE 32.2** The Ratio of the Number of I/Os Used by Simple Randomized Merge Sort (SRM) to the Number of I/Os Used by Merge Sort with Disk Striping, During a Merge of  $kD$  Runs, Where  $kD \approx M/2B$

	$D = 5$	$D = 10$	$D = 50$
$k = 5$	0.56	0.47	0.37
$k = 10$	0.61	0.52	0.40
$k = 50$	0.71	0.63	0.51

Note: The figures were obtained by simulation.

Further improvements can be obtained in merge sort by a more careful prefetching schedule for the runs. Barve et al. [35] and Kallahalla and Varman [114,115] have developed competitive and optimal methods for prefetching blocks in parallel I/O systems. Hutchinson et al. [112] have demonstrated a powerful duality between parallel writing and parallel prefetching, which gives an easy way to compute optimal prefetching and caching schedules for multiple disks. More significantly, they show that the same duality exists between distribution and merging, which they exploit to get a provably optimal and very practical parallel disk mergesort. Rather than use random starting points and round-robin stripes as in SRM, Hutchinson et al. order the stripes for each run independently, based upon the randomized cycling strategy discussed in Section “Sorting by Distribution” for distribution sort.

## A General Simulation

Sanders et al. [176] and Sanders [175] give an elegant randomized technique to simulate the Aggarwal–Vitter model of Section 32.3, in which  $D$  simultaneous block transfers are allowed regardless of where the blocks are located on the disks. On the average, the simulation realizes each I/O in the Aggarwal–Vitter model by only a constant number of I/Os in PDM. One property of the technique is that the read and write steps use the disks independently. Armen [29] had earlier shown that deterministic simulations resulted in an increase in the number of I/Os by a multiplicative factor of  $\log(N/D)/\log[\log(N/D)]$ .

## Handling Duplicates

Arge et al. [23] describe a single-disk merge sort algorithm for the problem of *duplicate removal*, in which a total of  $K$  distinct items are among the  $N$  items. It runs in  $O(n \max\{1, \log_m(K/B)\})$  I/Os, which is optimal in the comparison model. The algorithm can be used to sort the file, assuming that a group of equal items can be represented by a single item and a count.

A harder instance of sorting called *bundle sorting* arises when  $K$  distinct key values are among the  $N$  items, but all the items have different secondary information. Abello et al. [2] and Matias et al. [145] develop optimal distribution sort algorithms for bundle sorting using  $BundleSort(N, K) = O(n \max\{1, \log_m \min\{K, n\}\})$  I/Os, and Matias et al. [145] prove the matching lower bound. Matias et al. [145] also show how to do bundle sorting (and sorting in general) *in place* (i.e., without extra disk space). In distribution sort, for example, the blocks for the subfiles can be allocated from the blocks freed up from the file being partitioned; the disadvantage is that the blocks in the individual subfiles are no longer consecutive on the disk. The algorithms can be adapted to run on  $D$  disks with a speedup of  $O(D)$ , using the techniques described in the “Sorting by Distribution” and “Sorting by Merging” subsections.

## Permuting and Transposition

Permuting is the special case of sorting in which the key values of the  $N$  data items form a permutation of  $\{1, 2, \dots, N\}$ .

**Theorem 32.6.2** [15] *The average-case and worst-case number of I/Os required for permuting  $N$  data items using  $D$  disks is*

$$\Theta\left(\min\left\{\frac{N}{D}, \text{Sort}(N)\right\}\right) \quad (32.4)$$

The I/O bound (32.4) for permuting can be realized by using one of the sorting algorithms from Section 32.6 except in the extreme case  $B \log m = o(\log n)$ , in which case it is faster to move the data items one by one in a non-blocked way. The one-by-one method is trivial if  $D = 1$ , but with multiple disks there may be bottlenecks on individual disks; one solution for doing the permuting in  $O(N/D)$  I/Os is to apply the randomized balancing strategies of [202].

Matrix transposition is the special case of permuting in which the permutation can be represented as a transposition of a matrix from row-major order into column-major order.

**Theorem 32.6.3** [15] *With  $D$  disks, the number of I/Os required to transpose a  $p \times q$  matrix from row-major order to column-major order is*

$$\Theta\left(\frac{n}{D} \log_m \min\{M, p, q, n\}\right) \quad (32.5)$$

where  $N = pq$  and  $n = N/B$ .

When  $B$  is relatively large (for instance,  $1/2 M$ ) and  $N$  is  $O(M^2)$ , matrix transposition can be as hard as general sorting, but for smaller  $B$ , the special structure of the transposition permutation makes transposition easier. In particular, the matrix can be broken up into square submatrices of  $B^2$  elements such that each submatrix contains  $B$  blocks of the matrix in row-major order and also  $B$  blocks of the matrix in column-major order. Thus, if  $B^2 < M$ , the transpositions can be done in a simple one-pass operation by transposing the submatrices one-at-a-time in internal memory.

Matrix transposition is a special case of a more general class of permutations called bit-permute/complement (BPC) permutations, which in turn is a subset of the class of bit-matrix-multiply/complement (BMMC) permutations. BMMC permutations are defined by a  $\log N \times \log N$  nonsingular 0-1 matrix  $A$  and a  $(\log N)$ -length 0-1 vector  $c$ . An item with binary address  $x$  is mapped by the permutation to the binary address given by  $Ax \oplus c$ , where  $\oplus$  denotes bitwise exclusive-or. BPC permutations are the special case of BMMC permutations in which  $A$  is a permutation matrix, that is, each row and each column of  $A$  contain a single 1. BPC permutations include matrix transposition, bit-reversal permutations (which arise in the FFT), vector-reversal permutations, hypercube permutations, and matrix reblocking. Cormen et al. [62] characterize the optimal number of I/Os needed to perform any given BMMC permutation solely as a function of the associated matrix  $A$ , and they give an optimal algorithm for implementing it.

**Theorem 32.6.4** [62] *With  $D$  disks, the number of I/Os required to perform the BMMC permutation defined by matrix  $A$  and vector  $c$  is*

$$\Theta\left(\frac{n}{D} \left(1 + \frac{\text{rank}(\gamma)}{\log m}\right)\right) \quad (32.6)$$

where  $\gamma$  is the lower-left  $\log n \times \log B$  submatrix of  $A$ .

An interesting theoretical question is to determine the I/O cost for each individual permutation, as a function of some simple characterization of the permutation, like number of inversions.

## Fast Fourier Transform and Permutation Networks

Computing the fast Fourier transform (FFT) in external memory consists of a series of I/Os that permit each computation implied by the FFT directed graph (or butterfly) to be done while its arguments are in internal memory. A permutation network computation consists of an oblivious (fixed) pattern of I/Os such that any of the  $N!$  possible permutations can be realized; data items can only be reordered when they are in internal memory. A permutation network can be realized by a series of three FFTs [213].

**Theorem 32.6.5** *With  $D$  disks, the number of I/Os required for computing the  $N$ -input FFT digraph or an  $N$ -input permutation network is  $\text{Sort}(N)$ .*

Cormen and Nicol [61] give some practical implementations for one-dimensional (1-D) FFTs based upon the optimal PDM algorithm of [202]. The algorithms for FFT are faster and simpler than for sorting because the computation is nonadaptive in nature, and thus the communication pattern is fixed in advance.

## Lower Bounds on I/O

The most trivial batched problem is that of scanning (a.k.a. streaming or touching) a file of  $N$  data items, which can be done in a linear number  $O(N/DB) = O(n/D)$  of I/Os. Permuting is one of several simple problems that can be done in linear CPU time in the (internal memory) RAM model, but require a nonlinear number of I/Os in PDM because of the locality constraints imposed by the block parameter  $B$ .

The proof of the permutation lower bound (32.4) of Theorem 32.6.2 is due to Aggarwal and Vitter [15]. A stronger lower bound is obtained from a more refined argument that counts input operations separately from output operations [111]. For the typical case in which  $B \log m = \omega(\log N)$ , the I/O lower bound, up to lower order terms, is  $2n \log_m n$ . For the pathological, in which  $B \log m = o(\log N)$ , the I/O lower bound, up to lower order terms, is  $N/D$ . Permuting is a special case of sorting, and hence, the permuting lower bound applies also to sorting. In the unlikely case that  $B \log m = o(\log n)$ , the permuting bound is only  $\Omega(N/D)$ , and the comparison model must be used to get the full lower bound (32.3) of Theorem 6.1 [15]. The reader is referred to [199] for further discussion and references on lower bounds for sorting and related problems.

## 32.7 Matrix and Grid Computations

---

Dense matrices are generally represented in memory in row-major or column-major order. Matrix transposition, which is the special case of sorting that involves conversion of a matrix from one representation to the other, was discussed in the subsection on “Permuting and Transposition.” For certain operations such as matrix addition, both representations work well; however, for standard matrix multiplication (using only semiring operations) and LU decomposition, a better representation is to block the matrix into square  $\sqrt{B} \times \sqrt{B}$  submatrices, which gives the upper bound of the following theorem:

**Theorem 32.7.1** [108,177,202,212] *The number of I/Os required for standard matrix multiplication of two  $K \times K$  matrices or to compute the LU factorization of a  $K \times K$  matrix is  $\Theta(K^3/\min\{K, \sqrt{M}\}DB)$ .*

Hong and Kung [108] and Nodine et al. [155] give optimal EM algorithms for iterative grid computations, and Leiserson et al. [134] reduce the number of I/Os of naive multigrid implementations by a  $\Theta(M^{1/5})$  factor. Gupta et al. [102] show how to derive efficient EM algorithms automatically for computations expressed in tensor form.

If a  $K \times K$  matrix  $A$  is sparse, that is, if the number  $N_z$  of nonzero elements in  $A$  is much smaller than  $K^2$ , then it may be more efficient to store only the nonzero elements. Each nonzero element  $A_{ij}$  is represented by the triple  $(i, j, A_{ij})$ . Unlike the dense case, in which transposition can be easier than sorting (e.g., see Theorem 32.6.3 when  $B^2 \leq M$ ), transposition of sparse matrices is as hard as sorting.

**Theorem 32.7.2** *For a matrix stored in sparse format and containing  $N_z$  nonzero elements, the number of I/Os required to convert the matrix from row-major order to column-major order, and vice-versa, is  $\Theta(\text{Sort}(N_z))$ .*

The lower bound follows by reduction from sorting. If the  $i$ th item in the input of the sorting instance has key value  $x \neq 0$ , there is a nonzero element in matrix position  $(i, x)$ .

For further discussion of numerical EM algorithms, the reader is referred to the survey by Toledo [190]. Some issues regarding programming environments are covered in [59] and Section 32.14.

## 32.8 Batched Problems in Computational Geometry

---

Problems involving massive amounts of geometric data are ubiquitous in spatial databases [131,172,173], geographic information systems (GIS) [131,172,194], constraint logic programming [119,120], object-oriented databases [215], statistics, virtual reality systems, and computer graphics [90]. NASA's Earth Observing System project, the core part of the Earth Science Enterprise (formerly Mission to Planet Earth), produces petabytes ( $10^{15}$  bytes) of raster data per year [76]. Microsoft's TerraServer online database

of satellite images is over one terabyte in size [188]. A major challenge is to develop mechanisms for processing the data, or else much of the data will be useless.\*

For systems of this size to be efficient, fast EM algorithms and data structures are needed for basic problems in computational geometry. Luckily, many problems on geometric objects can be reduced to a small core of problems, such as computing intersections, convex hulls, or nearest neighbors. Useful paradigms have been developed for solving these problems in external memory.

**Theorem 32.8.1** *The following batched problems involving  $N = nB$  input items,  $Q = qB$  queries, and  $Z = zB$  output items can be solved using*

$$O((n + q)\log_m n + z) \tag{32.7}$$

*I/Os with a single disk:*

1. Computing the pairwise intersections of  $N$  segments in the plane and their trapezoidal decomposition,
2. Finding all intersections between  $N$  nonintersecting red line segments and  $N$  nonintersecting blue line segments in the plane,
3. Answering  $Q$  orthogonal 2-D range queries on  $N$  points in the plane (i.e., finding all the points within the  $Q$  query rectangles),
4. Constructing the 2-D and 3-D convex hull of  $N$  points,
5. Voronoi diagram and Triangulation of  $N$  points in the plane,
6. Performing  $Q$  point location queries in a planar subdivision of size  $N$ ,
7. Finding all nearest neighbors for a set of  $N$  points in the plane,
8. Finding the pairwise intersections of  $N$  orthogonal rectangles in the plane,
9. Computing the measure of the union of  $N$  orthogonal rectangles in the plane,
10. Computing the visibility of  $N$  segments in the plane from a point,
11. Performing  $Q$  ray-shooting queries in 2-D Constructive Solid Geometry (CSG) models of size  $N$ : The parameters  $Q$  and  $Z$  are set to 0 if they are not relevant for the particular problem.

Goodrich et al. [97], Zhu [217], Arge et al. [27], Arge et al. [24], and Crauser et al. [64,65] develop EM algorithms for those problems using the following EM paradigms for batched problems:

*Distribution sweeping*—a generalization of the distribution paradigm of Section 32.6 for “externalizing” plane sweep algorithms.

*Persistent B-trees*—an offline method for constructing an optimal-space persistent version of the B-tree data structure (see the subsection “B-trees and Variants”), yielding a factor of  $B$  improvement over the generic persistence techniques of Driscoll et al. [74].

*Batched filtering*—a general method for performing simultaneous EM searches in data structures that can be modeled as planar layered directed acyclic graphs; it is useful for 3-D convex hulls and batched point location. Multisearch on parallel computers is considered in [73].

*External fractional cascading*—an EM analog to fractional cascading on a segment tree, in which the degree of the segment tree is  $O(m^\alpha)$  for some constant  $0 < \alpha \leq 1$ . Batched queries can be performed efficiently using batched filtering; online queries can be supported efficiently by adapting the parallel algorithms of work of Tamassia and Vitter [187] to the I/O setting.

*External marriage-before-conquest*—an EM analog to the technique of Kirkpatrick and Seidel [123] for performing output-sensitive convex hull constructions.

*Batched incremental construction*—a localized version of the randomized incremental construction paradigm of Clarkson and Shor [56], in which the updates to a simple dynamic data structure

---

\*For brevity, in the remainder of this chapter, only with the single-disk case  $D = 1$  is presented. The single-disk I/O bounds for the batched problems can often be cut by a factor of  $\Theta(D)$  for the case  $D \geq 1$  by using the load balancing techniques of Section 32.6. In practice, disk striping (cf., Section 32.5) may be sufficient. For online problems, disk striping will convert optimal bounds for the case  $D = 1$  into optimal bounds for  $D \geq 1$ .

are done in a random order, with the goal of fast overall performance on the average. The data structure itself may have bad worst-case performance, but the randomization of the update order makes worst-case behavior unlikely. The key for the EM version so as to gain the factor of  $B$  I/O speedup is to batch together the incremental modifications.

## 32.9 Batched Problems on Graphs

---

The first work on EM graph algorithms was by Ullman and Yannakakis [192] for the problem of transitive closure. Chiang et al. [54] consider a variety of graph problems, several of which have upper and lower I/O bounds related to sorting and permuting. Abello et al. [2] formalize a functional approach to EM graph problems, in which computation proceeds in a series of scan operations over the data; the scanning avoids side effects and thus permits checkpointing to increase reliability. Kumar and Schwabe [128], followed by Buchsbaum et al. [49], develop graph algorithms based upon amortized data structures for binary heaps and tournament trees. Munagala and Ranade [151] give improved graph algorithms for connectivity and undirected breadth-first search, and Arge et al. [20] extend the approach to compute the minimum spanning forest (MSF). Meyer [148] provides some improvements for graphs of bounded degree. Arge [18] gives efficient algorithms for constructing ordered binary decision diagrams. Grossi and Italiano [101] apply their multidimensional data structure to get dynamic EM algorithms for MSF and 2-D priority queues (in which the *delete\_min* operation is replaced by *delete\_min<sub>x</sub>* and *delete\_min<sub>y</sub>*). Techniques for storing graphs on disks for efficient traversal and shortest path queries are discussed in [7,96,110,154]. Computing wavelet decompositions and histograms [205,206,208] is an EM graph problem related to transposition that arises in online analytical processing (OLAP). Wang et al. [207] give an I/O-efficient algorithm for constructing classification trees for data mining.

Table 32.3 gives the best known I/O bounds for several graph problems, as a function of the number  $V = \nu B$  of vertices and the number  $E = eB$  of edges. The best known I/O lower bound for these problems is  $\Omega((E/V)\text{Sort}(V) = e \log_m \nu)$ .

In the case of *semi-external graph problems* [2], in which the vertices fit in internal memory but not the edges (i.e.,  $V \leq M < E$ ), several of the problems in Table 32.3 can be solved optimally in external memory. For example, finding connected components, biconnected components, and minimum spanning forests can be done in  $O(e)$  I/Os when  $V \leq M$ . The I/O complexities of several problems in the general case remain open, including connected components, biconnected components, and minimum spanning forests in the deterministic case, as well as breadth-first search, topological sorting, shortest paths, depth-first search, and transitive closure. It may be that the I/O complexity for several of these problems is  $\Theta((E/V)\text{Sort}(V) + V)$ . For special cases, such as trees, planar graphs, outerplanar graphs, and graphs of bounded tree width, several of these problems can be solved substantially faster in  $O(\text{Sort}(E))$  I/Os [7,54, 141,142].

Chiang et al. [54] exploit the key idea that efficient EM algorithms can often be developed by a sequential simulation of a parallel algorithm for the same problem. The intuition is that each step of a parallel algorithm specifies several operations and the data they act upon. If the data arguments for each operation are brought together, which can be done by two applications of sorting, the operations can be performed by a single linear scan through the data. After each simulation step, sorting is again performed in order to reblock the data into the linear order required for the next simulation step. In list ranking, which is used as a subroutine in the solution of several other graph problems, the number of working processors in the parallel algorithm decreases geometrically with time, so the number of I/Os for the entire simulation is proportional to the number of I/Os used in the first phase of the simulation, which is  $\text{Sort}(N) = \Theta(n \log_m n)$ . The optimality of the EM algorithm given in [54] for list ranking assumes that  $\sqrt{m} \log m = \Omega(\log n)$ , which is usually true in practice. That assumption can be removed by use of the buffer tree data structure [17] (see Section 32.11 “B-trees and Variants”). A practical, randomized implementation of list ranking appears in [183]. Dehne et al. [69,70] and Sibeyn and Kaufmann [185] use a related approach and get efficient I/O bounds by simulating coarse-grained parallel algorithms in the BSP parallel model.

**TABLE 32.3** Best Known I/O Bounds for Batched Graph Problems for the Single-Disk Case  $D = 1$

Graph Problem	I/O bound, $D = 1$
List ranking, Euler tour of a tree, centroid decomposition, expression tree evaluation	$\Theta(\text{Sort}(V))$ [54]
Connected components, minimum spanning forest (MSF)	$O\left(\max\left\{1, \log\left(\log\frac{V}{e}\right)\right\}\frac{E}{V}\text{Sort}(V)\right)$ <p style="text-align: center;">[20, 77, 151] (deterministic)</p> $\Theta\left(\frac{E}{V}\text{Sort}(V)\right)$ [54] (randomized)
Bottleneck MSF, biconnected components	$O\left(\min\left\{V^2, \max\left\{1, \log\frac{V}{M}\right\}\frac{E}{V}\text{Sort}(V), (\log B)\frac{E}{V}\text{Sort}(V) + e \log V\right\}\right)$ <p style="text-align: center;">[2, 54, 77, 128] (deterministic)</p> $\Theta\left(\frac{E}{V}\text{Sort}(V)\right)$ [54, 77] (randomized)
Ear decomposition, maximal matching	$O\left(\min\left\{V^2, \max\left\{1, \log\frac{V}{M}\right\}\text{Sort}(E), (\log B)\text{Sort}(E) + e \log V\right\}\right)$ <p style="text-align: center;">[2, 54, 128] (deterministic)</p> $O(\text{Sort}(E))$ [54] (randomized)
Undirected breadth-first search	$O(\text{BundleSort}(E, V) + V)$ [151]
Undirected single-source shortest paths	$O(e \log e + V)$ [128]
Directed and undirected depth-first search, topological sorting, directed breadth-first search, directed single-source shortest paths	$O\left(\min\left\{\frac{ve}{m} + V, (V + e) \log v\right\}\right)$ [49, 54, 128]
Transitive closure	$O\left(Vv\sqrt{\frac{e}{m}}\right)$ [54]

*Note:* The number of vertices is denoted by  $V = vB$  and the number of edges by  $E = eB$ . The terms  $\text{Sort}(N)$  and  $\text{BundleSort}(N, K)$  are defined in Sections 32.4 and 32.6.

## 32.10 External Hashing for Online Dictionary Search

This section focuses on online data structures for supporting the dictionary operations of insert, delete, and lookup. Given a value  $x$ , the lookup operation returns the item(s), if any, in the structure with key value  $x$ . The two main types of EM dictionaries are hashing, which we discuss in this section, and tree-based approaches, which is deferred until Section 32.11. The advantage of hashing is that the expected number of probes per operation is a constant, regardless of the number  $N$  of items. The common element of all EM hashing algorithms is a predefined hash function:

$$\text{hash} : \{\text{all possible keys}\} \rightarrow \{0, 1, 2, \dots, K - 1\}$$

that assigns the  $N$  items to  $K$  address locations in a uniform manner. Hashing algorithms differ from one another in how they resolve the *collision* that results when there is no room to store an item at its assigned location.

The goals in EM hashing are to achieve an average of  $O(\text{Output}(Z)) = O(\lceil z \rceil)$  I/Os per lookup, where  $Z = zB$  is the number of items output,  $O(1)$  I/Os per insert and delete, and linear disk space. Most traditional hashing methods use a statically allocated table and are thus designed to handle only a fixed

**FIGURE 32.2** Extensible hashing with block size  $B = 3$ . The keys are indicated in italics. For convenience of exposition, the hash address of a key consists of its binary representation. For example, the hash address of key 4 is "...000100" and the hash address of key 44 is "...0101100". (a) The hash table after insertion of the keys 4, 23, 18, 10, 44, 32, 9. (b) Insertion of the key 76 into table location 100 causes the block with local depth 2 split into two blocks with local depth 3. (c) Insertion of the key 20 into table location 100 causes a block with local depth 3 to split into two blocks with local depth 4. The directory doubles in size and the global depth  $d$  is incremented from 3 to 4.

range of  $N$ . The challenge is to develop dynamic EM structures that can adapt smoothly to widely varying values of  $N$ .

EM hashing methods fall into one of two categories: *directory* methods and *directoryless* methods. Fagin et al. [79] proposed a directory scheme called *extensible hashing*, illustrated in Fig. 32.2: The directory, for a given  $d \geq 0$ , consists of a table (array) of  $2^d$  pointers. Each item is assigned to the table location corresponding to the  $d$  least significant bits of its hash address. The value of  $d$ , called the *global depth*, is set to the smallest value for which each table location has at most  $B$  items assigned to it. Each table location contains a pointer to a block where its items are stored. Thus, a lookup takes two I/Os: one to access the directory and one to access the block storing the item. If the directory fits in internal memory, only one I/O is needed. Several table locations may have many fewer than  $B$  assigned items, and for purposes of minimizing storage utilization, they can share the same disk block for storing their items by using a *local depth* smaller than the global depth. When new items are inserted and deleted, the blocks can overflow or underflow, and the local depths and global depth are changed accordingly.

The expected number of disk blocks required to store the data items is asymptotically  $n/\ln 2 \approx n/0.69$ ; that is, the blocks tend to be about 69% full [147]. At least  $\Omega(n/B)$  blocks are needed to store the directory. Flajolet [86] showed on the average that the directory uses  $\Theta(N^{1/B}/nB) = \Theta(N^{1+1/B}/B^2)$  blocks, which can be superlinear in  $N$  asymptotically; however, for practical values of  $N$  and  $B$ , the  $N^{1/B}$  term is a small constant, typically less than 2, and directory size is within a constant factor of optimal.

The resulting directory is equivalent to the leaves of a perfectly balanced trie [124], in which the search path for each item is determined by its hash address, except that hashing allows the leaves of the trie to

be accessed directly in a single I/O. Any item can thus be retrieved in a total of two I/Os. If the directory fits in internal memory, only one I/O is needed.

A disadvantage of directory schemes is that two I/Os rather than one I/O are required when the directory is stored in external memory. Litwin [136] and Larson [130] developed a directoryless method called *linear hashing* that expands the number of data blocks in a controlled regular fashion. In contrast to directory schemes, the blocks in directoryless methods are chosen for splitting in a predefined order. Thus the block that splits is usually not the block that has overflowed, so some of the blocks may require auxiliary overflow lists to store items assigned to them. On the other hand, directoryless methods have the advantage that there is no need for access to a directory structure, and thus searches often require only one I/O.

### 32.11 Multiway Tree Data Structures

An advantage of search trees over hashing methods is that the data items in a tree are sorted, and thus the tree can be used readily for 1-D range search. The items in a range  $[x, y]$  can be found by searching for  $x$  in the tree and then performing an inorder traversal in the tree from  $x$  to  $y$ . In this section we explore some important search-tree data structures in external memory.

#### B-trees and Variants

Tree-based data structures arise naturally in the online setting, in which the data can be updated and queries must be processed immediately. Binary trees have a host of applications in the (internal memory) RAM model. In order to exploit block transfer, trees in external memory generally use a block for each node, which can store  $\Theta(B)$  pointers and data values.

The well-known balanced multiway *B-tree* due to Bayer and McCreight [39,58,124] is the most widely used nontrivial EM data structure. The degree of each node in the B-tree (with the exception of the root) is required to be  $\Theta(B)$ , which guarantees that the height of a B-tree storing  $N$  items is roughly  $\log_B N$ . B-trees support dynamic dictionary operations and 1-D range search optimally in linear space,  $O(\log_B N)$  I/Os per insert or delete, and  $O(\log_B N + z)$  I/Os per query, where  $Z = zB$  is the number of items output. When a node overflows during an insertion, it splits into two half-full nodes, and if the splitting causes the parent node to overflow, the parent node splits, and so on. Splittings can thus propagate up to the root, which is how the tree grows in height. Deletions are handled in a symmetric way by merging nodes.

In the  $B^+$ -tree variant, pictured in Fig. 32.3, all the items are stored in the leaves, and the leaves are linked together in symmetric order to facilitate range queries and sequential access. The internal nodes store only key values and pointers and thus can have a higher branching factor. In the most popular variant of  $B^+$ -trees, called  $B^*$ -trees, splitting can usually be postponed when a node overflows, by “sharing” the node’s data with one of its adjacent siblings. The node needs to be split only if the sibling is also full; when that happens, the node splits into two, and its data and those of its full sibling are evenly redistributed, making each of the three nodes about  $2/3$  full. This local optimization reduces how often new

**FIGURE 32.3**  $B^+$ -tree multiway search tree. Each internal and leaf node corresponds to a disk block. All the items are stored in the leaves; the darker portion of each leaf block indicates its relative fullness. The internal nodes store only key values and pointers,  $\Theta(B)$  of them per node. Although not indicated here, the leaf blocks are linked together sequentially.

nodes must be created and thus increases the storage utilization. Because fewer nodes are in the tree, search I/O costs are lower. When no sharing is done (as in  $B^+$ -trees), Yao [214] shows that nodes are roughly  $\ln 2 \approx 69\%$  full on the average, assuming random insertions. With sharing (as in  $B^*$ -trees), the average storage utilization increases to about  $2 \ln(3/2) \approx 81\%$  [32,129]. Storage utilization can be increased further by sharing among several siblings, at the cost of more complicated insertions and deletions. Some helpful space-saving techniques borrowed from hashing are partial expansions [33] and use of overflow nodes [186].

A cross between B-trees and hashing, where each subtree rooted at a certain level of the B-tree is instead organized as an external hash table, was developed by Litwin and Lomet [137] and further studied in [30,138]. O’Neil [158] proposed a B-tree variant called the SB-tree that clusters together on the disk symmetrically ordered nodes from the same level so as to optimize range queries and sequential access. Rao and Ross [165,166] use similar ideas to exploit locality and optimize search tree performance in internal memory. Reducing the number of pointers allows a higher branching factor and thus faster search.

Partially persistent versions of B-trees have been developed by Becker et al. [41] and Varman and Verma [195]. By persistent data structure, we mean that searches can be done with respect to any timestamp  $y$  [74,75]. In a partially persistent data structure, only the most recent version of the data structure can be updated. In a fully persistent data structure, any update done with timestamp  $y$  affects all future queries for any time after  $y$ . An interesting open problem is whether B-trees can be made fully persistent. Salzberg and Tsotras [171] survey work done on persistent access methods and other techniques for time-evolving data. Lehman and Yao [132], Mohan [149], and Lomet and Salzberg [140] explore mechanisms to add concurrency and recovery to B-trees.

Arge and Vitter [28] introduce a powerful variant of B-trees called *weight-balanced B-trees*, with the property that the weight of any subtree at level  $h$  (i.e., the number of nodes in the subtree rooted at a node of height  $h$ ) is  $\Theta(a^h)$ , for some fixed parameter  $a$  of order  $B$ . By contrast, the sizes of subtrees at level  $h$  in a regular B-tree can differ by a multiplicative factor that is exponential in  $h$ .

It is sometimes useful to augment B-trees with parent pointers. Order queries such as “Does leaf  $x$  precede leaf  $y$  in the total order represented by the tree?” can be answered using  $O(\log_b N)$  I/Os by following parent pointers starting at  $x$  and  $y$ . The update operations insert, delete, cut, and concatenate can be done in  $O((1 + (b/B) \log_m n) \log_b N)$  I/Os amortized, for any  $2 \leq b \leq B/2$ , which is never worse than  $O((\log_b N)^2)$  by appropriate choice of  $b$ .

Agarwal et al. [4] apply level-balanced B-trees in a data structure for point location in monotone subdivisions, which supports queries and (amortized) updates in  $O((\log_b N)^2)$  I/Os. They also use it to dynamically maintain planar *st*-graphs using  $O((1 + (b/B)(\log_m n) \log_b N)$  I/Os (amortized) per update, so that reachability queries can be answered in  $O(\log_b N)$  I/Os (worst-case). (Planar *st*-graphs are planar directed acyclic graphs with a single source and a single sink.) An interesting open question is whether level-balanced B-trees can be implemented in  $O(\log_b N)$  I/Os per update. Such an improvement would immediately give an optimal dynamic structure for reachability queries in planar *st*-graphs.

Arge [17] developed the elegant *buffer tree* data structure to support *batched dynamic* operations, such as in sweep line applications, where the queries do not have to be answered right away or in any particular order. The buffer tree is a balanced multiway tree, but with degree  $\Theta(m)$  rather than degree  $\Theta(B)$ , except possibly for the root. Its key distinguishing feature is that each node has a buffer that can store  $\Theta(M)$  items (i.e.,  $\Theta(m)$  blocks of items). Items in a node are pushed down to the children when the buffer fills. Emptying a full buffer requires  $\Theta(m)$  I/Os, which amortizes the cost of distributing the  $M$  items to the  $\Theta(m)$  children. Each item thus incurs an amortized cost of  $O(m/M) = O(1/B)$  I/Os per level, and the resulting cost for queries and updates is  $O((1/B) \log_m n)$  I/Os amortized.

Buffer trees provide a natural amortized implementation of priority queues for *time-forward processing* applications like discrete event simulation, sweeping, and list ranking [54]. Govindrajana et al. [98] use time-forward processing to construct a well-separated pair decomposition of  $N$  points in  $d$  dimensions in  $O(\text{Sort}(N))$  I/Os, and they apply it to the problems of finding the  $K$  nearest neighbors for each point and the  $K$  closest pairs. Brodal and Katajainen [48] provide a worst-case optimal priority queue, in the sense that every sequence of  $B$  *insert* and *delete\_min* operations requires only  $O(\log_m n)$  I/Os. Practical

implementations of priority queues based upon these ideas are examined in [47,174]. Further experiments on buffer trees appear in [109].

## 32.12 Spatial Data Structures and Range Search

A fundamental database primitive in spatial databases and GIS is range search, which includes dictionary lookup as a special case. An orthogonal range query, for a given  $d$ -dimensional rectangle, returns all the points in the interior of the rectangle. Various forms of 2-D orthogonal range search are pictured in Fig. 32.4. Other types of spatial queries include point location queries, ray shooting queries, nearest neighbor queries, and intersection queries, but for brevity we restrict our attention primarily to range searching.

Two types of spatial data structures are used: data-driven and space-driven. R-trees and kd-trees are data-driven since they are based upon a partitioning of the data items themselves, whereas space-driven methods like quad trees and grid files are organized by a partitioning of the embedding space, akin to order-preserving hash functions. In this section, primarily data-driven data structures are discussed. The goal is generally to perform queries in  $O(\log_B N + z)$  I/Os, use linear storage space (namely,  $O(n)$  disk blocks), and support dynamic updates in  $O(\log_B N)$  I/Os.

### Linear-Space Spatial Structures

Grossi and Italiano [101] construct an elegant multidimensional version of the B-tree called the *cross tree*. Using linear space, it combines the data-driven partitioning of weight-balanced B-trees at the upper levels of the tree with the space-driven partitioning of methods like quad trees at the lower levels of the tree. For  $d > 1$ ,  $d$ -dimensional orthogonal range queries can be done in  $O(n^{1-1/d} + z)$  I/Os, and inserts and deletes take  $O(\log_B N)$  I/Os. The O-tree of Kanth and Singh [121] provides similar bounds. Cross trees also support the dynamic operations of cut and concatenate in  $O(n^{1-1/d})$  I/Os. In some restricted models for linear-space data structures, the 2-D range search query performance of cross trees and O-trees can be considered to be optimal, although it is much larger than the logarithmic bound of Criterion 1.

One way to get multidimensional EM data structures is to augment known internal memory structures, such as quad trees and kd-trees, with block-access capabilities. Examples include *kd-B-trees* [168], *buddy trees* [180], and *hB-trees* [78,139]. *Grid files* [107,127,152] are a flattened data structure for storing the cells of a 2-D grid in disk blocks. Another technique is to “linearize” the multidimensional space by imposing a total ordering on it (a so-called space-filling curve), and then the total order is used to organize the points into a B-tree [93,117,160]. Linearization can also be used to represent nonpoint data, in which the data items are partitioned into one or more multidimensional rectangular regions [1,159]. All the methods described in this paragraph use linear space, and they work well in certain situations; however, their worst-case range query performance is no better than that of cross trees, and for some methods, like grid files, queries can require  $\Theta(n)$  I/Os, even if there are no points satisfying the query. The reader is referred to [10,91,153] for a broad survey of these and other interesting methods. Space-filling curves arise again in connection with R-trees, which is described next.

**FIGURE 32.4** Different types of 2-D orthogonal range queries: (a) Diagonal corner 2-sided 2-D query equivalent to a stabbing query (cf., subsection “Specialized Structures for 2-D Orthogonal Range Search”), (b) 2-sided 2-D query, (c) 3-sided 2-D query, and (d) general 4-sided 2-D query.

## R-trees

The *R-tree* of Guttman [104] and its many variants are a practical multidimensional generalization of the B-tree for storing a variety of geometric objects, such as points, segments, polygons, and polyhedra, using linear disk space. Internal nodes have degree  $\Theta(B)$  (except possibly the root), and leaves store  $\Theta(B)$  items. Each node in the tree has associated with it a bounding box (or bounding polygon) of all the items in its subtree. A big difference between R-trees and B-trees is that in R-trees the bounding boxes of sibling nodes are allowed to overlap. If an R-tree is being used for point location, for example, a point may lie within the bounding box of several children of the current node in the search. In that case, the search must proceed to all such children.

In the dynamic setting, several popular heuristics are used to determine to insert new items into an R-tree and how to rebalance it; see [10,91,99] for a survey. The *R\*-tree* variant of Beckmann et al. [42] seems to give best overall query performance. New R-tree partitioning methods by de Berg et al. [68] and Agarwal et al. [9] provide some provable bounds on overlap and query performance.

In the static setting, in which there are no updates, constructing the *R\*-tree* by repeated insertions, one by one, is extremely slow. A faster alternative to the dynamic R-tree construction algorithms mentioned above is to bulk-load the R-tree in a bottom-up fashion [1,116,159]. The quality of the bottom-up R-tree in terms of query performance is generally not as good as that of an *R\*-tree*, especially for higher-dimensional data [45,118].

In order to get the best of both worlds—the query performance of *R\*-trees* and the bulk construction efficiency of Hilbert R-trees—Arge et al. [22] and van den Bercken et al. [193] independently devised fast bulk loading methods based upon buffer trees that do top-down construction in  $O(n \log_m n)$  I/Os, which matches the performance of the bottom-up methods within a constant factor. The former method is especially efficient and supports dynamic batched updates and queries.

## Specialized Structures for 2-D Orthogonal Range Search

Diagonal corner 2-sided queries (see Fig. 32.4(a)) are equivalent to stabbing queries, which have the following form: “Given a set of 1-D intervals, report all the intervals ‘stabbed’ by the query value  $x$ .” (That is, report all intervals that contain  $x$ .) A diagonal corner query  $x$  on a set of 2-D points  $\{(a_1, b_1), (a_2, b_2), \dots\}$  is equivalent to a stabbing query  $x$  on the set of closed intervals  $\{[a_1, b_1], [a_2, b_2], \dots\}$ . Arge and Vitter [28,199] introduced a new paradigm we call *bootstrapping* to support such queries in optimal I/O bounds and space: The data structure uses  $O(n)$  disk blocks, queries use  $O(\log_B N + z)$  I/Os, and updates take  $O(\log_B N)$  I/Os. In another example of bootstrapping, Arge et al. [25] achieve the same bounds for 3-sided orthogonal 2-D range searching (see Figure 32.4(c)).

The dynamic data structure for 3-sided range searching can be generalized using the filtering technique of Chazelle [51] to handle general 4-sided queries with optimal I/O query bound  $O(\log_B N + z)$  and optimal disk space usage  $O(n(\log n)/\log(\log_B N + 1))$  [25]. The update bound becomes  $O((\log_B N) (\log n)/\log(\log_B N + 1))$ , which may not be optimal.

## Other Types of Range Search

For other types of range searching, such as in higher dimensions and for nonorthogonal queries, different filtering techniques are needed. So far, relatively little work has been done, and many open problems remain.

Vengroff and Vitter [196] develop the first theoretically near-optimal EM data structure for static 3-D orthogonal range searching. They create a hierarchical partitioning in which all the points that dominate a query point are densely contained in a set of blocks. Compression techniques are needed to minimize disk storage. With some recent modifications [204],  $(3+k)$ -sided 3-D range queries, where  $k$  of the dimensions ( $0 \leq k \leq 3$ ) have finite ranges, can be done in  $O(\log_B N + z)$  I/Os, which is optimal, and the space usage is  $O(n(\log n)^{k+1}/(\log(\log_B N + 1))^k)$ . The result also provides optimal  $O(\log N + Z)$ -time query performance for 3-sided 3-D queries in the (internal memory) RAM model, but using  $O(N \log N)$  space.

By the reduction in [52], a data structure for 3-sided 3-D queries also applies to 2-D *homothetic range search*, in which the queries correspond to scaled and translated (but not rotated) transformations of an arbitrary fixed polygon. An interesting special case is “fat” orthogonal 2-D range search, where the query rectangles are required to have bounded aspect ratio. For example, every rectangle with bounded aspect ratio can be covered by two overlapping squares. An interesting open problem is to develop linear-sized optimal data structures for fat orthogonal 2-D range search. By the reduction, one possible approach would be to develop optimal linear-sized data structures for 3-sided 3-D range search.

Agarwal et al. [6] consider halfspace range searching, in which a query is specified by a hyperplane and a bit indicating one of its two sides, and the output of the query consists of all the points on that side of the hyperplane. They give various data structures for halfspace range searching in two, three, and higher dimensions, including one that works for simplex (polygon) queries in two dimensions, but with a higher query I/O cost. They have subsequently improved the storage bounds for halfspace range queries in two dimensions to obtain an optimal static data structure satisfying Criteria 1 and 2 of Section 32.12.

The number of I/Os needed to build the data structures for 3-D orthogonal range search and halfspace range search is rather large (more than  $\Omega(N)$ ). Still, the structures shed useful light on the complexity of range searching and may open the way to improved solutions. An open problem is to design efficient construction and update algorithms and to improve upon the constant factors.

Callahan et al. [50] develop dynamic EM data structures for several online problems in  $d$  dimensions. For any fixed  $\epsilon > 0$ , they can find an approximately nearest neighbor of a query point (within a  $1 + \epsilon$  factor of optimal) in  $O(\log_B N)$  I/Os; insertions and deletions can also be done in  $O(\log_B N)$  I/Os. They use a related approach to maintain the closest pair of points; each update costs  $O(\log_B N)$  I/Os. Govindrajana et al. [98] achieve the same bounds for closest pair by maintaining a well-separated pair decomposition. For finding nearest neighbors and approximate nearest neighbors, two other approaches are partition trees [5,6] and locality-sensitive hashing [95]. Numerous data structures and lower bounds have been developed for range queries and related problems on spatial data. Refer to [10,91,153,199] for a broad survey.

## Dynamic and Kinetic Data Structures

The preceding sections have outlined cases of data structures in which the data items change dynamically. The bootstrapping paradigm discussed in the two previous subsections is a very useful approach for converting static data structures that are efficient in internal memory into dynamic ones that are efficient for external memory.

In another approach to dynamic data, Arge and Vahrenhold [26] obtain I/O bounds for dynamic point location in general planar subdivisions similar to those of [4], but without use of level-balanced trees. Their method uses a weight-balanced base structure at the outer level and a multislab structure for storing segments similar to that of Arge and Vitter [28]. They use an externalization of Bentley’s logarithmic method [44,161] to construct a data structure to answer vertical rayshooting queries in the multislab structures. Arge et al. [8] apply the logarithmic method (in both the binary form and B-way variant) to get EM versions of kd-trees, BBD trees, and BAR trees.

In some applications, the data items are moving and their spatial coordinates change in a regular manner. Early work on temporal data generally concentrated on time-series data or multiversion data [171]. A question of growing interest in this mobile age is how to store and index continuously moving items, such as mobile telephones, cars, and airplanes (e.g., see [113,170,211]). Two main approaches are used for storing moving items: The first technique is to use the same sort of data structure as for nonmoving data, but to update it whenever items move sufficiently so far as to trigger important combinatorial *events* that are relevant to the application at hand [38]. A different approach is to store each item’s location and speed trajectory, so that no updating is needed as long as the item’s trajectory plan does not change. Such an approach requires fewer updates, but the representation for each item generally has higher dimension, and the search strategies are therefore less efficient.

Kollios et al. [126] developed a linear-space indexing scheme for moving points along a (1-D) line, based upon the notion of partition trees. Their structure supports a variety of range search and approximate

nearest neighbor queries. For example, given a range and time, the points in that range at the indicated time can be retrieved in  $O(n^{1/2+\epsilon} + k)$  I/Os, for arbitrarily small  $\epsilon > 0$ . Updates require  $O((\log n)^2)$  I/Os. Agarwal et al. [5] extend the approach to handle range searches in two dimensions, and they improve the update bound to  $O((\log_B n)^2)$  I/Os. They also propose an event-driven data structure with the same query times as the range search data structure of Arge and Vitter [25] discussed earlier, but with the potential need to do many updates. A hybrid data structure combining the two approaches permits a tradeoff between query performance and update frequency.

R-trees offer a practical generic mechanism for storing multidimensional points and are thus a natural alternative for storing mobile items. One approach is to represent time as a separate dimension and to cluster trajectories using the R-tree heuristics. However, the orthogonal nature of the R-tree does not lend itself well to diagonal trajectories. For the case of points moving along linear trajectories, Šaltenis et al. [170] build the R-tree upon only the spatial dimensions, but parameterize the bounding box coordinates to account for the movement of the items stored within. They maintain an outer approximation of the true bounding box, which they periodically update to refine the approximation. Agarwal and Har-Peled [11] show how to maintain a provably good approximation of the minimum bounding box with need for only a constant number of refinement events.

## 32.13 String and Text Algorithms

---

The simplest and most commonly used method to index text in large documents or collections of documents is the *inverted file*, which is analogous to the index at the back of a book. The words of interest in the text are sorted alphabetically, and each item in the sorted list has a list of pointers to the occurrences of that word in the text. In an EM setting, a hybrid approach makes sense, in which the text is divided into large chunks (consisting of one or more blocks) and an inverted file is used to specify the chunks containing each word; the search within a chunk can be carried out by using a fast sequential method, such as the Knuth–Morris–Pratt [125] or Boyer–Moore [46] methods. This particular hybrid method was introduced as the basis of the widely used GLIMPSE search tool [144]. Another way to index text is to use hashing to get small signatures for portions of text. The reader is referred to [31,88] for more background on the above methods.

In a conventional B-tree,  $\Theta(B)$  unit-sized keys are stored in each internal node to guide the searching, and thus the entire node fits into one or two blocks; however, if the keys are variable-sized text strings, the keys can be arbitrarily long, and there may not be enough space to store  $\Theta(B)$  strings per node. Pointers to  $\Theta(B)$  strings could be stored instead in each node, but access to the strings during search would require more than a constant number of I/Os per node. In order to save space in each node, Bayer and Unterauer [40] investigated the use of prefix representations of keys. Ferragina and Grossi [83,84] recently developed an elegant generalization of the B-tree called the *String B-tree* or simply *SB-tree* (not to be confused with the SB-tree [158] mentioned in Section 32.11). The query time to search in an SB-tree for a string of  $\ell$  characters is  $O(\log_B N + \ell/B)$ , which is optimal. Insertions and deletions can be done in the same I/O bound. Ferragina and Grossi [83,84] apply SB-trees to the problems of string matching, prefix search, and substring search. Ferragina and Luccio [85] apply SB-trees to get new results for dynamic dictionary matching; their structure even provides a simpler approach for the (internal memory) RAM model.

Tries and Patricia tries are commonly used as internal memory data structures for storing sets of strings. One particularly interesting application of Patricia tries is to store the set of suffixes of a text string. The resulting data structure, called a *suffix tree* [146,210], can be built in linear time and supports search for an arbitrary substring of the text in time linear in the size of the substring. A more compact (but static) representation of a suffix tree, called a *suffix array* [143], consisting of the leaves of the suffix tree in symmetric traversal order, can also be used for fast searching. (See [103] for general background.) Farach et al. [80] show how to construct SB-trees, suffix trees, and suffix arrays on strings of total length  $N$  using  $O(n \log_m n)$  I/Os, which is optimal. Clark and Munro [55] give a practical implementation of dynamic suffix trees that use about five bytes per indexed suffix. Crauser and Ferragina [63] present an extensive

set of experiments on various text collections in which they compare the practical performance of some novel and known suffix array construction algorithms.

Arge et al. [21] consider several models for the problem of sorting  $K$  strings of total length  $N$  in external memory. They develop efficient sorting algorithms in these models, making use of the SB-tree, buffer tree techniques, and a simplified version of the SB-tree for merging called the *lazy trie*.

**Theorem 32.13.1** [21] *The number of I/Os needed to sort  $K$  strings of total length  $N$ , where there are  $K_1$  short strings of total length  $N_1$  and  $K_2$  long strings of total length  $N_2$  (i.e.,  $N = N_1 + N_2$  and  $K = K_1 + K_2$ ), is*

$$O\left(\min\left\{\frac{N_1}{B} \log_m\left(\frac{N_1}{B} + 1\right), K_1 \log_M(K_1 + 1)\right\} + K_2 \log_M(K_2 + 1) + \frac{N}{B}\right) \quad (32.8)$$

Lower bounds for various models of how strings can be manipulated are given in [21]. There are gaps in some cases between the upper and lower bounds for sorting.

## 32.14 The TPIE External Memory Programming Environment

---

Three basic approaches are used for supporting development of I/O-efficient code, which we call *access-oriented*, *array-oriented*, and *framework-oriented*. TPIE falls primarily into the third category with some elements of the first category. Access-oriented systems preserve the programmer abstraction of explicitly requesting data transfer. They often extend the read-write interface to include data type specifications and collective specification of multiple transfers, sometimes involving the memories of multiple processing nodes. Examples of access-oriented systems include the UNIX file system at the lowest level, higher-level parallel file systems such as Whiptail [182], Vesta [60], PIOUS [150], and the high-performance storage system [209], and I/O libraries MPI-IO [59] and LEDA-SM [66].

Array-oriented systems access data stored in external memory primarily by means of compiler-recognized data types (typically arrays) and operations on those data types. The external computation is directly specified via iterative loops or explicitly data-parallel operations, and the system manages the explicit I/O transfers. Array-oriented systems are effective for scientific computations that make regular strides through arrays of data and can deliver high-performance parallel I/O in applications such as computational fluid dynamics, molecular dynamics, and weapon system design and simulation. Array-oriented systems are generally ill-suited to irregular or combinatorial computations. Examples of array-oriented systems include PASSION [189], Panda [179] (which also has aspects of access orientation), PI/OT [164], and ViC\* [57].

TPIE [22,191,197] provides a framework-oriented interface for batched computation as well as an access-oriented interface for online computation. Instead of viewing batched computation as an enterprise in which code reads data, operates on it, and writes results, a framework-oriented system views computation as a continuous process during which a program is fed streams of data from an outside source and leaves trails of results behind. TPIE programmers do not need to worry about making explicit calls to I/O routines. Instead, they merely specify the functional details of the desired computation, and TPIE automatically choreographs a sequence of data movements to feed the computation. The reader is referred to [199] for further discussion of TPIE and some examples of timing experiments in TPIE.

## 32.15 Dynamic Memory Allocation

---

The amount of internal memory allocated to a program may fluctuate during the course of execution because of demands placed on the system by other users and processes. EM algorithms must be able to adapt dynamically to whatever resources are available so as to preserve good performance [162]. The algorithms in the previous sections assume a fixed memory allocation; they must resort to virtual memory if the memory allocation is reduced, often causing a severe degradation in performance.

Barve and Vitter [37] discuss the design and analysis of EM algorithms that adapt gracefully to changing memory allocations. In their model, without loss of generality, an algorithm (or program)  $\mathcal{P}$  is allocated internal memory in phases: During the  $i$ th phase,  $\mathcal{P}$  is allocated  $m_i$  blocks of internal memory, and this memory remains allocated to  $\mathcal{P}$  until  $\mathcal{P}$  completes  $2m_i$  I/O operations, at which point the next phase begins. The process continues until  $\mathcal{P}$  finishes execution. We say that  $\mathcal{P}$  is *dynamically optimal*, no other algorithm can perform more than a constant number of sorts in the worst-case for the same sequence of memory allocations.

Barve and Vitter [37] define a precise model and give dynamically optimal strategies for sorting, matrix multiplication, and buffer tree operations. Previous work was done on memory-adaptive algorithms for merge sort [162,216] and hash join [163], but the algorithms handle only special cases and can be made to perform nonoptimally for certain patterns of memory allocation.

## 32.16 Conclusions

---

In this chapter, several useful paradigms for the design and implementation of efficient external memory (EM) algorithms and data structures were described. The problem domains we have considered include sorting, permuting, FFT, scientific computing, computational geometry, graphs, databases, geographic information systems, and text and string processing. Interesting challenges remain in virtually all these problem domains. One difficult problem is to prove lower bounds for permuting and sorting without an item indivisibility assumption. Another promising area is the design and analysis of EM algorithms for efficient use of multiple disks. Optimal bounds have not yet been determined for several basic EM graph problems like topological sorting, shortest paths, breadth-first and depth-first search, and connected components. There is an intriguing connection between problems that have good I/O speedups and problems that have fast and work-efficient parallel algorithms. Several problems remain open in the dynamic and kinetic settings, such as range searching, ray shooting, point location, and finding nearest neighbors.

A continuing goal is to develop optimal EM algorithms and to translate theoretical gains into observable improvements in practice. For some of the problems that can be solved optimally up to a constant factor, the constant overhead is too large for the algorithm to be of practical use, and simpler approaches are needed. In practice, algorithms cannot assume a static internal memory allocation; they must adapt in a robust way when the memory allocation changes.

Many interesting challenges and opportunities in algorithm design and analysis arise from new architectures being developed, such as networks of workstations and hierarchical storage devices. Active (or intelligent) disks, in which disk drives have some processing capability and can filter information sent to the host, have recently been proposed to further reduce the I/O bottleneck, especially in large database applications [3,167]. MEMS-based nonvolatile storage has the potential to serve as an intermediate level in the memory hierarchy between DRAM and disks. It could ultimately provide better latency and bandwidth than disks, at less cost per bit than DRAM [178,198].

## Acknowledgments

### 33.1 Introduction

---

The I/O system is a critical bottleneck for many modern data-intensive applications. The demand for greater storage capacity and high-speed access to stored data is growing rapidly. Disks, the most common secondary-storage medium in use today, have shown remarkable improvements in capacity and performance over the past decade. Innovations in disk technology have resulted in higher recording densities, smaller form factors, increased spindle speeds, and the increased availability of multi-zoned disks with variable transfer rates. Nonetheless, the storage requirements of modern applications is growing at an even faster rate, exceeding the impressive capacity of modern disk drives, and necessitating the use of multiple storage devices. Simultaneously the I/O rates required by these applications has outstripped the data rates that can be provided by single disks, despite the very significant improvements that have been made.

Consider as one example the growing use of digital multimedia in diverse applications ranging from entertainment and education to medicine and commerce. Multimedia or multimedia-enhanced applications routinely manipulate digitized images and video and audio data, requiring tremendous amounts of storage capacity, and placing stringent real-time constraints on the delivery rate to ensure smooth playback. A single hour-long MPEG-compressed video stream recorded at a rate of 4 Mbits/s, would require almost 2 GB of storage. A storage system with hundred or thousands of such clips would require several storage devices, perhaps a combination of disks to keep the more popular clips online, and slower tertiary tape storage to archive less popular video streams. The data transfer rate of a single disk is able to support the real-time retrieval of at most a few tens of concurrent streams, and the capacity decreases with increased video resolution and playback speeds. Analogous issues arise in other applications like real-time databases [47] where large numbers of sensory inputs need to be continually monitored and logged in an event database; critical events in turn may trigger the execution of data analysis routines that need to be complete within stipulated time bounds, placing a tremendous strain on the I/O subsystem.

Spatial databases in geographic information systems [7], temporal and kinetic databases that track the evolution or movement of objects in time [2,47], Web and application servers, graphics and visualization, and data mining systems, are other examples of the growing list of data-centric applications requiring the use of parallel I/O [1]. Even in compute-intensive domains like scientific computing applications, the scale of problems being addressed necessitates the use of advanced data management techniques, including the use of concurrent I/O to achieve acceptable performance [41].

## 33.2 Parallel I/O Organization

---

In this chapter, a parallel I/O system will refer to a disk-based I/O subsystem, made up of multiple disk drives that can access their data in parallel. Within this broad framework, different parallel I/O organizations are conceivable and supported by different vendors. RAID (an acronym that now stands for redundant array of independent disks) systems provide increased storage capacity and bandwidth by incorporating multiple disk drives within a single storage unit, and employ fault-tolerance mechanisms to cope with the increased failure probability stemming from the use of multiple devices [15]. Different RAID organizations (traditionally referred to as RAID levels) using different redundancy techniques to achieve fault tolerance have been proposed. RAID 1 uses data mirroring, whereby the entire disk contents are mirrored on an additional disk. RAID 4 and RAID 5 systems (RAID 5 is probably the most popular organization used in practice), employ the concept of a parity block to achieve fault tolerance. The multiple-disk system is viewed as a collection of stripes. A stripe consists of a block from each disk. One block of each stripe is designated as a parity block; it stores the bitwise exclusive-or of the corresponding bits of each of the other blocks in that stripe. In the event of a single-disk failure, the blocks on the failed disk can be reconstructed from the blocks in the same stripe on the working disks. The storage overhead for fault-tolerance is much less than the 100% redundancy of RAID 1 systems. The penalty, however, is the increased time for a write, since an update to a data block requires a read-modify-write operation on the parity block as well. A RAID 4 system uses a single designated disk to hold the parity blocks of all the stripes. In RAID 5 the use of a roving parity block, that associates different parity disks for different stripes, alleviates the potential parity-disk bottleneck of a RAID 4 design. Other RAID organizations have been since proposed. RAID 6 systems permit the failure of up to two disks without incurring any loss of data; these systems either use two parity blocks with differently computed parities, or employ a two-dimensional arrangement of disks with associated row and column parities. RAID 0 does not provide any fault tolerance, but allows data to be striped across multiple disks thereby allowing high-bandwidth transfers to and from the disks. Hybrid combination like RAID 10 and RAID 53 attempt to combine the advantages of different RAID levels in a hybrid architecture [51].

The interconnection between the disk system and the server is also undergoing changes to facilitate the increasingly parallel and distributed nature of storage systems. Traditional disk architectures use bus-based interconnects like the small computer system interconnect (SCSI) to connect a set of devices to the host [53]. A SCSI interconnect permits only a small number (7 or 15 depending on the SCSI protocol level) of devices to be connected to a single controller using the shared bus. The maximum transfer rate is small, starting at 5 MB/s for the original SCSI-1 protocol up to 40 MB/s for UltraSCSI.

More scalable I/O architectures are based on the use of switched interconnections. The high performance parallel interface (HIPPI) [29] defines a point-to-point interconnection, with high speed peak data transfer rates of 100 MB/s (HIPPI-800) to 800 MB/s (HIPPI-6400). Multiple devices are interconnected using a cross-point switch. Fiber channel refers to a set of standards [25] being developed by the American National Standards Institute (ANSI) that allows for an active intelligent interconnection scheme, called a fabric, to connect devices. It attempts to combine both network-oriented communication methods and dedicated hardware-based channel communication into a single I/O interface for both channel and network users. Different fiber channel topologies are supported including point-to-point, cross-point switched, or an arbitrated loop (or ring topology) network. Fiber channel supports its own protocol, as well as higher level protocols such as the FDDI, SCSI, HIPPI, and IPI, enhancing its versatility, but increasing the potential compatibility problems as well. The fibre channel standard addresses the

need for fast transfers, up to 1 Gbits/s, of large amounts of information. Other emerging interconnect standards include the switched InfiniBand architecture, a synthesis of formerly competing System I/O and NextGeneration I/O proposals, with projected peak bidirectional rates of up to 6 GB/s [30].

Another trend in I/O organizations is the decentralization of storage devices [24,45]. Storage area networks (SAN) and network-attached storage devices (NASD) are two such directions towards reducing the tight coupling between servers and devices in traditional I/O architectures. In a SAN, multiple servers and devices are connected together by a dedicated high-speed network different from, and in addition to, the local area network (LAN) connecting the servers and clients. Data transfer between a server and a device occurs over this dedicated back-end network. Networked storage architectures have several potential benefits. They facilitate sharing of disk-resident data between multiple servers by avoiding the three-step process (read I/O, network transfer, write I/O) required in transferring data on traditional server-hosted I/O architectures. Furthermore, they permit autonomous data transfer between devices simplifying backup and data replication for performance or reliability, and encourage the spatial distribution of devices on the network, while maintaining the capability for centralized management. A network-attached storage device [26] allows many of the server functions to be offloaded directly to the device. Once a request is authenticated by the server and forwarded to the device, data transfer to the network proceeds independently without further involvement of the server. In principle a NASD can be directly connected to the LAN or may serve as an independent module in a back-end SAN.

Highly parallel I/O organizations with high-bandwidth interconnections that have the capability of supporting hundreds of concurrent I/O transfers are a characteristic of current and evolving I/O architectures. The physical realization in terms of interconnection and communication protocols, redundancy and fault-tolerance, and balance between distribution and centralization of resources are a continuing topic of current research. Complex issues dealing with cost, performance, reliability, interoperability, security, and ease of configuration and management will need to be resolved, with perhaps different configurations suitable in different application domains.

Whatever the physical manifestation, managing hundreds of concurrent I/O devices in order to fully exploit their inherent parallelism and high interconnection bandwidth is a challenging problem. To study the issues at a high level, configuration-independent abstract models such as the parallel disk model (PDM) [58] have been proposed. Two extremes of logical I/O organizations based on the memory buffer can be identified: in a shared-buffer organization there is a centralized memory buffer shared by all the disks, and all accesses are routed through the buffer. In a distributed-buffer organization each disk has a private buffer used exclusively to buffer data from that disk. The shared configuration has the potential to make better use of the buffer space by dynamically changing the portion of the buffer devoted to any disk based on the load. In contrast, the performance of the distributed configuration can be limited by a few heavily loaded disks. Hybrid configurations are possible as in a logically shared but physically partitioned buffer. Such an architecture provides the scalability and modularity inherent in having distributed resources while providing increased resource utilization due to sharing.

### 33.3 Performance Model for Parallel I/O

---

Parallel I/O systems have the potential to improve I/O performance if one can exploit disk parallelism by performing multiple concurrent I/Os; however, it is a challenging problem to successfully exploit the available disk bandwidth to reduce application I/O latency. According to increasing evidence, traditional disk management strategies can severely under-utilize available bandwidth and therefore do not scale well, leading to excessive I/O service time. As a consequence, several new algorithms for managing parallel I/O resources, with the explicit intention of exploiting I/O parallelism have been recently advanced [5,11,32–36,50,57].

The performance of a parallel I/O system is fundamentally determined by the pattern of disk accesses. The simplest form of data access, sequential reading of a file, represents the canonical application that can benefit from parallel I/O. Disk striping provides the natural solution for such an access pattern. The file is broken into blocks, and the blocks are placed in a round-robin fashion on the  $D$  disks, so that every  $D$ th block is placed on the same disk. A main memory buffer of  $D$  blocks is used. In each I/O an entire stripe

of  $D$  consecutive blocks, one block from each disk, is read into the memory buffer. The number of I/O steps is reduced by a factor of  $D$  over sequentially accessing the file from a single disk. Despite its simplicity, disk striping is not the best solution for most other data access problems. For instance, generalizing the above problem to concurrently read  $N$  sequential files, a disk-striping solution would read  $D$  blocks of a single file in each I/O. The total buffer space required in this situation is  $ND$  blocks. A more resource-efficient solution is to perform concurrent, independent read I/Os on the different disks. In one parallel I/O, blocks from  $D$  different files are fetched from the  $D$  disks; this requires only  $1/D$ th the buffer of a disk striping solution if the blocks are consumed at the same rates. In fact, if the blocks are consumed at a rate comparable to the I/O time for a block, then by using independent I/Os only  $\Theta(D)$  blocks of buffer suffice.

In contrast to the uniform access patterns implied by the previous examples, a skewed data access pattern results in hot spots, in which a single disk is repeatedly accessed in a short time period. The bandwidth of the multiple-disk system is severely underutilized in this situation, and the performance degrades to that of a single disk. Consider, for instance, the retrieval of constant data length (CDL) video data, in which the frames are packed into fixed-size data blocks; the blocks are then placed on the disks using either striped, random, or other disk allocation policy. If a number of such streams are read concurrently, the access pattern consists of an interleaving of the blocks that depends on the playback times of the blocks. For constant-bit rate (CBR) video streams the playback time of a block is fixed, and (assuming striped allocation) the accesses are spread uniformly across the disks as in the example on multiple file access. In the case of variable bit rate (VBR) video data streams, the accesses are no longer uniformly distributed across the disks, but depend on the relative playback times of each of the blocks. Consequently, both the load on a disk and the load across the disks varies as a function of time. In this case, simply reading the blocks in the time-ordered interleaving of blocks, may no longer maximize the disk parallelism, and more sophisticated scheduling strategies are necessary to maximize the number of streams that can be handled by the I/O system [22].

The abstract model of the I/O system that will be used to analyze the quality of different schedules is based on the PDM [58]: the I/O system consists of  $D$  independent disks, which can be accessed in parallel, and has a buffer of capacity  $M$ , through which all disk accesses occur. The computation requests data in blocks—a block is the unit of disk access. The I/O trace of a computation is characterized by a reference string, which is an ordered sequence of I/O requests made by the computation. In serving a reference string the buffer manager determines which blocks to fetch and when to fetch them so that the computation can access the blocks in the order specified by the reference string. The computation waits for data from the I/O system only when the data are not available in the buffer. Additionally, when an I/O is initiated on one disk, blocks can be concurrently fetched from other disks. The number of parallel I/Os that are issued is a measure of performance in this model. Because the buffer is shared by all disks it is possible to allocate buffer space unevenly to different disks to meet the changing load on different disks. The PDM assumes unit time I/Os. In many applications like those dealing with streaming data, data logging or in several scientific computations, where large block sizes are natural, this is a viable and useful idealization. In these situations, the number of I/Os has a direct relationship to the I/O time. In other cases where requests are for small amounts of data and access times are dominated by the seek and rotational latency components, no analytical models are widely applicable. In these cases, empirical evaluations need to be employed in estimating performance [19,23].

### 33.4 Mechanisms for Improving I/O Performance

---

Prefetching and caching are two fundamental techniques that are employed for increasing I/O performance. Prefetching refers to the process of initiating a read from a disk before the computation demands the data. In a parallel I/O system, while a read progresses on one disk, reads can be started concurrently on other disks to prefetch data that are required later. These prefetched blocks are held in the I/O buffer till needed. In this way a temporary concentration of accesses to a small subset of the disks is tolerated by using the time to prefetch from the disks that are currently idle; when the locality shifts to the latter set of disks, the required data are already present in the buffer.

In contrast to prefetching that masks disk latencies by overlapping the access with that of I/Os to other disks, caching attempts to exploit temporal locality in the accesses. A selected subset of the recently accessed blocks are held in the I/O buffer in the expectation that they will be referenced again soon, thereby avoiding repeated disk accesses for the same block. Although both prefetching and caching are well-known techniques employed ubiquitously in computer systems and networking, deploying these mechanisms effectively in a parallel I/O system raises a unique set of challenges.

The I/O schedule determines the set of blocks that are fetched in each parallel I/O operation. The schedule is constructed dynamically so as to minimize the total number of parallel I/Os. This requires the scheduler to decide which blocks to prefetch, and, when the need for replacement arises, to decide which blocks in the buffer to cache and which to evict. Prefetching and caching in parallel I/O systems is fundamentally different from that in systems with a single disk, and requires the use of substantially different algorithms [11,32–36]. In a single-disk system, prefetching is used to overlap I/O operations with CPU computations. This is usually done using asynchronous I/O whereby a computation continues after making the I/O request without blocking. A stall model for analyzing the performance of overlapped I/O and computation was proposed in [17] for a single disk system; prefetching and caching algorithms to minimize stall time as a function of CPU and I/O speeds were presented in [5,17]. Disk scheduling algorithms that reorder I/O requests to minimize the disk seek times [59] can also be considered as a form of prefetching in single-disk systems.

In parallel I/O systems prefetching allows overlap between accesses on different disks thereby hiding the I/O latency behind the access latency on some other disk. The scheduler has to judiciously decide on questions like how much buffer to allocate for prefetching and how much for caching, which blocks to prefetch, and which blocks to cache. For instance, to utilize the available bandwidth, it may appear desirable to keep a large number of disks busy prefetching data during an I/O; however, excessive prefetching can fill up the buffer with blocks, which may not be used until much later in the computation. Such blocks have the adverse effects of choking the buffer and reducing the parallelism in fetching more immediate blocks. In fact, even when the problem does not involve the use of caching, the decisions of which blocks to prefetch and when to do so is not trivial.

Another issue needs to be addressed to employ prefetching and caching effectively. In order to prefetch accurately (rather than speculatively) some knowledge of future accesses is required. This is embodied in the notion of lookahead, which is a measure of the extent of knowledge about the future accesses that is available in making prefetching and caching decisions. Obtaining this lookahead has been the area of much active research [13,40,43,50]. In some applications like external sorting the lookahead can be obtained dynamically by using a sample of the data to accurately predict the sequence of block requests [10]. In video retrieval the sequence is determined by the playback times of blocks in the set of concurrently accessed streams; summary statistics of the streams are used to obtain the lookahead at run time [22]. Indexes in database systems can similarly be used to provide information about the actual sequence of data blocks that must be accessed. In broadcast servers the set of requests are prioritized by the system to maximize utilization of the broadcast channel [4]; the prioritized request sequence provides the lookahead for required I/O accesses. Access patterns can be revealed to the system either using programmer provided hints [50], or the system may attempt to uncover sequential or strided access patterns automatically at run time [40]. Speculative execution is another technique based on executing program code speculatively to determine the control path and the blocks accessed in the path [13].

### **33.5 Limitations of Simple Prefetching and Caching Strategies**

---

In [11,32], the problem of scheduling read-once reference strings, in which each block is accessed exactly once, was considered. Such reference strings are characteristic of streaming applications like multimedia retrieval. Simple intuitive algorithms that work well in a single-disk scenario were analyzed and shown to have poor performance in the multiple-disk case. For instance, consider a natural scheduling algorithm

that we refer to as *aggressive prefetching*. In each I/O, the next block required from each disk is fetched provided there is enough free buffer space; if not then only the block demanded immediately by the computation is read. Such an aggressive prefetching scheme, while intuitively attractive, can be shown to have poor worst-case as well as average-case performance. There exist worst-case reference strings for which aggressive prefetching can perform  $\Theta(D)$  times as many I/Os as the optimal scheduling strategy [11]. In the average case, when the accesses are assumed to be randomly distributed across the disks with independent uniform probability, it has been shown that reading a reference string of length  $N$  requires  $\Theta(N/D)$  I/Os using a buffer of size  $\Omega(D^2)$  blocks [48].

The problem with aggressive prefetching is that it prefetches too deep on some disks, holding up buffer space that could better be used in fetching more immediately required blocks. A simple heuristic to correct for this is to place a bound on the depth of prefetching. One such attractive policy is to always give priority to a block that is required earlier in the reference string over one that is accessed later, whenever there is insufficient buffer space to hold both blocks. Intuitively this scheme tries to keep all disks busy by fetching greedily, but prevents blocks that are prefetched very much earlier than their time of usage from holding up buffer space that can be used by other more urgently needed blocks. This greedy algorithm is referred to as earliest required first (ERF) prefetching.

Consider the following example of an I/O system with three disks and an I/O buffer of capacity 6. Let the blocks labeled  $a_i$  (respectively  $b_i, c_i$ ) be placed on disk A (respectively B, C), and the reference string be

$$a_1 \ a_2 \ a_3 \ a_4 \ b_1 \ c_1 \ a_5 \ b_2 \ c_2 \ a_6 \ b_3 \ c_3 \ a_7 \ b_4 \ c_4 \ c_5 \ c_6 \ c_7$$

Figure 33.1(a) shows the I/O schedule constructed by the ERF algorithm described above. In the first step blocks  $a_1, b_1,$  and  $c_1$  are fetched concurrently in one I/O. When block  $a_2$  is requested, blocks  $a_2, b_2,$  and  $c_2$  are fetched in parallel in step 2. Subsequently the buffer contains five blocks:  $a_2, b_1, b_2, c_1,$  and  $c_2$ . Next when  $a_3$  is requested, an I/O needs to be done to fetch it; however, there is buffer space for only one additional block besides  $a_3$ , and the choice is between fetching  $b_3, c_3,$  or neither. Fetching greedily in the order of the reference string means that we fetch  $b_3$ . Continuing in this manner we obtain a schedule of length 9. Figure 33.1(b) presents an alternative schedule for the same reference string. The first two steps in the schedule are identical to the previous case. In step 3,  $c_3$  that occurs after  $b_3$  is prefetched; and in step 4,  $c_4$  is fetched by evicting  $b_2$  even though  $c_4$  is referenced only after  $b_4$ ; however, by doing so the overall length of the schedule is reduced to 7, better than the previous schedule.

Disk A	$a_1$	$a_2$	$a_3$	$a_4$	$a_5$	$a_6$	$a_7$		
Disk B	$b_1$	$b_2$	$b_3$		$b_4$				
Disk C	$c_1$	$c_2$			$c_3$	$c_4$	$c_5$	$c_6$	$c_7$

(a)

Disk A	$a_1$	$a_2$	$a_3$	$a_4$	$a_5$	$a_6$	$a_7$
Disk B	$b_1$	$b_2$			$b_2$	$b_3$	$b_4$
Disk C	$c_1$	$c_2$	$c_3$	$c_4$	$c_5$	$c_6$	$c_7$

(b)

FIGURE 33.1 (a) Greedy ERF schedule. (b) Optimal schedule.

The ERF algorithm was analyzed in [11]. It was shown that there exist reference strings for which ERF will perform  $\Theta(\sqrt{D})$  times as many I/Os as the optimal schedule. For the average case, under the same assumptions as for aggressive prefetching, it can be shown that ERF can read an  $N$  block reference string in  $\Theta(N/D)$  I/Os using a buffer of size  $\Omega(D \log D)$  blocks [10]. Hence, although ERF improves upon aggressive prefetching, it does not construct the optimal-length schedule.

In the previous discussion all blocks were implicitly assumed to be distinct. Such reference strings are called read-once and are characteristic of streaming applications like multimedia retrieval. General reference strings where each block can be accessed repeatedly introduce additional issues related to caching. In particular, decisions need to be made regarding which blocks to evict from the buffer. In a single-disk system the optimal offline caching strategy is to use the MIN algorithm [12] that always evicts the block whose next reference is furthest in the future; however, it is easy to show that using this policy in a multiple-disk situation does not necessarily minimize the total number of parallel I/Os that are required. In fact, there exist reference strings for which the use of the MIN policy necessitates  $\Theta(D)$  times as many I/Os as an optimal caching strategy [34].

### 33.6 Optimal Parallel-Disk Prefetching

---

In this section we present an *online* prefetching algorithm L-OPT for read-once reference strings. L-OPT uses  $L$ -block lookahead; at any instant L-OPT knows the next  $L$  references, and uses this lookahead to determine blocks to fetch in the next I/O. It uses a priority assignment scheme to determine the currently most useful blocks to fetch and to retain in the buffer. As the lookahead window advances and information about further requests are made available, the priorities of blocks are dynamically updated to incorporate the latest information. When considered as an offline algorithm for which the entire reference string is known in advance, it has been shown that L-OPT is the optimal prefetching algorithm that minimizes the number of parallel I/Os [32].

L-OPT is a priority-controlled greedy prefetching algorithm. A priority-controlled greedy prefetching scheme provides a general framework for describing different prefetching algorithms. Blocks in the lookahead are assigned priorities depending on the scheduling policy in effect. The scheduler fetches one block each from as many disks as possible in every I/O, while ensuring that the buffer never retains a lower-priority block in preference to fetching one with a higher priority, if necessary by evicting the lower-priority blocks. Algorithm priority-controlled greedy I/O describes the algorithm formally using the definitions below.

Different prefetching policies can be implemented using this framework merely by changing the priority function. For instance, to implement the ERF prefetching algorithm the priority of blocks should decrease with their position in the reference string. This is easily achieved if the priority function assigns the  $i$ th block in the reference string a priority equal to  $-i$ . Similarly, prefetching strategies akin to aggressive prefetching can be emulated by assigning the  $i$ th referenced block from each disk a priority of  $+\infty$  if it is the demand block and  $-i$  otherwise.

#### Definitions

1. Let  $\Sigma = b_1, b_2, \dots, b_n$  denote the reference string. If  $b_i$  is a block in the lookahead, let  $disk(b_i)$  denote the disk from which it needs to be fetched and let  $priority(b_i)$  be the block's priority.
2. At the instant when  $b_i$  is referenced, let  $B_i$  denote the set of blocks in the lookahead that are present in the buffer.
3. When  $b_i$  is referenced, let  $H_i$  be the maximal set of (up to)  $D$  blocks, such that if  $b \in H_i$  then priority of  $b$  is the largest among all blocks from  $disk(b)$  in the lookahead but not present in the buffer.
4. Let  $B_i^+$  be the maximal set of (up to)  $M$  blocks with the highest priorities in  $H_i \cup B_i$ ; in the case of ties the block occurring earlier in  $\Sigma$  is preferred.

## Algorithm Priority-Controlled Greedy I/O

On a request for a block,  $b_i$ , the algorithm takes the following actions.

If  $b_i$  is present in the buffer then no I/O is necessary.

If  $b_i$  is not present in the buffer then

- update priorities of blocks using blocks revealed since the last I/O;
- accommodate the blocks to be read in, evict the blocks in  $B_i - B_i^+$ ; and
- initiate an I/O to fetch the blocks in  $H_i \cap B_i^+$ .

Service the request for block  $b_i$ .

Implementing the priority-controlled greedy I/O algorithm can be done using a simple forecasting data structure similar to that in [10], to maintain the list of blocks with highest priority on each disk. On a hit in the buffer, the algorithm does not need to do any bookkeeping. When the requested block is not present in the buffer the algorithm needs to find the set of blocks to fetch and the corresponding set of blocks to evict from the buffer. If we have all the blocks in the buffer maintained and sorted in order of their priorities, then we can choose the  $D$  blocks to fetch and evict in  $O(M + D)$  time. With standard linked data structures, logarithmic update times are sufficient for these operations.

In contrast to the static priority assignments for ERF and aggressive prefetching, the priority function of the optimal algorithm L-OPT depends on the relative distribution of the load on different disks. Furthermore, as more lookahead is revealed, the previously assigned priorities of blocks may change as a result of the new information. At any time, the blocks in the lookahead are partitioned into two subsequences called the current and future window, respectively. At the start all blocks in the lookahead are in the current window and the future window is empty. As new blocks are revealed they are added to the future window. When the last block of the current window is referenced, the future window becomes the current window and a new (empty) future window begins. The priorities of blocks in the current window are fixed at the time the window became current, and do not change; however, the priorities of blocks in the future window are updated to reflect new additions. All blocks in the future window have priorities less than that of any block in the current window.

The priority assignment routine used by L-OPT to determine the priorities of blocks in a given piece of the reference string is described below. At any instant the priority of a block is a reflection of how urgently that block must be fetched. The lower the priority of a block, the later it can be fetched. The central idea is to set the priority of a block as low as possible, subject to two constraints. Blocks from the same disk are assigned priorities in order of their reference. Second, no block can have such a low priority that  $M$  or more blocks referenced after it have a higher or same priority. In the routine below the variables *lowestPriorityOnDisk*[ $d$ ] and *lowestPriority* track the smallest priority that can be assigned to a block without violating the two constraints. The former is incremented whenever a block is placed on disk  $d$ . The variable *lowestPriority* is incremented whenever  $M$  blocks with priority *lowestPriority* or higher have been placed. A block is assigned the larger of these two priorities.

### L-OPT: Priority Assignment

Assign priorities to blocks  $\langle b_1, b_2, \dots, b_n \rangle$  of the reference string.

Initialize

- lowestPriority* to 1
- numberOfBlocksPlaced* to 0
- lowestPriorityOnDisk*[1... $D$ ] to 0
- blocksWithPriority*[1... $n$ ] to 0

for  $i$  from  $n$  down to 1

- if (*lowestPriority* > *lowestPriorityOnDisk*(*disk*( $b_i$ ))) then assign
  - lowestPriorityOnDisk*(*disk*( $b_i$ ))  $\leftarrow$  *lowestPriority*
  - assign *priority*( $b_i$ )  $\leftarrow$  *lowestPriorityOnDisk*(*disk*( $b_i$ )))

```

increment lowestPriorityOnDisk(disk( $b_i$ ))
increment blocksWithPriority(priority( $b_i$ ))
increment numberOfBlocksPlaced
if (numberOfBlocksPlaced =  $M$ ) then
    decrement numberOfBlocksPlaced by blocksWithPriority(lowestPriority)
    increment lowestPriority

```

By using the priority assignment described here, it has been shown that L-OPT always creates a schedule that is within a factor  $\Theta(\sqrt{MD/L})$  times the length of the schedule created by the optimal *offline* algorithm, and that this is the best possible ratio. In addition, L-OPT's schedule is never more than twice the length of that created by any *online* algorithm (including algorithms that consistently make fortuitously correct guesses) that has the same amount of lookahead. Finally, note that if the entire reference string is known in advance, then L-OPT is the optimal offline algorithm [32].

### 33.7 Optimal Parallel-Disk Caching

---

For general reference strings where blocks may be repeatedly accessed, the buffer manager must decide which blocks to cache and which to evict. As noted earlier, the optimal single-disk caching policy embodied in the MIN algorithm can be decidedly suboptimal in the parallel I/O case. Prefetching and caching need to harmoniously cooperate in the multiple-disk situation. The caching problem has been studied by several researchers in the recent past for different I/O organizations. For a distributed-buffer configuration where each disk has its own private buffer, an algorithm P-MIN that generalizes MIN to multiple disks was shown to be optimal [57]. P-MIN uses the furthest forward reference policy on each disk independently to determine the eviction candidate for that disk. It initiates an I/O only on demand; in the ensuing I/O operation it prefetches aggressively from every disk unless the reference to the block to be prefetched is further than the references of all blocks currently in that buffer. For a shared-buffer configuration in the stall-model of computation, a sophisticated near-optimal algorithm called Reverse-Aggressive to minimize the stall time was proposed and analyzed in [36].

Recently, an optimal prefetching and caching algorithm, SUPERVISOR, for the parallel disk model was presented in [34]. Like the L-OPT algorithm for prefetching, SUPERVISOR uses the general framework of priority-controlled greedy I/O. The scheme for assigning priorities to references is, however, considerably more complex than that used by L-OPT for read-once reference strings. Just as a low priority with respect to prefetching indicates that an I/O for that block can be delayed, a low priority with respect to caching indicates that the block can be evicted from the buffer.

Intuitively, SUPERVISOR assigns priorities in accordance with two principles: issue prefetches for blocks close to their reference so that they do not wastefully occupy buffer space, and avoid caching a block if there is any later free I/O slot available, which can be used to fetch it. Among possible candidates for a block to cache, it is desirable to cache a block that will occupy the buffer for a smaller duration. Hence, the question to be answered is: Given that at some time we would like two previously referenced blocks in the buffer, which of these should have been cached and which should be fetched now? It is preferable to cache the block whose previous reference is closer to the current time, as this reduces the buffer pressure between the two previous accesses. SUPERVISOR uses this intuition to assign priorities to blocks for prefetching and caching.

The formal details of the priority assignment algorithm used by SUPERVISOR are presented in [34]. The routine examines subsets of the lookahead consisting of  $M$  distinct references and then assigns priorities to one block from each disk. The idea behind the assignment can be understood by considering the largest subsequence of the lookahead including the last reference and having at most  $M$  distinct references. All blocks which are assigned the smallest priority should belong to this set. Otherwise there will be some reference such that  $M$  or more blocks referenced after it have a higher, or same priority. Which among these blocks should have the lowest priority? The lowest priority can be assigned to, at most, one distinct reference from each disk. Additionally, among two blocks from the same disk, this priority is assigned to the block with the previous reference outside this subsequence is earlier, because we would rather not

cache this block. It is shown in [34] that SUPERVISOR, which assigns priorities based on the above principle is the optimal offline algorithm for parallel prefetching and caching in the parallel disk model.

### 33.8 Randomized Data Placement

---

Randomizing the placement of blocks on the disks of a parallel I/O system is a method to reduce I/O serialization caused by hot spots [10,11,33,35,37,52,55]. If blocks are distributed on the disks randomly then the maximum number of accesses to a single disk in any sequence of requests can be bounded with high probability. There are two potential benefits of randomized placement: the amount of memory buffer required to smooth out the imbalance in disk accesses is greatly reduced, and good performance can be achieved using simpler prefetching and caching algorithms.

In a randomized data placement scheme each block is placed on any of the  $D$  disks with a uniform probability  $1/D$ . The performance of two simple prefetching algorithms using randomized placement has been analyzed in [10,33]. Using the results of [46], aggressive prefetching was shown to read a reference string of  $N$  blocks in an expected number  $\Theta(N/D)$  I/Os using a buffer of size  $\Theta(D^2)$  blocks [32]. Note that  $\lceil N/D \rceil$  is the minimum number of I/Os needed to read  $N$  blocks, so the scheme performs within a constant factor of the minimum possible number of I/Os. The performance of ERF that gives preference to blocks that occur earlier in the reference string was analyzed in [10] and shown to require an expected  $\Theta(N/D)$  I/Os using a smaller buffer, of size  $\Theta(D \log D)$  blocks. In an online situation the two prefetching algorithms require different lookahead information. The aggressive prefetching algorithm only needs to know the ordered sequence of accesses to be made from each disk independently. The greedy priority-based algorithm needs to know the global ordering of accesses across the disks. In some applications like external merging for instance, the global ordering can be inferred from the local ordering by using a small amount of preprocessing [10].

Recently, it was shown how randomized placement coupled with data replication can be used to improve I/O performance [37,50,55], particularly in [37] where two copies of each block are allocated randomly to the disks. A scheduling algorithm decides which of the copies should be read in an I/O. It was shown that  $N$  blocks can be read in  $\lceil N/D \rceil + 1$  I/Os with high probability, using only  $\Theta(D)$  blocks of buffer storage [52].

For general reference strings a simple caching and prefetching algorithm that can be used in conjunction with randomized data placement was presented in [35]. The algorithm uses the ERF policy for prefetching and a variant of the least recently used buffer replacement policy to handle evictions. It was shown that the expected number of I/Os performed by this algorithm is within a factor  $\Theta[\log D/\log(\log D)]$  of the number of I/Os performed by an optimal scheduling algorithm.

Randomized data placement can generally provide good expected performance using less buffer memory and simpler disk management algorithms than those required to deal with worst-case data placements.

### 33.9 Out-of-Core Computations

---

Out-of-core computation deals with the problems of solving computational problems that are too large for the entire data set to fit in primary memory. Although the virtual memory mechanisms of modern operating systems can handle the problem transparently by paging the required data in and out of main memory on demand, the performance of such a solution is usually poor. Improved performance is achieved by optimizing the algorithm to be sensitive to the constraints of the I/O subsystem. The computation should be structured to provide spatial locality using data clustering, accesses should be organized to expose temporal locality, and declustering should be used to exploit the parallelism provided by the underlying I/O system. In many cases traditional in-core algorithms that deal with minimizing the number of computations without explicit consideration of the data access costs perform poorly when the data is disk-resident, necessitating the development of new algorithms or requiring radical restructuring of the known algorithms to achieve good I/O performance.

External or out-of-core algorithms using parallel data transfers can be traced to the work by Aggarwal and Vitter [3], generalizing earlier models, which dealt with sequential or nonblocked data transfers. The model used in that work was more powerful than the PDM that models multiple-disk systems. A number of out-of-core algorithms for external sorting, computational geometry, FFT data permutations, linear algebra computations, scientific codes, and data structures for indexing complex multidimensional data have since been developed [1–3,9,20,21,27,46,56,58]. The reader is referred to [1] and the references therein for a comprehensive bibliography and discussion of these works.

Run-time environments to increase efficiency and simplify the programming effort in applications requiring parallel I/O has been addressed by several research groups [6,8,14,16,18,28,31,38,39,42,44,54]. For a detailed discussion of the different proposals the reader is referred to [41,49].

## 33.10 Conclusion

---

Parallel I/O systems consisting of multiple concurrent devices are necessary to handle the storage and bandwidth requirements of modern applications. Parallel I/O hardware and interconnection technology will continue to evolve to meet the growing demands. New algorithms and system software are essential to effectively manage the hundreds of richly interconnected concurrent devices. Caching and prefetching are two fundamental techniques to improve data access performance by exploiting temporal locality and latency hiding. In a parallel I/O system using these mechanisms effectively involve challenging issues, which have been extensively studied over the past few years. These have resulted in the design of optimal algorithms for prefetching and caching, techniques to obtain lookahead of the I/O accesses, external algorithms for important problems, and file system and I/O primitives to support parallel I/O. As systems grow larger and more complex, challenging problems to control and manage the parallelism automatically and effectively will continue to be explored. Building on the fundamental understanding of what works and the algorithms required to control them, tools to automatically perform configuration, dynamic declustering, replication, prefetching, and caching will continue to be developed. Finally, although this chapter deals primarily with disk I/O, it can be readily seen that many of the issues transcend device specificity and apply in more general contexts dealing with managing and processing multiple concurrent I/O streams, using limited storage and bandwidth resources, as in embedded system environments.

A steady increase in recording densities and data rates of magnetic hard drives during last 15 years are mostly due to advances in recording materials, read/write heads, and mechanical designs. The role of signal processing and coding has been to make the best use of the capacity and speed potentials offered by these advances. As the recording technology matures, the read channel is becoming more and more

advanced, reaching the point where it uses equally or even more complicated signal processing, coding and modulation algorithms than any other telecommunication channel and where, due to the speed, power consumption, and cost requirements, the challenges in implementing new architectures and designs have been pushed to today's integrated circuit manufacturing technology limits.

This chapter reviews advanced signal processing, modulation, coding techniques, and architectures for magnetic recording read channel. In the most general terms, the *read channel* controls the reading and writing the data to/from magnetic medium (unjustifiably the “write” part has disappeared from its name). The operations performed in the data channel are: *timing recovery*, *equalization*, *data detection*, *modulation coding/decoding*, and limited *error control*. Besides this, so called *data channel*, a read channel also has a *servo channel*, which role is to sense head position information, and, together with the head positioning servo system, to regulate a proper position of the head above the track. This chapter gives an in-depth treatment of all of these subsystems.

We begin with the review of the magnetic recording principles. We describe basic recording physics and explain how the interactions among neighboring magnetic domains cause intersymbol interference (ISI). Then we introduce a partial response signaling as a method of controlling the ISI. The first section also describes physical and logical organization of data on a disk and methods of increasing recording density.

The second section gives a block diagram of a state-of-the-art read channel and explain its subsystems. We explain organization of data on the disc tracks, servo sectors and data sectors, seeking and tracking operations, and phase and frequency acquisition. The section on servo information detection explains sensing radial information and read channel subsystem used to perform this operation.

The treatment of the data channel begins with an in-depth treatment of partial response signaling and adaptive equalization-standard techniques used in today's read channels. The novel equalization approaches and *generalized* partial response polynomials are also discussed in this section. We continue with a maximum likelihood sequence detection algorithm—Viterbi algorithm—and a noise predictive Viterbi algorithm, which enhances the performance by exploiting the fact that noise is highly colored and can be therefore predicted to some extent. The data detection also includes error event correction through post-processing, a new technique used in latest generation of read channels, as well as novel soft decoding and iterative decoding techniques.

The fourth part of the chapter discusses modulation and error control coding. Modulation coding in a read channel serves a variety of important roles. Generally speaking modulation coding eliminates those sequences from a recorded stream that would degrade the error performance, for example, long runs of consecutive like symbols that impact the timing recovery, or/and sequences that result in a signal on a small Euclidian distance. We complete the coding section with error control coding—both traditional algebraic techniques such as Reed Solomon codes, as well as with new trends such as iterative decoding. The error control coding is not part of present read channel chips, but will be integrated in the next generation of so-called “super chips.”

We conclude this chapter by the review of read channel technology including novel read channel architectures such as postprocessor, super chip, etc., as well as the issues of digital design, chip testing, and manufacturing.

## 34.1 Recording Physics and Organization of Data on a Disk

---

*Bane Vasić and Miroslav Despotović*

### Magnetic Recording Basics

The basic elements of a magnetic recording system are read/write head, which is an electromagnet with a carefully shaped ferrous core, and a rotating disk with a ferromagnetic surface. Since the core of the electromagnet is ferrous, the magnetic flux preferentially travels through the core. The core is deliberately broken at an air gap. In the air gap, the flux creates a fringing field that extends some distance from the core.

To record data on a surface of a disk, the modulated signal current, typically bipolar, is passed through the electromagnet coils thus generating a fringing magnetic field. The fringing magnetic field creates a remanent magnetization on the ferromagnetic surface, i.e., the ferromagnetic surface becomes permanently magnetic. The magnetic domains in the surface act like tiny magnets themselves and create their own fringing magnetic field above the ferromagnetic surface. The data are recorded in concentric tracks as a sequence of small magnetic domains with two senses of magnetization depending on a sign of writing current. In this, so-called *saturation recording*, the amplitude of two writing current signal levels are chosen sufficiently large so as to magnetize to saturation the magnetic medium in one of two directions. In this way, the nonlinear hysteresis effect does not affect domains recorded over previously recorded ones.

In a simple reading scenario the reading head flies over the disk-spinning surface (at head-to-medium velocity,  $v$ ) and passes through the fringing magnetic fields above the magnetic domains. Depending on a head type, the output voltage induced in the electromagnet is proportional to the spatial derivative of the magnetic field created by the permanent magnetization in the material in the case of inductive heads, or is proportional to the fringing magnetic field in the case of magneto-resistive heads. Today's hard drives use magneto-resistive heads for reading, because of their higher sensitivity. Pulses sensed by a head in response to transition on the medium are amplified and then detected to retrieve back the recorded data. For both types of heads, it is arranged that the head readback signal responds primarily to transitions of the magnetization pattern. The simplest, single parameter model for an isolated magnetic *transition response* is the so-called Lorentzian pulse

$$g(t) = \frac{1}{1 + \left(\frac{2t}{PW_{50}}\right)^2}$$

where  $t_{50}$  is a parameter representing the pulse width at 50% of the maximum amplitude. Simplicity and relatively good approximation of the channel response are the main reasons for attractiveness of this model. The family of  $g(t)$  curves for different  $t_{50}$  values is depicted in Fig. 34.3. The width at half amplitude

FIGURE 34.1 (a) Longitudinal recording. (b) Perpendicular recording.

FIGURE 34.2 Magnetic domains representing bits.

FIGURE 34.3 Transition response  $g(t)$ —mathematical model.

FIGURE 34.4 Sketch of a typical readback waveform in magnetic recording.

defines the recording process *resolution*, i.e.,  $PW_{50}$ ,\* as a spatial, while  $t_{50}$ , as a temporal measure, is alternatively in use ( $PW_{50} = vt_{50}$ ).

Ideal conditions for readback process would be to have head that is sensing the medium in an infinitely narrow strip in front of the head; however, head resolution is limited, so that the head output depends on “past” and “future” bit cell magnetization patterns. Such dependence causes superposition of isolated transition responses partly canceling each other. This phenomenon is known as intersymbol interference (ISI). The interference is largest for transitions at minimum spacing, i.e., a spacing of a single bit cell  $T$ . The response to two physically adjacent transitions is designated *dibit response* or *symbol response*, i.e.,  $h(t) = g(t) - g(t - T)$ . Typical readback waveform illustrating these types of responses is depicted in Fig. 34.4.

Mathematically, the noiseless input-output relationship can be expressed as

$$y(t) = \sum_{i=-\infty}^{\infty} x_i h(t - iT) = \sum_{i=-\infty}^{\infty} (x_i - x_{i-1}) g(t - iT)$$

\*This is not so strict because, contrary to this, some authors use  $PW_{50}$  designating temporal resolution.

where  $\mathbf{y}$  and  $\mathbf{x} \in \{-1, +1\}$  are readback and recorded sequences, respectively. Notice that every transition between adjacent bit cells yields a response  $\pm 2g(t)$ , while no transition in recorded sequence produces zero output.

Normalized measure of the *information density*\* is defined as the ratio  $D = t_{50}/T$  showing how many channel bits are packed “under” the dispersed pulse of duration  $t_{50}$ . Case in which we are increasing density ( $D > 2$ ) is accompanied by an increase of duration of  $h(t)$  expressed in units of  $T$ , as well as rapid decrease of the amplitude of dibit response, which is equivalent to lowering of signal-to-noise ratio in the channel. As a consequence, any given bit will interfere with successively more preceding and subsequent bits producing more severe ISI. At low normalized information densities, peaks of the transition responses are clearly separated, so it is possible to read recorded data in simple manner by detecting these peaks, i.e., *peak detectors*. Contrary to this, high-density detectors have to implement more sophisticated detection methods in order to resolve combination of these effects. One of the most important techniques to combat ISI in magnetic recording channels is partial-response (PR) signaling with maximum-likelihood (ML) sequence detection, i.e., PRML detection, Section 34.5. The applicability of this scheme in magnetic recording channels was suggested over 30 years ago [4], but the advance in technology enabled first disk detectors of this type at the beginning of nineties [2].

The basic idea of a PR system is that certain controlled amount of ISI, at the channel equalizer output, is left for a detector to combat with. The nature of controlled ISI is defined by a PR. This method avoids full channel equalization and intolerable noise enhancement induced by it in a situation when amplitude distortions, as a result of increased density, are severe. In magnetic recording systems the PR detector reconstructs recorded sequence from samples of a suitable equalized readback signal at time instants  $t = iT$ ,  $i \geq 0$ . The equalization result is designed in a manner that produces just a finite number of *nonzero*  $h(t)$  samples  $h_0 = h(0)$ ,  $h_1 = h(T)$ ,  $h_2 = h(2T)$ , ...,  $h_K = h(KT)$ . This is usually represented in a compact *partial-response polynomial* notation  $h(D) = h_0 + h_1D + h_2D^2 + \dots + h_KD^K$ , where the dummy variable  $D^i$  signifies a delay of  $i$  time units  $T$ . Then the “sampled” input-output relationship is of the form

$$y(jT) = \sum_{i=j-K}^j x_i h(jT - iT)$$

For channel bit densities around  $D \approx 2$ , the target PR channels is usually the class-4 partial response (PR4), described by  $h(D) = 1 - D^2 = (1 - D)(1 + D)$ . At higher recording densities Thapar and Patel [6] introduced a general class of PR models with PR polynomial in the form  $h_n(D) = (1 - D)(1 + D)^n$ ,  $n \geq 1$  that is a better match to the actual channel discrete-time symbol response. Notice that the PR4 model corresponds to the  $n = 1$  case. The channel models with  $n \geq 2$  are usually referred to as “extended class-4” models, and denoted by  $E^{n-1}$ PR4 (EPR4,  $E^2$ PR4). Recently, the modified  $E^2$ PR4 ( $ME^2$ PR4) channel,  $h(D) = (1 - D^2)(5 + 4D + 2D^2)$ , was suggested due to its robustness in high-density recordings. Notice that as the degree of PR polynomials gets higher, the transition response,  $g(t)$ , becomes wider and wider in terms of channel bit intervals,  $T$  (EPR4 response extends over 3-bit periods,  $E^2$ PR4 over 4), i.e., the remaining ISI is more severe.

The transfer characteristics of the Lorentzian model of the PR4 saturation recording channel (at densities  $D \approx 2$ ), is close to transition response given by

$$g(t) = \frac{\sin\left(\pi \frac{t}{T}\right)}{\pi \frac{t}{T}} + \frac{\sin\left(\pi \frac{t-T}{T}\right)}{\pi \frac{t-T}{T}}$$

---

\*When channel coding is introduced, this density is greater than the user information density because of added redundancy in the recorded channel sequence.

FIGURE 34.5 Trellis representation of EPR4 channel outputs.

generating the output waveform described by

$$y(t) = \sum_{i=-\infty}^{\infty} (x_i - x_{i-1})g(t - iT) = \sum_{i=-\infty}^{\infty} (x_i - x_{i-2}) \frac{\sin\left(\pi \frac{t - iT}{T}\right)}{\pi \frac{t - iT}{T}}$$

Note that  $g(t) = 1$  at consecutive sample times  $t = 0$  and  $t = T$ , while at all other discrete time instants, its value is 0. Such transition response results in known ISI at sample times, leading to output sample values that, in the absence of noise, take values from the ternary alphabet  $\{0, \pm 2\}$ . In order to decode the readback PR sequence it is useful to describe the channel using the *trellis state diagram*. This is a diagram similar to any other graph describing a finite-state machine, where states indicate the content of the channel memory and branches between states are labeled with output symbols as a response to the certain input (the usual convention is that for the upper branch leaving a state we associate input  $-1$  and  $+1$  for the lower). The EPR4 channel has memory length 3, its trellis has  $2^3 = 8$  states, and any input sequence is tracing the path through adjacent trellis segments.

An example of the trellis diagram is given in Fig. 34.5 for the EPR4 channel. However, notice that in PR trellis there are also distinct states for which there exist mutually identical paths (output sequences) that start from those states, so that we can never distinguish between them (e.g., the all-zero paths emerging from the top and bottom states of the EPR4 trellis). Obviously, such a behavior can easily lead to great problems in detection in situations when noise can confuse us in resolving the current trellis state (e.g., the bottom one for the upper in the running example). Such a trellis is so-called *quasi-catastrophic* trellis and further details on this subject could be found in [3].

A common approach to studying the PR channel characteristics is to analyze its frequency spectra. Basically, when the recording density is low ( $D \approx 0.5$ ) and readback pulses are narrow compared to the distance between transitions, such a signal contains a high-frequency component (highest frequency components correspond to the fastest edge of the signal). With the growth of density, the spectral energy distribution move towards lower frequency range. This means that for the system with  $D = 2$ , the signal spectrum is concentrated below half of the channel bit rate given by  $1/T$ . The power of the highest spectral components outside this half-bandwidth range is negligible. This means that for high-density recording we can limit the channel bandwidth to  $1/2T$  without loss of information and filtering the high frequencies containing noise only.

Finding the Fourier transform of the dibit response we obtain the frequency response for the PR4 channel given by

$$H(w) = 1 - e^{i2wT}, \quad |H(w)| = 2 \sin(wT), \quad 0 \leq w \leq \frac{\pi}{T}$$

FIGURE 34.6 Frequency response of PR4 and EPR4 channel.

For higher order PR channels we have different transition responses and accordingly different frequency responses calculated in a similar fashion as for the PR4 channel. The frequency response for these channels is shown in Fig. 34.6.

These lower frequency spectrum distributions of PR channels are closer to a typical frequency content of raw nonequalized pulses. Hence, equalization for extended PR channels can become less critical and requires less high frequency boost that may improve signal-to-noise ratio.

## Physical Organization of Data on Disk

In most designs, the head is mounted on a slider, which is a small sled-like structure with rails. Sliders are designed to form an air bearing that gives the lift force to keep the slider-mounted head flying at the small and closely controlled height (the so-called Winchester technology). A small flying height is desirable because it amplifies the readback amplitude and reduces the amount of field from neighboring magnetic domains picked by the head, thus enabling sharper transitions in the readback signal and recording more data on a disk; however, the surface imperfections and dust particles can cause the head to “crash.” Controlling the head-medium spacing is of critical importance to ensure high readback signal, and stable signal range. It is also important during reading to keep the head center above the track being read to reduce magnetization picked up from neighboring tracks. The signal induced in the head as a result of magnetic transitions in a neighboring track is known as a cross-talk or inter-track interference. In order to position the head, special, periodic, wedge-like areas, the so-called *servo wedges*, are reserved on a disk surface for radial position information. They typically consume 5–10% of the disk surface available. An arch of a track laying in a servo wedge is called a *servo sector*. The area between servo wedges is used to record data, and a portion of a track between two servo sectors is referred to as a *data sector* or *data field*. In other words, the data and servo fields are time multiplexed, or using disk drive terminology, the servo field is *embedded* in the data stream. To estimate radial position a periodic waveform in a servo sector is detected, and the radial position error signal is calculated based on the current estimated position of a head and the actual position of the track to be followed, and then used in a head positioning servo system (Fig. 34.7).

## Logical Organization of Data on a Disk

On a disk, data are organized in *sectors*. For a computer system, the sector is a sequence of (8-bit) bytes within each addressable portion of data on a disk drive. The sector size is typically 512 bytes. For an error control system, the sector is a sequence of error control codewords or blocks. For interleaved error control systems, each sector contains as many blocks as there are interleave cycles. The block elements

FIGURE 34.7 Data and servo sectors.

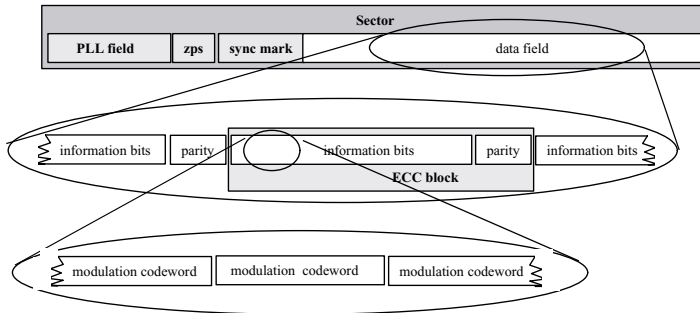

FIGURE 34.8 Format of data on a disk.

are symbols that are not necessarily eight bit long. In the most general terms, the symbols are used in the error control coding (ECC) system to calculate and describe error locations and values.

A read channel sees a sector as a sequence of modulation codewords together with synchronization bits. Synchronization field is partitioned into a sector address mark, or sync mark, typically of length around 20 bits, and phase lock loop (PLL) field, a periodic pattern whose length is about 100 bits used for PLL synchronization. In addition to this, a secondary sync mark is placed within a data field and used for increased reliability. A zero-phase start pattern of length 8–16 bits is used for initial estimation of phase in the PLL. Figure 34.8 illustrates the format of user data on a disk.

## Increasing Recording Density

Increasing areal density of the data stored on a disk can be achieved by reducing lengths of magnetic domains along the track (increasing linear density) and by reducing a track width and track pitch (increasing radial density). Although the radial density is mostly limited by the mechanical design of the drive and ability to accurately follow the track, the linear density is a function of properties of magnetic materials and head designs, and ability to detect and demodulate recorded data.

As linear density increases, the magnetic domains on a surface become smaller and thus thermally unstable, which means that lower energy of an external field is sufficient to demagnetize them. This effect is known as a superparamagnetic effect [1]. Another physical effect is the finite sensitivity of the read head, i.e., at extremely high densities, since the domains are too small; the signal energy becomes so small as to be comparable with the ambient thermal noise energy.

The orientation of magnetization on a disk can be longitudinal, which is typical for today's systems, or perpendicular. The choice of the media influences the way the magnetization is recorded on the disk. Media with needle shaped particles oriented longitudinally tend to have a much higher remanent magnetization in the longitudinal direction, and favor longitudinal recording. The head design must support the favorable orientation of magnetization. Longitudinal orientation requires head shapes that promote

longitudinal fields such as ring heads. Similarly, some media are composed of crystallites oriented perpendicularly to the field. Such media have a much higher remanent magnetization in the perpendicular direction, and favor perpendicular recording. If a head design promotes perpendicular fields, such as single pole heads, the result is perpendicularly recorded magnetization.

Some recent experiments have shown that media that favor perpendicular recording have better thermal stability. This is why, lately, perpendicular recording is attracting a considerable attention in magnetic recording community. Typically, in perpendicular recording a recording surface is made of a hard ferromagnetic material, i.e., material requiring large applied fields to permanently magnetize it. Once magnetized, the domains remain very stable, i.e., large fields are required to reverse the magnetization. The recording layer is made thick so that, since each magnetic domain contains a large number of magnetic particles, larger energy is required for demagnetization. The low remanence, low coercivity, materials (the so-called *soft materials*) are placed beneath hard ferromagnetic surface (soft underlayer) and used to conduct magnetic field back to another electromagnet pole. A pole-head geometry is used, so that the medium can effectively travel through the head gap, and be exposed to stronger magnetic field. A pole-head/soft-underlayer configuration can produce about twice the field that a ring head produces. In this way sharp transitions can be supported on relatively thick perpendicular media, and high frequencies (that get attenuated during readback) are written firmly. However, effects of demagnetizing fields are much more pronounced in perpendicular recording systems, because in longitudinal media the transitions are not that sharp.

## Physical Limits on Recording Density

At extremely high areal densities each bit of information is written on a very small area. The track width is small and magnetic domains contain relatively small numbers of magnetic particles. Because the particles have random positions and sizes, large statistical fluctuations or noise on the recovered signal can occur. The signal-to-noise ratio is proportional to the track width, and is inversely proportional to the mean size of the particle and the standard deviation of the particle size. Therefore, increasing the track size, increasing the number of particles by increasing media thickness, and decreasing the particle size will improve the signal-to-noise ratio. Uniaxial orientation of magnetic particles also gives higher signal-to-noise ratio; however, the requirement for thermal stability over periods of years dictates a lower limit to the size of magnetic particles in a magnetic domain because ambient thermal energy causes the magnetic signals to decay. Achieving both small particle size and thermal stability over time can be done by using magnetic materials with higher coercivity, but there is a strong practical upper limit to the coercivity that can be written, and it is determined by the saturation magnetization of the head material.

In addition to the basic physics, a number of practical engineering factors must be considered at extremely high densities. In particular, these factors include the ability to manufacture accurately the desired head geometries and control media thickness, the ability to closely follow the written tracks, to control head flying height, and the ability to maintain a very small, stable magnetic separation.

## The Future

The hard drive areal densities have grown at an annual rate approaching 100%. Recently a 20 Gbit/in.<sup>2</sup> has been demonstrated [5], and some theoretical indications of feasibility of extremely high densities approaching 1 Tbit/in.<sup>2</sup> have been given [8,9]. Although the consideration related to user needs including higher capacity, speed, error performance, reliability, environment condition tolerances, etc. are important, the factors affecting cost tend to dominate read channel architecture and design considerations. Thus, achieving highest recording density with lowest component costs at high manufacturing yields is the ultimate goal.

With areal densities growing at an annual rate approaching 100%, real concern continues to be expressed that we may be approaching a limit to conventional magnetic recording technology; however, as long as the read channel is concerned, large opportunities are available to improve on the existing signal processing, both with detectors better matched to the channel and by applying more advanced detection, modulation, and coding schemes.

## 34.2 Read Channel Architecture

*Bane Vasić, Pervez M. Aziz, and Necip Sayiner*

The read channel is a device situated between the drive's controller and the recording head's preamplifier (Fig. 34.9). The read channel provides an interface between the controller and the analog recording head, so that digital data can be recorded and read back from the disk. Furthermore, it reads back the head positioning information from a disk and presents it to the head positioning servo system that resides in

FIGURE 34.9 The block diagram of a disk drive.

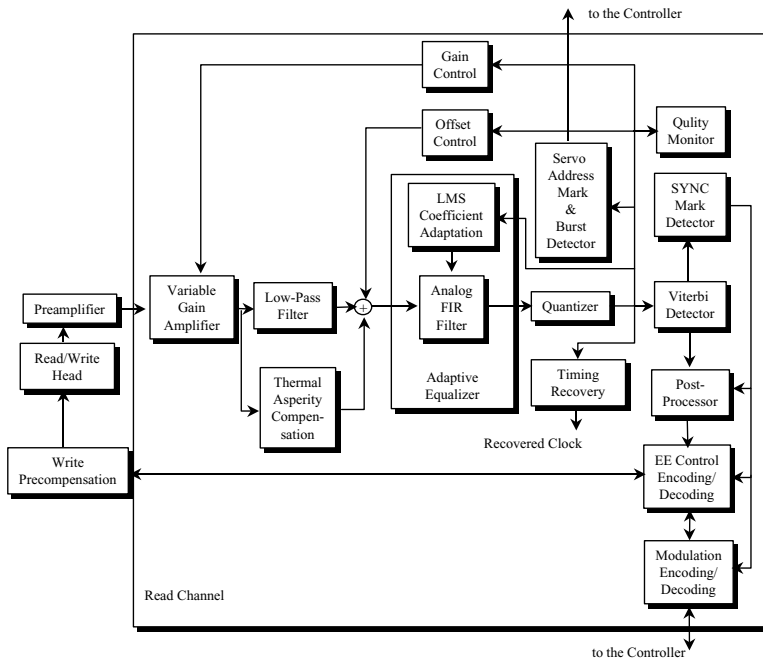

FIGURE 34.10 A typical read channel architecture.

the controller. A typical read channel architecture is shown in Fig. 34.10. During a read operation, the head generates a pulse in response to magnetic transitions on the media. Pulses are then amplified by the preamplifier that resides in the arm electronics module, and fed to the read channel. In the read channel, the readback signal is additionally amplified and filtered to remove noise and to shape the waveform, and then the data sequence is detected (Fig. 34.10). The data to be written on a disk are sent from a read channel to a write driver that converts them into a bipolar current that is passed through the electromagnet coils. Prior to sending to read channel, user data coming from computer (or from a network in the network attached storage devices) are encoded by an error control system. Redundant bits are added in such a way to enable a recovery from random errors that may occur during reading data from a disk. The errors occur due to number of reasons including: demagnetization effects, magnetic field fluctuations, noise in electronic components, dust and other contaminants, thermal effects, etc. Traditionally, the read channel and drive controller have been separate chips. The latest architectures have integrated them into so called “super-chips.”

## Analog Front End

As a first step, the read signal is normalized with respect to gain and offset so that it falls into an expected signal range. Variation of gain and offset is a result of variations in the head media spacing, variations in magnetic and mechanical and electronic components in the drive, preamplifier and read channel. The front end also contains a thermal asperity (TA) circuit compensation. Thermal asperity occurs when head hits a dust particle or some other imperfection on a disk surface. At the moment of impact, the temperature of the head rises, and a large signal at the head’s output is generated. During TA a useful readback signal appears as riding on the back of a low frequency signal of much higher energy. The beginning of this “background” signal can be easily predicted and the TA signal itself suppressed by a relatively simple filter.

High-frequency noise is then removed with a continuous-time low pass filter to permit a sampling of the signal without aliasing of high-frequency noise back into the signal spectrum. The filter frequently includes programable cut-off frequency, which can be used to shape the signal to optimize data detection. A programmable cut-off frequency is essential since the disk rotates with constant angular velocity, and data rate varies by approximately a factor of two from the inner to outer radius of the disc. It is also important for the analog filter bandwidth to be switched to allow for low cut-off frequencies when processing servo sector information.

## Precompensation

Nonlinear bit shift in magnetic recording is the shift in position of a written transition due to the demagnetizing field from adjacent transitions. In a PRML channel, the readback waveform is synchronously sampled at regular intervals, and the sample values depend on the position of written transitions. Therefore, nonlinear bit shift leads to error in sample values which, in turn, degrades the channel performance. The write precompensation is employed to counteract the nonlinear bit shift. However, determining the nonlinear bit shift is not simple and straightforward especially when one tries to fine tune each drive for its optimum precompensation. The precompensation circuit generates the write clock signal whose individual transition timing is delayed from its nominal position by the required precompensation amount. The amount of precompensation and the bit patterns requiring precompensation can be found using the extracted pulse shape [10,18]. Another approach is a frequency-domain technique that offers simple measurement procedure and a possible hardware implementation using a band-pass filter [32] or using PRML sample values [33].

## Partial-Response Signaling with Maximum Likelihood Sequence Estimation

After sampling with a rate  $1/T$ , the read signal is passed through an analog or digital front end filter and detected using a maximum likelihood sequence detector. The partial-response signaling with maximum likelihood (PRML) sequence estimation is proposed for use in magnetic recording by Kobayashi 30 years ago [15,16]. In 1990 IBM produced the first disk drives employing PRML detection. Today's all read channels are based on some version of the PRML. Cideciyan et al. [3] described a complete PRML systems including equalization, gain and timing control, and Viterbi detector. All basic functions of a PRML system have remained practically unchanged, until the introduction of a postprocessor that performs a special type of soft error correction after maximum likelihood sequence detection. Also, significant improvements in all the subsystems have been made during last 10 years. The term "partial response" comes from the fact that the sample of the equalized signal at, say, time  $nT$  ( $T$  is a signaling interval), contains information not only on data bits at time  $nT$ , but also on neighboring bits, i.e., magnetic transitions. The number of adjacent bits that determine the sample at  $nT$  is referred to as *channel memory*. The channel memory is a parameter that can be selected in the process of defining a read channel architecture. The channel memory and the details of the partial response selection are made based on an attempt to have the partial response be as close a match to the channel as possible. Since the complexity of a maximum likelihood detector is an exponential function of a memory, it is desirable to keep the memory low, but, the equalization required to achieve this might boost the high-frequency noise, which result in decrease of a signal-to-noise ratio, called *equalization loss*. The typical value of channel memory in today's read channels is 4. The value of an equalized sample at time  $nT$ ,  $y_n$  can be written as

$$y_n = \sum_{k=0}^{L_h} h_k x_{n-k}$$

where  $x_n$  is a user-data bit recorded at time  $n$  ( $x_n \in \{-1, +1\}$ ), and  $L_h$  is a channel memory. The coefficients  $h_k$  form,  $h(D) = \sum_{k=0}^{L_h} h_k \cdot D^k$ , a *partial response polynomial* or *partial response target* ( $D$  is a formal, time-delay variable). The main idea in partial response equalization is to equalize the channel to a known and short target that is matched to the channel spectrum so that noise enhancement is minimum. Therefore, the

deliberate inter-symbol interference is introduced, but since the target is known, the data can be recovered, as explained in the previous article.

## Adaptive Equalization

To properly detect the user-data it is of essential importance to maintain the partial response target during the detection. This implies that channel gain, finite-impulse response (FIR) filter coefficients, and sampling phase must be adaptively controlled in real-time. Continuous automatic adaptations allow the read channel to compensate for signal variations and changes that occur when drive operation is affected by changes in temperature or when the input signals are altered by component aging. Comparing the equalizer output samples with the expected partial response samples generates an error signal, which is used to produce adaptive control signals for each of the adaptive loops. For filter coefficients control, a least-mean square (LMS) algorithm is used [4]. LMS operates in the time domain to find filter coefficients that minimize the mean-squared error between the samples and the desired response. Initial setting of the filter coefficients is accomplished by training the filter with an on-board training sequence, and the adaptation is continued while chip is reading data. Adaptation can be in principle performed on all coefficients simultaneously at lower clock rate or on one coefficient at a time. Because disk channels variations are slow relative to the data rate, the time-shared coefficient adaptation achieves the same optimum filter response while consuming less power and taking up less chip area. Sometimes, to achieve better loop stability, not all filter coefficients are adapted during reading data. Also, before writing, data are scrambled to whiten the power spectral density and ensure proper filter adaptation.

The FIR filter also compensates for the large amount of group-delay variation that may be caused by a low-pass filter with a nonlinear phase characteristics. Filters with nonlinear characteristics, such as the Butter-worth filter, are preferred over, say, an equi-ripple design of the same circuit complexity, because they have much better roll-off characteristics. The number of FIR filter coefficients in practical read channels has been as low as 3 and as high as 10 with various trade-offs associated with the different choices, which can be made.

## Viterbi Detection

In many communications systems, a symbol-by-symbol detector is used to convert individual received samples at the output of the channel to corresponding detected bits. In today's PRML channels, a Viterbi detector is a maximum likelihood detector that converts an entire *sequence* of received equalized samples to a corresponding sequence of detected bits. Let  $\mathbf{y} = (y_n)$  be the sequence of received equalized samples corresponding to transmitted bit sequence  $\mathbf{x} = (x_n)$ . Maximum likelihood sequence estimation maximizes the probability density  $p(\mathbf{y}|\mathbf{x})$  across all choices of transmitted sequence  $\mathbf{x}$  [7]. In the absence of noise and mis-equalization, the relationship between the noiseless equalized samples  $z_n$  and the corresponding transmitted bits is known by the Viterbi detector and is given by

$$z_n = \sum_{k=0}^L h_k x_{n-k} \quad (34.1)$$

In the presence of noise and mis-equalization the received samples will deviate from noiseless values. The Viterbi detector considers various bit sequences and efficiently compares the corresponding expected PR channel output values with those actually received. For Gaussian noise at the output of the equalizer and equally probable input bits, maximizing  $p(\mathbf{y}|\mathbf{x})$  is equivalent to choosing as the correct bit sequence the one closest in a (squared) Euclidean distance sense to the received samples. Therefore, the following expression needs to be minimized

$$\min_{\mathbf{x}_k} \left( \sum_{n=0}^{P-1} \left[ y_n - \sum_{k=0}^L h_k x_{n-k} \right]^2 \right) \quad (34.2)$$

The various components of (34.3) are also known as branch metrics. The Viterbi detector accomplishes the minimization in an efficient manner using a trellis-based search rather than an exhaustive search. The search is effectively performed over a finite window known as the decision delay or path memory length of the Viterbi detector. Increasing the window length beyond a certain value leads to only insignificant improvements of the bit detection reliability or bit error rate (BER).

Despite the efficient nature of the Viterbi algorithm the complexity of a Viterbi detector increases exponentially with the channel memory of the PR target. A target with channel memory of  $L - 1$  requires for example a  $2^{L-1}$  state Viterbi detector trellis. For a fully parallel Viterbi implementation, each Viterbi state contains an add-compare-select (ACS) computational unit, which is used to sum up the branch metrics of (34.4) and keep the minimum metric paths for different bit sequences. Also required for the hardware is a  $2^{L-1} \cdot P$  bit memory to keep a history of potential bit sequences considered across the finite decision delay window.

## Timing Recovery

A phase-locked loop (PLL) is used to regenerate a synchronous clock from the data stream. The PRML detector use decision directed timing recovery typically with a digital loop filter. The digital loop filter parameters can be easily controlled using programmable registers and changed when read channel switches from acquisition to tracking mode. Because a significant pipelining is necessary in the loop logic to operate at high speeds, the digital loop filter architecture exhibits a relatively large amount of latency. It can affect considerably the acquisition time when the timing loop must acquire significant phase and frequency offsets. To ensure that only small frequency offsets are present, the synchronizer VCO is phase-locked to the synthesizer during nonread times. For fast initial adjustment of the sampling phase, a known preamble is recorded prior to user data. The time adjustment scheme is obtained by applying the stochastic gradient technique to minimize the mean squared difference between equalized samples and data signal estimates. To compensate for offset between the rate of the signal received and the frequency of the local timing source the loop filter design allows for a factor  $\Delta T_n$  to be introduced, so that the sample at discrete time  $n$  is taken  $T + \Delta T_n$  seconds after the sample at discrete time  $n - 1$ . In acquisition mode, in order to quickly adjust the timing phase, large values for loop gains are chosen. In tracking mode, the loop gains are lowered to reduce loop bandwidth.

## Read Channel Servo Detection

In an *embedded* servo system (introduced in the previous article), the radial position of the read head is estimated from two sequences recorded on servo wedges: *track addresses* and *servo-bursts*. The track address provides a unique number for every track on a disk, while a servo-burst pattern is repeated on each track or on a group of tracks. Determining the head position using only the track number is not sufficient because the head has to be centered exactly on a given track. Therefore, the servo-burst waveform is used in conjunction with the track address to determine the head position. Using the servo-burst pattern, it is possible to determine the off-track position of a head with respect to a given track with a high resolution. While positioning the head over a surface, the disk drive can be in either *seeking* or *tracking* operation mode. In a seeking mode, the head moves over multiple tracks, trying to reach the track with a desired address as quickly as possible, while in a tracking mode, the head tries to maintain its position over a track. The track addresses are therefore used mostly in the seeking mode, while servo-burst information is usually used in the tracking mode [25,30].

In read channels, periodic servo-burst waveforms are detected and used to estimate radial position. The radial position error signal is calculated based on the current estimated position and the position of the track to be followed, and then used in an external head positioning servo system. Generally, two types of position estimators are in use: maximum likelihood estimators based on a matched filtering and sub-optimal estimators based on averaging the area, or the peaks, of the incoming periodic servo-burst waveform. A variety of techniques have been used to demodulate servo bursts including amplitude, phase,

and null servo detectors. Today, most read channels use an amplitude modulation with either peak or area detection demodulators.

Older generation channels generally implemented the servo functions in analog circuitry. The analog circuitry of these servo channels partially duplicates functions present in the digital data channel. Now, several generations of read-channel chips have switched from analog to digital circuits and digital signal processing [8,34]. These channels reduce duplication of circuits used for servo and data and provide a greater degree of flexibility and programmability in the servo functions.

Typically, a single analog-to-digital converter (ADC) or quantizer is used for both data detection and servo position error signal estimation [8,20,27,34], but quantizer requirements are different in data and servo fields. Compared to position error signal estimators, data detectors require a quantizer with higher sampling clock rate. On the other hand position error signal estimators require a quantizer with finer resolution. A typical disk drive has a data resolution requirement of around 6 bits, and a servo resolution requirement of around 7 or 8 bits. Furthermore, servo bursts are periodic waveforms as opposed to data streams. In principle, both the lower sampling clock rate requirement in the servo field and the periodicity property of servo-burst signals can be exploited to increase the detector quantization resolution for position error signal estimation. The servo field is oversampled asynchronously to increase the effective quantizer resolution.

Track densities in today's hard drives are higher than 25,000 tracks per inch, and the design of a tracking servo system is far from trivial. Some of the recent results include [Saks97], [2,24–26]. Increasing the drive level servo control loop bandwidth is extremely important. Typical bandwidth of a servo system is about 1.5 kHz, and is mainly limited by the parameters that are out of reach of a read channel designer, such as mechanical resonances of voice coil motor, arm holding a magnetic head, suspension, and other mechanical parameters.

Another type of disturbance with a mechanical origin, that has to be also detected and controlled in a read channel, is repeatable runout (RRO) in the position of the head with respect to the track center. These periodic disturbances are inherent in any rotating machine, and can be the result of an eccentricity of the track, offset of the track center with respect to the spindle center, bearing geometry, and wear and motor geometry. The frequencies of the periodic disturbances are integer multiples of the frequency of rotation of the disk, and if not compensated they can be a considerable source of tracking error. In essence the control system possesses an adaptive method to learn online the true geometry of the track being followed, and a mechanism of continuous-time adaptive runout cancellation [31].

## Postprocessor

Due to the channel memory and noise coloration, maximum likelihood sequence detector (Viterbi detector) produces some error patterns more often than others. They are referred to as *dominant error sequences*, or *error events*, and can be obtained analytically or through experiments and/or simulation. Relative frequencies of error events strongly depend on a recording density.

Parity check processors combine syndrome decoding and soft-decision decoding [35]. Error event likelihoods needed for soft decoding can be computed from a channel sequence by some kind of soft-output Viterbi algorithm. By using a syndrome calculated for a received codeword, a list is created of all possible *positions* where error events can occur, and then error event likelihoods are used to select the most likely position and most likely type of the error event. Decoding is completed by finding the error event position and type. The decoder can make two type of errors: it fails to correct if syndrome is zero or it makes a wrong correction if syndrome is nonzero, but the most likely error event or combination of error events do not produce right syndrome.

A code must be able to detect a single error from the list of dominant error events, and should minimize the probability of producing zero syndrome when more than one error event occur in a codeword.

Consider a linear code given by an  $(n - k) \times n$  parity check matrix  $H$ , with  $H$  capable of correcting or detecting dominant errors. If all errors from a list were contiguous and shorter than  $m$ , then a cyclic  $n - k = m$  parity bit code could be used to correct a single error event; however, in reality, the error

sequences are more complex, and occurrence probabilities of error events of lengths 6, 7, 8, or more are not negligible. Furthermore, practical reasons (such as decoding delay, thermal asperities, etc.) dictate using short codes, and consequently, in order to keep code rate high, only a relatively small number of parity bits is allowed, making the design of error event detection codes nontrivial.

The detection is based on the fact that we can calculate the likelihoods of each of dominant error sequences at each point in time. The parity bits serve to detect the errors, and to provide some localization in error type and time. The likelihoods are then used to choose the most likely error events (type and location) for corrections. The likelihoods are calculated as the difference in the squared Euclidean distances between the signal and the convolution of maximum likelihood sequence estimate and the channel partial response, versus that between the signal and the convolution of an alternative data pattern and the channel partial response. During each clock cycle, the lowest  $M$  are chosen, and the syndromes for these error events are calculated. Throughout the processing of each block, a list is maintained of the  $N$  most likely error events, along with their associated error types, positions, and syndromes. At the end of the block, when the list of candidate error events is finalized, the likelihoods and syndromes are calculated for each of six combinations of two candidate error events which are possible. After disqualifying those pairs of candidates, which overlap in the time domain, and those candidates and pairs of candidates which produced a syndrome, which does not match the actual syndrome, the candidate or pair, which remains and which has the highest likelihood, is chosen for correction.

## Modulation Coding

Modulation of constrained coding is used to translate an arbitrary sequence of input data to a channel sequence with special properties required by the physics of the medium [21]. Two large important classes of channel constraints are run-length and spectral constraints. The run-length constraints [12] bound the minimal and/or maximal lengths of certain types of channel subsequences, while the spectral constraints include dc-free [11] and higher order spectral-null constraints [6,23]. The spectral constraints also include codes that produce spectral zero at rational sub-multiples of symbol frequency as well as constraints that give rise to spectral lines. The most important class of runlength constraints is a  $(d, k)$  constraint, where  $d + 1$  and  $k + 1$  represent minimum and maximum number of consecutive like symbols or space between the adjacent transitions. Bounding minimal length consecutive like symbols controls ISI in the excess bandwidth systems and reduces transition noise. Bounding the upper limits of the mark lengths improves timing recovery and automatic gain control. In order to keep code rate high, today's read channels employ only  $k$  constrained codes. Typical code rates are: 16/17, 24/25, 32/34, 48/49. Modulation decodes can be either block-by-block or sliding-window. Block decoders determine data word by using a single codeword, while sliding-window decoders require so-called look-ahead, which means that the output data word is a function of several consecutive codewords. Due to inherent nonlinearity, a modulation decoder may produce multiple errors as a result of a single erroneous input bit. If a sliding-window decoding is used, an error can affect several consecutive data blocks. This effect is known as an *error propagation*. The block codes are favored because they do not propagate errors.

A mathematically rigorous code design approach based on symbolic dynamics was developed by Marcus and Siegel et al. [19,22]. The algorithm is known as the "state splitting algorithm" or Adler, Coppersmith, and Hassner (ACH) algorithm [1]. Another constrained coding approach, championed by Immink [14] emphasizes the low-complexity encoding and decoding algorithms [13]. Despite this nice mathematical theory, design of constrained codes remains too difficult to be fully automated, and in the art of designing efficient codes, human intervention and skill are still necessary.

## Error Control Coding

In a conventional hard disk drives the error control coding (ECC) system does not reside in a read channel; however, the ECC performance is linked to the performance of a detection algorithm, error propagation in a modulation code, and it is natural to try to expand the read channel functionality to error control as well. A new trend in industry is aimed toward designing an integrated circuit, so called *super chip* with a such expanded functionality.

In the most general terms, the purpose of ECC is to protect user data, and this is achieved by including redundant, so-called *parity* bits along with the data bits. The codes used in hard drives belong to a large class of ECC schemes, called block codes. A block code is a set of codewords (or blocks) of a fixed length  $n$ . The length is expressed in number of symbols, and a symbol is a binary word of length  $m$ . Other parameters of a block code are  $k$ -number of data symbols in the block, and  $t$ -number of symbols correctable by the ECC system [17,36].

Reed–Solomon (RS) codes [28] have been the class of codes most often used in the magnetic disk storage for the last 15 years. The reason is their excellent performance in presence of error events that exhibit burstiness, which is typical for magnetic recording channels, and lend themselves to high-speed encoding/decoding algorithms required for high-speed disk drives [5,9,37]. Very often RS codes are interleaved to reduce effect of long error burst, and to reduce the implementation cost by eliminating conversion of bytes to possibly longer code symbols used in encoding and decoding. The parameters of RS codes satisfy the following relations:  $n \leq 2^m - 1$ , number of parity symbols  $n - k \geq 2t$ , and code rate of the RS code  $r = k/n$ .

In today's hard drives typically, a part of ECC decoding is performed in hardware with a throughput equal to the data rate, and the other part is performed in firmware with much lower speed. In some cases, such as thermal asperities, no error control is sufficient to recover the data. In this case, it is necessary to retry reading the same sector. A choice between hardware or firmware correction depends on the application, the data transfer protocol, and the bus transfer rate. In applications such as single-user workstations, short data transfers dominate, but streaming data transfers occasionally occurs (during boot, large file transfers, etc.). Additionally, data read from the disk drive can be transmitted to the host computer in a physically sequential or in any convenient order. If the bus transfer rate is higher than the ECC hardware throughput, and if sufficiently long ECC firmware buffer is available to store all the sectors, or if sectors are transmitted to the host computer in any convenient order all firmware error recovery can be performed in parallel with disk reads without interrupting streaming read operations. In the case of short packet transfers, it is better to perform read retry in parallel with firmware error correction. Retries in conjunction with hardware correction typically consume less time than firmware error correction. On the other hand, for long streaming transfers, correcting errors in firmware in parallel with reading the sector is better strategy, provided that the firmware ECC throughput is high enough to prevent buffer overflow. A detailed treatment of an error control system design considerations can be found in [29].

## The Effect of Thermal Asperities

As explained earlier, if a head hits a dust particle, a long thermal asperity will occur, producing a severe transient noise burst, loss of timing synchronization, or even off-track perturbation. Error events caused by TAs are much less frequent than random error events, but they exist and must be taken into account during read channel design. If there were no TA protection in the read channel, a loss of lock in timing recovery system would occur, causing massive numbers of data errors well beyond the error correction capability of any reasonable ECC system. Despite TA protection, the residual error cannot be completely eliminated, and many bits will be detected incorrectly; however, the read channel should be designed to enable proper functioning of timing recovery in the presence of bogus samples. Typically, the read channel estimates the beginning and length of TA and sends this information to the ECC system, which may be able to improve its correction capability using so-called erasure information; however, since the TA starting location is not known precisely, and the probability of random error in the same sector is not negligible, the ECC system can miscorrect, which is more dangerous than not to detect the error.

## Error Performance Measures

A commonly used measure of ECC performance is a BER, which is defined as a ratio of unrecoverable error events and total user data bits. An unrecoverable error event is a block that contains more erroneous symbols than the ECC system can correct, and it may contain as many as exist in a single data block protected by the ECC system. Various applications require different BERs, but they are typically in the

range of  $10^{-12}$ – $10^{-15}$ . Another ECC performance measure is undetected bit error rate (UBER), which is a number of undetected error events per total number of user bits. In some cases the ECC system detect that the sector contain errors, but is not able to correct them. Then a controller asks a read channel to retry reading the same sector. The *retry rate per bit* is a useful measure of a data throughput. The hard drive standards of a retry rate is  $10^{-14}$ . The performance measure used depends on the application. For example UBER is much more important for bank transactions than for multimedia applications ran on PC. All performance measures depend on a symbol length, number of correctable errors, and symbol error statistics. On the other hand symbol error statistics depend on the read channel error event distribution.

### 34.3 Adaptive Equalization and Timing Recovery

---

*Pervez M. Aziz*

Adaptive signal processing plays a crucial role in storage systems. Proper detection of the readback signal by a Viterbi detector assumes that the signal has the right gain, is equalized to the partial response, and is sampled at the proper sampling instances. In this section, the focus is mainly on equalization and timing recovery. Some of the basic algorithms employed in equalization and timing recovery are reviewed. Various architectures and algorithms are presented, which have been used in state-of-the-art read channels. Finally, comparative performance data for some of these architectures are presented.

#### Adaptive Equalization

What is equalization? It is the act of shaping the read back magnetic recording signal to look like a target signal specified by the partial response (PR). The equalized signal is made to look like the target signal in both the time and frequency domain. In this subsection, various equalization architectures and

strategies are reviewed, which have been popular historically and still being used in present day read channels. A quick review of the well-known least mean square (LMS) algorithm used for adaptive equalizers is also provided. Finally, the performance implications of selecting several different equalizer architectures is explored. This performance is measured in terms of bit error rate (BER) at the output of the read channel's Viterbi detector.

### Equalization Architectures and Strategies

In PRML channels the read back signal will be sampled at some point in the data path for further digital signal processing. A continuous time filter (CTF) with a low-pass characteristic will be present as an anti-aliasing filter [1] prior to the sampling operation so that high-frequency noise is not aliased into the signal band. This same CTF may also play a role in equalizing the read back signal to the target partial response. Various architectures can be used to perform the required equalization. The equalizer architecture can consist of a CTF, a finite impulse response filter (FIR), or both. The CTF parameters may be fixed, programmable, or adaptive. The FIR filter coefficients may be fixed, programmable, or adaptive. In addition, the FIR operation may occur in the sampled data analog domain or digital domain. Following equalization, the data are detected using a Viterbi detector. Of course, quantization by an analog-to-digital converter (ADC) occurs at some point before the Viterbi detector.

Figure 34.11 shows some examples of various equalizer architecture configurations. The first architecture (Type 1) consists of a CTF-only equalizer. The CTF is comprised of an all-pole low-pass filter section whose purpose is to reject high-frequency noise for anti-aliasing. One key parameter in the CTF is its low-pass bandwidth determined by its cutoff or corner frequency,  $f_c$ . The type of CTF,  $f_c$ , and its order (or the number of poles it contains) will determine its low-pass rolloff characteristic. If the CTF is expected to take part in equalization, it must also be able to provide some boost and does so by typically having one or two real zeros at some frequency  $f_z$  in its transfer function. These parameters are noted in the figure.

The second architecture (Type 2) is one where both the CTF and an analog FIR are involved in performing equalization. The third architecture (Type 3) is an analog FIR-only architecture in that the CTF design does not consist of any zeros, i.e., its main role is to perform anti-aliasing and not provide any boost for equalization. Finally, the last architecture (Type 4) is one where a CTF and FIR are both involved in equalization except that the FIR operation is done digitally.

In general, there is a clear trade-off between the degree of flexibility of the equalizer and implementation complexity. The read-back signal characteristics change across the disk surface as manifested by somewhat

FIGURE 34.11 Various equalizer architectures.

**FIGURE 34.12** Normalized pole locations for sixth-order Butterworth and equiripple linear phase filters as well as mixed filters.

different channel bit densities (*cbds*) or  $pw_{50}/T$ . Consequently, programmability of the equalizer parameters is a minimum requirement for optimum performance. The signal or some of the equalizer parameters themselves may change with chip ageing and temperature variations [2]. Therefore, it is often desirable for some of the equalizer parameters to be continually adaptive to be able to compensate for these effects.

### CTF Configurations

Two common types of CTFs, which have been used in read channels are Butterworth filters and equiripple linear phase filters. Butterworth filters have a maximally flat magnitude response but nonlinear phase response. Equiripple linear phase filters, as their name implies, have linear phase and constant group delay over the passband [3,4]. For a given order, the Butterworth filters will have sharper rolloff characteristics. One could also consider *mixed* filters whose poles are chosen to lie some percentage of the distance in between the poles of a Butterworth and equiripple linear phase filter. Figure 34.12 shows the normalized pole location on the *s* plane for a sixth-order Butterworth, a sixth-order equiripple linear phase filter, as well as the poles for various sixth order mixed filters, which are 25%, 50%, 75%, and 90% away from the poles of the equiripple filter. Note that the Butterworth poles lie on the unit circle. Figure 34.13 shows the corresponding magnitude responses for the filters, while Fig. 34.14 shows the group delay responses. As can be observed, the Butterworth has the sharpest lowpass rolloff and the equiripple filter has the shallowest rolloff but constant group delay over the passband.

The CTF parameters can be programmable or adaptive [5,6]; however, most CTFs that have been used in actual read channels have had programmable bandwidth and boosts any adaptivity being left to the FIR. Adaptive CTF systems face some challenging issues as discussed in [7]. Also, some work has been done to analytically determine the optimum CTF transfer functions [8,9].

The performance of equalizers involving several CTF configurations will be compared: fourth-order Butterworth (*b4*), sixth-order Butterworth (*b6*), seventh-order equiripple linear phase (*e7*) all with single zeros. We also examine a seventh-order equiripple linear phase CTF with two zeros (*e7tz*). The linear phase of the all pole section is kept in the *e7tz* filter. Another filter considered is the fourth-order 50% mixed filter with one zero (*em4*).

**FIGURE 34.13** Magnitude response for sixth-order Butterworth and equiripple linear phase filters as well as mixed filters.

**FIGURE 34.14** Group delay response for sixth-order Butterworth and equiripple linear phase filters as well as mixed filters.

### FIR Filter and the LMS Algorithm

The FIR filter is important for equalization. Whether implemented as an analog sampled data filter or a digital filter the FIR filter produces output samples  $y(n)$  in terms of input samples  $x(n)$  as

$$y(n) = \sum_{k=0}^{L-1} h(k)x(n-k) \tag{34.3}$$

where  $h(k)$  are the FIR filter tap weights. As noted, it is very desirable for the FIR to be adaptive. The FIR taps are adapted based on the well-known LMS algorithm [10,11]. Other adaptive algorithms can also be found in [12] and [13].

The basic idea is to minimize the mean squared error with respect to some desired or ideal signal. Let the desired or ideal signal be  $\hat{y}(n)$  in which case the error is  $e(n) = y(n) - \hat{y}(n)$ . This minimization is achieved by adjusting the tap value in the direction opposite to the derivative (with respect to the tap values) of the expected value of the mean squared error. Dispensing with the expected value leads to the LMS or stochastic gradient algorithm. The stochastic gradient for the  $k$ th tap weight is

$$\begin{aligned}\Delta(k,n) &= -\frac{\partial}{\partial h(k)}(e^2(n)) = -2e(n)\frac{\partial \hat{e}(n)}{\partial h(k)} = -2e(n)\left[\frac{\partial y(n)}{\partial h(k)} - \hat{y}(k)\frac{\partial \hat{y}(n)}{\partial h(k)}\right] \\ &= -2e(n)\frac{\partial y(n)}{\partial h(k)}\end{aligned}\quad (34.4)$$

where the partial derivative of  $\hat{y}(n)$  with respect to  $h(k)$  is zero. We can now expand  $y(n)$  as in Eq. (34.3) to further obtain

$$\Delta(k,n) = -2e(n)x(n-k) \quad (34.5)$$

The gradient would actually be scaled by some tap weight update gain  $t_{ug}$  to give the following tap update equation:

$$h(k,n+1) = h(k,n) - 2t_{ug}e(n)x(n-k) \quad (34.6)$$

The choice of this update gain depends on several factors: (a) it should not be too large so as to cause the tap adaptation loop to become unstable, (b) it should be large enough that the taps converge within a reasonable amount of time, (c) it should be small enough that after convergence the adaptation noise is small and does not degrade the BER performance. In practice, during drive optimization in the factory the adaptation could take place in two steps, initially with higher update gain and then with lower update gain. During the factory optimization different converged taps will be obtained for different radii on the disk surface. Starting from factory optimized values means that the tap weights do not have to adapt extremely fast and so allows the use of lower update gains during drive operation. Also, this means that the tap weights need not all adapt every clock cycle—instead a round-robin approach can be taken, which allows for sharing of the adaptation hardware across the various taps. A simpler implementation can also be obtained by using the signed LMS algorithm whereby the tap update equation is based on using 2- or 3-level quantized version of  $x(n-k)$ . For read channel applications, this can be done without hardly any loss in performance.

A few other issues should be emphasized about the adaptive FIR. During a read event, the FIR filter is usually adapted after the initial gain and timing recovery operations are performed over a preamble field. Nevertheless, during the rest of the read event, the FIR filter equalizes the signal at the same time that the gain and timing loops are operating. The adaptive gain loop uses an automatic gain control (AGC) block to apply the correct gain to the signal to achieve the desired partial response target values. Likewise the adaptive timing recovery loop works to adjust the sampling phase to achieve the desired PR target values. It is necessary to minimize the interaction between these adaptive loops. The FIR filter will typically have one tap as a “main” tap, which is fixed to minimize its interaction with the gain loop. Another tap such as the one preceding or following the main tap can be fixed (but allowed to be programmable) to minimize interaction with the timing loop [14]. In some situations it may be advantageous to have additional constraints to minimize the interaction with the timing loop [15].

### Performance Characterization

The performance of various equalizer architectures based on bit error rate simulations can now be characterized. The equalizer types (with reference to Fig. 34.11) actually simulated are of Types 2 (CTF + analog FIR) and 3 (anti-aliasing CTF + analog FIR). One can consider the case where there are very few

taps as an approximation of the Type 1 (CTF only) equalizer. Although many actual read channel architectures do use digital FIRs (Type 4), we do not consider this type for simulations here. Although a digital FIR filter may be cost effective for implementation given a particular technology, it does have two disadvantages compared with the analog FIR. With the analog FIR, quantization noise is added *after* equalization and so is not enhanced through the equalizer whereas for the digital FIR the quantization noise does pass through the equalizer and could be enhanced. Consequently, fewer quantization levels can be used and this results in reduced chip area and power dissipation with the analog FIR. Also, the digital FIR is likely to have more latency in producing its final output and this extra latency may not hurt significantly but is nonetheless not beneficial for the timing loop.

**Simulation Environment and Optimization Procedure**

The simulation environment, including two system simulation models, and the optimization methodology by which the optimum performance is obtained for each equalizer architecture can now be described. Finally, BER results quantifying the performance of the various architectures are presented.

To obtain a simulation bound for the performance of the best possible equalizer we use the system of Fig 34.15. The signal + noise is fractionally sampled at a rate of  $T/5$  and filtered with a fractionally spaced FIR filter equalizer, which equalizes the signal to an EPR4 target. The channel bit period is  $T$ . The output of the equalizer is then sampled at the channel bit rate of  $T$  and these samples are presented to the EPR4 Viterbi. The FIR has 125 taps (spanning  $25T$ ). The FIR tap weights are adapted from zero starting values using the LMS algorithm. There is no quantization, AGC, or timing recovery. Therefore, the performance is solely determined by the noise.

Pseudo random data are 16/17 modulation encoded to generate a signal at various *cbds* based on a Lorentzian pulse shape. For each *cbd*, the SNR needed by the “ideal”  $T/5$  oversampled system of Fig 34.15 to produce a BER of  $10^{-5}$  is determined. SNR is defined as the ratio of the isolated pulse peak to rms noise in the Nyquist band. The (*cbd*, SNR) pairs are used for performing simulations with the practical system of Fig. 34.16, which accurately models an actual read channel chip and a version of the  $T/5$  system where the equalized samples are quantized before being detected with the Viterbi detector. Signals at

FIGURE 34.15 Block diagram of system with five times oversampled equalizer.

FIGURE 34.16 Block diagram and simulation model of practical symbol rate sampled read channel system.

several *cbds* or *PW50/T* values 1.9, 2.4, and 2.8 are examined. The SNRs needed for 1e-5 BER for these densities are 21.66, 22.90, and 24.70 dB, respectively.

Let us now describe the simulation model for the actual read channel system. A block diagram of this system is shown in Fig. 34.16. The system consists of AGC, CTF, *T* rate sampled analog FIR equalizer, ADC quantizing the equalizer output, and an EPR4 Viterbi detector. Three decision directed adaptive loops are used: LMS tap update loop, AGC loop, and digital PLL (DPLL) timing recovery loop. Note that in this practical system the adaptive feedback loops are updated not based on known data but on tentative or preliminary decisions made by the read channel. The algorithm used for the tap update is the signed LMS algorithm as implied by the 3-level slicer shown in the figure.

Using the practical system model, BER simulations are performed for the various CTFs mentioned earlier and FIRs of various number of taps. The simulations are performed with this realistic system using the SNRs mentioned earlier. This allows the calculation of the BER degradation of the realistic system with respect to the *T/5* system for a given *cbd* and SNR.

For each CTF type, *cbd*, and FIR length we simulate the BER of the system across a space of equalizer parameters  $f_c, f_z$  (which determines CTF boost), and the fixed programmable tap of the FIR, which is labeled as *pt* in Fig. 34.16. The parameters are varied across the following ranges:  $f_c$  is varied between 20% and 38% of the channel bit rate,  $f_z$  is varied to provide boosts between 2.6 and 8.6 dB, while the programmable tap is varied between 40% and 60% of the main tap value. For CTFs with two zeros the zeros are adjusted such that the total boost is in the above range. For the 10-tap FIR the fourth tap is chosen to be the fixed main tap while for the 6- and 3-tap filters the second tap is chosen as the main tap. For the other taps, the analog tap range was kept to be relatively large at  $\pm 80\%$  of the main tap value. In a real system, one would choose smaller ranges based on tap settings fitting into the smaller range, which produced good results. For the equalizer configuration involving the FIR only equalizer, FIRs with 4–20 taps are examined. The programmable tap *pt* is re-optimized for each *cbd* and FIR filter length.

**Results**

Before comparing BER results across different equalizers, some results from the equalizer optimization procedure are illustrated. Figure 34.17 shows a contour plot of the BER obtained with the *b4* CTF with a 10-tap FIR at a *cbd* of 2.4 and a SNR, which gives close to  $10^{-5}$  BER. The horizontal axis is CTF corner frequency ( $f_c$ ) and the vertical axis is CTF boost in decibel. The plot is for one particular value of the programmable FIR tap *pt*. The numbers on the contour plot are  $10 \times \log_{10}(\text{BER})$  so that  $10^{-5}$  BER would correspond to 100. We observe that good BERs result for a large range of boosts and range of  $f_c$ 's centered

FIGURE 34.17 Boost bandwidth optimization.

**FIGURE 34.18** CTF BER performance degradation with respect to oversampled ideal system vs.  $cbd$  with 10-tap FIR.

in the plot. Upon examining contour plots for all the CTFs, we concluded that the  $b4$  CTF achieves good BERs for  $f_c$ 's typically in the center of the range explored, while the  $b6$  CTF the performance is better at somewhat higher  $f_c$ 's; however, the linear phase CTFs achieve good BERs at very low  $f_c$ 's. This is because CTFs with worse rolloff characteristics require a smaller  $f_c$  to provide enough attenuation at the Nyquist frequency for anti-aliasing. We observe that the BER performance is mostly insensitive to the boost. This is because the adaptive FIR is able to provide any remaining equalization needed. In practice, there will be a trade-off in how much boost the CTF is able to provide and the corresponding analog tap ranges required by the FIR to provide any necessary remaining equalization—the more equalization the FIR has to provide, the larger tap ranges it will require.

Now compare the BER performance of various Type 2 (CTF + analog FIR) equalizers. Figure 34.18 shows the BER performance of different CTFs with a 10-tap FIR. The horizontal axis is  $cbd$  and the vertical axis is the BER degradation (in dB) of the optimum BER with respect to the BER of  $10^{-5}$  achieved by the ideal oversampled system using the  $T/5$  equalizer. The performance of the CTFs is similar across all  $cbd$ 's—they perform within 0.15 dB of one another. All perform within 0.25–0.4 dB of the  $10^{-5}$  BER achieved by the  $T/5$  system. The linear phase of the seventh-order CTFs does not necessarily yield superior performance. A final comment is needed about the plot—one should not expect a fixed or monotonic relationship between  $cbd$  and the practical system BER in this plot. This is due to the finite resolution of the equalizer optimization search and the fact that BERs are based on observing 100 (vs. even larger number) bit errors.

As noted, the previous results were with a 10-tap FIR. Further simulations of the various CTFs with a 6-tap or even 3-tap show that the optimum BER performance is not very different than that with a 10-tap FIR. These results are presented in Fig. 34.19 where the BER degradation (again with respect to the  $10^{-5}$  achieved by the ideal system) of the optimum BER obtained for the various CTFs is plotted versus the number of FIR taps for  $cbd = 2.4$ . This initially appears to be a surprising result, but this is not unreasonable when one observes that with fewer number of taps, a large percentage of the CTF programmings result in poor BER performance. This effect is shown in Fig. 34.20, which plots the percentage of CTF programmings (with respect to the total number of programmings producing convergent tap weights) producing BER worse than  $4 \times 10^{-5}$ . With more taps the percentage of poor programmings decreases. Thus, FIR filters with a few taps, with appropriately optimized CTF settings, can perform as well as a FIR with 10 taps; however, the difficulty in keeping the nonadaptive CTF parameters correct in the presence of realistic device conditions makes such a FIR with few taps impractical to use.

Finally, examine the performance of Type 3 equalizers. Here, the anti-aliasing CTF is a seventh-order linear phase filter. The performance of this equalizer is a function of the number of FIR taps. The BER

FIGURE 34.19 CTF BER degradation with respect to oversampled ideal system vs. number of taps ( $cbd = 2.4$ ).

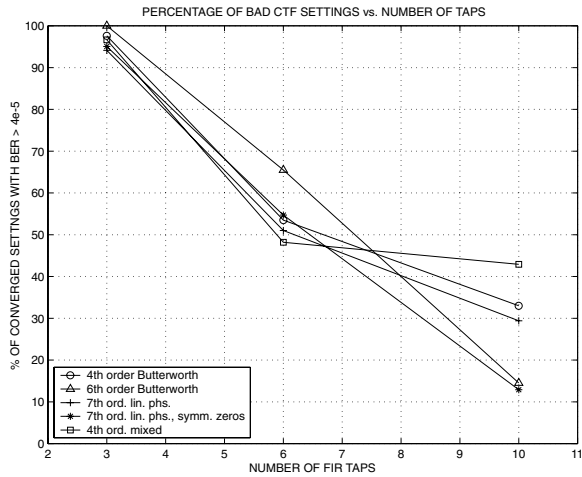

FIGURE 34.20 Percentage of bad CTF settings vs. number of taps ( $cbd = 2.4$ ).

performance are shown in Fig. 34.21. The vertical axis is again the degradation with respect to the ideal system BER of  $10^{-5}$ . The programmable tap of the FIR is optimized to yield the best performance in each case. The main tap is placed roughly in the center. There is benefit in increasing the number of taps from 4 to 6 to 10. Beyond 10 taps, however, there is more latency in the timing loop as the main tap position is more delayed. This causes increased phase errors to enter the timing loop and outweighs the benefit of enhanced equalization obtained with more taps. Although one could increase the number of taps while keeping the main tap location mostly fixed, the FIR will then not be able to cancel the precursor ISI as well with a CTF, which is not involved in equalization. Also shown (dashed plot) is the performance of a Type 2 equalizer (CTF, with its corner frequency optimized and with an optimized zero included to provide boost). Clearly the Type 2 equalizer outperforms the Type 3 equalizer.

### Actual Equalizer Architectures

Various equalization architectures and examined their performance have been considered. Let us now examine what actual architectures read channel vendors are using. Table 34.1 summarizes some of the most commonly used architectures. For example, Agere Systems [Note: storage products unit of AT&T was

**TABLE 34.1** Examples of Equalizers Implemented on Read Channel Chips

Company	CTF			FIR			Type (Fig. 34.11)	Ref/Yr	Comments
	Type	Order	Zeros	Taps	Adaptive?	Analog/Digital			
Agere	But	4th	2	10	yes	analog	2	[16], 1995	8 adaptive taps

Marvell	EqRip	7th	?	7	yes	digital	2	[20], 1997	—

**FIGURE 34.21** BER degradation with respect to oversampled ideal system vs. number of taps with anti-aliasing CTF (no boost).

spun off to Lucent Technologies in 1996 and again spun off to Agere Systems in 2001) has been using a Type 2 architecture with a fourth-order Butterworth CTF and 10-tap analog FIR. The CTF has a programmable corner frequency and zero for providing boost. This architecture is still in place now. Most other vendors have used Type 4 architectures (digital FIR) but with seventh-order equiripple linear phase filters. The linear phase filters typically have two programmable zeros to provide boost. In the examples of the Cirrus equalizers, the digital FIR does not appear to be adaptive. Some vendors such as Cirrus and Marvell seem to have increased the number of FIR taps or the number of adaptive (vs. only programmable) taps as the years have gone by. The Datapath equalizer cited is one of the few examples of an all CTF equalizer.

**Conclusions**

The performance of various CTF + adaptive analog FIR (Type 2) equalizers in equalizing a signal to an EPR4 target has been quantified. It is shown that regardless of the number of taps in the FIR and CTF type, the BER performance of the CTF + FIR equalizers is approximately the same if the optimum fixed equalizer parameters (CTF corner frequency, boost, FIR fixed tap) are chosen.

Therefore, the choice of CTF type should be based on other constraints such as area, power, speed (data rate), as well the benefit of having one less analog block. It has also been shown that as the number of taps is increased, the space of CTF parameter programmings producing BERs close to the optimum increases significantly. Therefore, one can trade-off the cost of the FIR filter versus required accuracy in the CTF setting and the sensitivity of the resulting performance.

The performance of Type 3 equalizers consisting of a  $T$  spaced FIR filter with only a Nyquist anti-aliasing CTF was also examined. Also, the Type 3 equalizer cannot approach the performance of a system whose CTF is involved in equalization and is optimized. Therefore, to make a valid comparison between FIR and CTF equalizers, one must include a reasonably optimum CTF prior to the FIR.

It has been demonstrated that a wide variety of optimized CTF + FIR equalizers can perform within 0.25 dB of the quantized system using the oversampled  $T/5$  equalizer. As this 0.25 dB includes performance losses due to AGC and timing recovery, there is very little space left for improved equalization with any other equalizer architecture.

## Adaptive Timing Recovery

In storage systems such as PRML magnetic recording channels a clock is used to sample the analog waveform to provide discrete samples to symbol-by-symbol ( $s/s$ ) and sequence (Viterbi) detectors. Improper synchronization of these discrete samples with respect to those expected by the detectors for a given partial response will degrade the eventual BER of the system. The goal of adaptive timing recovery is to produce samples for the  $s/s$  or sequence detector, which are at the desired sampling instances for the partial response being used. In this subsection, the basics of timing recovery as well as commonly used algorithms for timing recovery in magnetic recording channels are reviewed. Two classes of timing recovery algorithms are presented: symbol rate VCO-based and interpolation-based algorithms. After a discussion of the trade-offs between these two types of algorithms, the focus will be on the traditional symbol rate VCO algorithms for the rest of the discussion. One of these timing recovery algorithms from first principles will be derived. An analytical framework for comparing the performance of such algorithms using timing loop noise induced output jitter as the performance criterion is provided. Finally, quantitative comparative performance data for some of these algorithms based on the jitter analysis as well as simulations, which measure timing loop jitter and BER, is provided.

### Timing Recovery Basics

#### *Symbol Rate VCO versus Interpolative Timing Recovery*

Timing recovery schemes, which have been considered for magnetic recording channels, can be broadly classified into two groups: traditional symbol rate VCO-based schemes and interpolative schemes, [21,22], which sample slightly above the symbol rate. The key difference between the schemes is that the symbol rate VCO scheme adapts or adjusts the phase and frequency of the sampling clock to produce the desired samples whereas interpolative timing recovery samples the analog waveform using a uniformly sampled clock to produce samples from which the desired samples are interpolated.

Figure 34.22 shows high-level block diagrams of both approaches. Let us describe the VCO-based approach first. For the sake of the discussion the VCO approach is shown with an analog FIR equalizer. Consequently the sampling occurs at the input of the FIR equalizer. The noisy equalized output  $y(k)$  must be used to detect the timing error present in these samples. This is done using a phase detector. The phase detector transforms an amplitude error in the samples to  $\Delta(k)$ , which is related to the desired change in the sampling phase. The phase detector output is also called the timing gradient.

The phase detector may require the use of the noisy equalized samples  $y(k)$  or other signals derived from it. The other signals may be the preliminary or tentative decisions  $\hat{d}(k)$ s, decision directed estimates of  $y(k)$ , which are  $\hat{y}(k)$  or other signals. These auxiliary signals are generated by the block labeled "Signal Generation for Phase Detector." The  $y(k)$ s are used to generate preliminary (tentative) decisions  $\hat{d}(k)$  and an error signal  $e(k)$ , and a decision directed estimate of the ideal equalized sample value,  $\hat{y}(k)$ .

The phase detector output is filtered by a loop filter  $T(z)$ . The loop filter  $T(z)$  is usually a second order DPLL with an additional delay term  $z^{-L}$ , which models any latency through the timing loop. Such latency arises from the group delay of the FIR, computations in the DPLL, calculating the signals needed by the phase detector, etc. The filtered phase detector output is the input to a VCO, which causes the actual

FIGURE 34.22 (i) Symbol rate VCO-based timing recovery loop. (ii) Interpolative timing recovery loop.

sampling phase  $\tau$  to change. The VCO is an analog circuit under digital control. The analog part can be a phase mixer, which is capable of adjusting the timing phase by small fractions of  $T$  where  $T$  is the channel bit period. In such a case, the VCO acts as an amplitude to time converter and so modeled as a simple gain. To give physical meaning to the system, the units of the signals are noted: the equalized output after quantization by the ADC is in amplitude units of LSBs, the timing gradient  $\Delta(k)$  or phase detector output is proportional to an amplitude error and so is also in LSBs. The loop filter provides a frequency dependent gain, so the input of the VCO is LSBs. The VCO has a gain of  $K_V$  in units of  $T/\text{LSB}$ , so the output of the VCO has units of time,  $T$ . The VCO gain can also be thought of as a clock update gain. For the specific system we will consider later, the phase mixer can make changes in the sampling phase in steps of  $0, \pm 1, \pm 2 T/64$  or more. The choice of this factor of 64 is such that the quantization of timing phase adjustment is well below the ADC quantization noise floor.

Let us now describe the interpolative timing recovery loop of Fig. 34.22. As noted, with this scheme, an asynchronous clock is used to sample the input to the ADC after which a FIR filter performs the necessary equalization. The asynchronous equalized samples are now used to interpolate samples at the correct sampling instances dictated by the partial response. This is done with the interpolation filter, which can be thought of as a filter which delays its input by an amount  $\tau$ , which is a fraction of the channel bit period  $T$  [21]. Such an interpolation filter's transfer function is  $z^{-\tau}$ . The samples  $y(k)$  at the output of the interpolation filter drive the phase detector and loop filter as in the VCO-based timing loop. The loop filter output after being processed by the phase offset calculator produces the required sampling phase change. For good operation, the loop must be able to produce a large number of fractional delays (such as 32 or 64) and correspondingly would require as many such filters for each of these delays. Figure 34.22 noted that the asynchronous sampling was performed at slightly above the Nyquist rate. The reasons for this is to accommodate a frequency offset between the written signal and the clock used to perform the asynchronous sampling. The magnitude of this frequency offset is usually limited in practical systems to 1% or less and so very little oversampling is required; however, oversampling ratios

of up to 5% produce some improvement in performance by reducing the sensitivity of the aliasing with respect to the phase of the asynchronous sampling clock.

The advantages of the ITR-based timing loops are that they are all digital timing loops, which are more amenable for design, verification, and less susceptible to process variations. Also, for the ITR timing loop, the delays in the equalization filter and ADC do not contribute to the timing loop latency; however, the interpolation filter is not an extremely small piece of hardware and could make the ITR timing loop consume more chip area and power than a VCO-based loop. Practical design issues with the ITR-based system such as adaptation of the equalizer based on asynchronous samples [22] and design of the interpolation filter, have not been discussed. From a performance point of view, there is no significant difference between the ITR- or VCO-based approaches as indicated by simulation results in [21]. This also seems reasonable based on our observation in the subsection on adaptive equalization where it was noted that a read channel system with practical equalization and timing recovery performed within a few tenths of a decibel of the corresponding “ideal” system. Therefore, the choice between all digital ITR-based system or a conventional VCO-based system needs to be based on the relative merits of both systems from an ease of design and area/power standpoint.

**Timing Loop Modes**

Let us now further describe the operation of the entire timing loop. The entire timing recovery process occurs in several steps: zero phase start (ZPS), acquisition mode (ACQ), and tracking mode (TRK). During the ZPS and ACQ modes the disk controller must guarantee that the read channel is reading a preamble signal known to the timing loop. The preamble signal for almost all magnetic recording channels is a 2T pattern, which is the periodic data sequence “...11001100...” The purpose of the ZPS is to obtain a good estimate of the initial phase error between the readback signal and the desired samples for the 2T pattern. Once this estimate is obtained the sampling clock’s phase is changed by the calculated amount to approximate the desired sampling phase. The next step is the ACQ process where the sampling phase error is further reduced and the frequency offset between the input signal and the sampling clock is compensated for to produce even more accurately sampled preamble samples. Because the preamble is a known signal pattern, timing recovery is facilitated in that the preliminary decisions can be obtained more reliably with less loop latency. Consequently, high loop filter update gains can be used. Once this initial acquisition is complete, the timing loop transitions into a TRK, which is intended for tracking slow variations in timing. In this mode the signal may contain any excess preamble as well as random data, but no a priori assumption about the signal is made. The tentative decisions in the TRK mode are obtained with more loop latency and are not as reliable. The loop filter update gains are correspondingly lower. A summary of the operation described is provided in Fig. 34.23. More fine gradations of the loop filter gains (beyond the high/medium/low gains shown in Fig. 34.23 can be made across ACQ and TRK to produce improved performance [23]. Of course, there is a trade-off between improved performance and somewhat enhanced circuit complexity so that one would choose to increase the complexity only, until diminishing returns in performance is reached.

Mode Name	ZPS	Acquisition (ACQ)	Tracking (TRK)
Assumed Data	Preamble	Preamble	Excess preamble / regular random data
Loop Filter Gains	Zero	High / medium	Medium / low

**FIGURE 34.23** Timing loop operational modes: zero phase start, acquisition, and tracking.

## Symbol Rate Timing Recovery Schemes

Now consider in more detail the traditional symbol rate VCO-based schemes. A decision directed baud or symbol rate timing recovery algorithm was first proposed by Mueller and Muller [24]. Their technique relied on the concept of a “timing function.”  $f(\tau)$ , which generates the proper amount of timing phase adjustment for a given phase shift,  $\tau$ , in the signal. The function should be monotonic, and have a zero output for zero sampling phase error. The Mueller and Muller (MM) technique provides a means to derive a timing function from a linear combination of samples of the channel's impulse response. In practice, one can design timing gradients where the expected value equals the suitably defined timing function. The timing gradients can be used to obtain the corresponding phase adjustment signal. In some magnetic recording systems using a PR4 target, a MM timing gradient with a second order DPLL was used to produce the necessary timing phase updates [8,25].

One can also derive timing recovery schemes based on other criteria such as the minimum mean square error (MMSE) criterion. MMSE methods seek to minimize the expectation of the square of an error signal  $e(k, \tau)$  with respect to the timing phase. The error signal is obtained by subtracting the received equalized samples  $y(k, \tau)$  from the corresponding “ideal” samples  $\hat{y}(k)$ . The minimization is done by adjusting the timing phase in the direction opposite to the derivative of the expected value of the squared error. In practice, one ignores the expected value and minimizes the squared error resulting in a stochastic gradient algorithm. MMSE timing recovery has been proposed in [26] and examined to some degree in [27] for PR magnetic recording channels. Another criterion, the maximum likelihood (ML) criterion, has also been used to derive a phase detector [28].

The derivation of the MMSE gradient is reviewed, and note that the MMSE gradient yields suitable timing functions. Also formulated is the MMSE timing recovery in the framework of a slope lookup table (SLT) instead of a discrete time filtered version of symbol rate spaced equalized samples  $y(k, \tau)$ . The SLT approach leads to an efficient implementation with slopes expressed directly in terms of a discrete time filtered version of the data bits  $d(k)$  instead of the equalized signal samples.

A methodology for an analytical performance evaluation of the timing loop where the timing loop output noise jitter is the performance criterion. The analysis is described in detail for the SLT-based MMSE timing loop and also applied to the MM timing loop. The quantitative results from this technique are used to compare the SLT and MM timing loops. The ML loop is not considered further here as it has somewhat adverse jitter properties compared with the other two timing loops [29]. Finally, simulations results comparing the SLT and MM timing loops in terms of output noise jitter as well as BER performance are presented.

### MMSE Slope Lookup Table (SLT) Timing Recovery

Let us review MMSE timing recovery from first principles. The discussion is along the lines of [26] and [27]. The expectation of the square of the error,  $e(k, \tau) = y(k, \tau) - \hat{y}(k)$ , is minimized with respect to the timing or sampling phase. Here,

$$\hat{y}(k) = \sum_{p=0}^{P-1} h(p) \hat{d}(k-p) \quad (34.7)$$

and in the absence of any channel impairments we would have  $\hat{d}(k) = d(k)$  and  $\hat{y}(k) = y(k)$ . The derivative of the expectation needs to be obtained with respect to  $\tau$ . Ignoring the expectation operator we obtain a stochastic gradient algorithm [26]:

$$\begin{aligned} \frac{\partial}{\partial \tau} (e^2(k, \tau)) &= 2y(k, \tau) \frac{\partial y(k, \tau)}{\partial \tau} - 2\hat{y}(k) \frac{\partial y(k, \tau)}{\partial \tau} = -2e(k, \tau) \frac{\partial y(k, \tau)}{\partial \tau} \\ &= -2e(k, \tau) \left[ \frac{dy(t)}{dt} \right]_{t=kT+\tau} = -2e(k, \tau) s(k, \tau) \end{aligned} \quad (34.8)$$

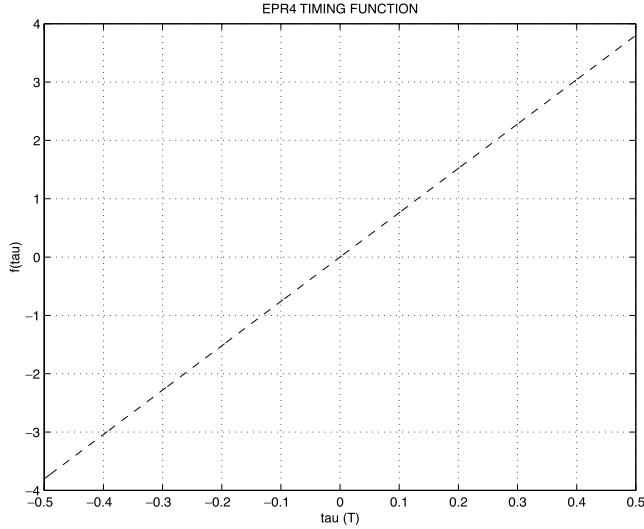

FIGURE 34.24 Timing function for an EPR4 partial-response channel.

Note that the MM approach was to generate a timing gradient from a suitably defined timing function  $f(\tau)$ . Here, a timing gradient has been derived from the MMSE criterion; however, the resulting timing gradient should be a valid timing function, i.e., be monotonic, and have a zero-crossing for zero sampling phase error. This has been shown in [27]. An expression for the timing function in terms of the PR channel coefficients is [29]

$$f(\tau) = \sum_{l=-\infty}^{\infty} \left[ \sum_{\substack{p=0 \\ l \neq p}}^{p-1} h(p) \frac{(-1)^{l-p}}{(l-p)T} \right]^2 \quad (34.9)$$

The result of plotting  $f(\tau)$  in Eq. (34.9) for EPR4 is shown in Fig. 34.24. Let us now consider a MMSE-based timing gradient or phase detector formulated in terms of a SLT. The signal slope is modeled in terms of a slope generating filter, which when used to filter the data  $d(k)$  produces the slopes:

$$s(k) = d(k) \times \psi(k) = \sum_{c=-C_1}^{C_2} \psi(c) d(k-c) \quad (34.10)$$

where the negative coefficient index indicates that the slope at time  $k$  depends on future bits (accommodated by delaying the slope and adding the delay into the model as additional latency).  $C_1 + C_2 + 1$  is the number of nonzero coefficients of the slope filter's impulse response,  $\psi$ . The SLT output  $\hat{s}(k)$  approximates  $s(k)$ , which depends on the data pattern. Such a SLT can be derived for any PR by correlating the data with the actual signal slopes. In practice, it is enough to use fewer terms from the filter. Therefore, the simplified SLT output can be represented as

$$\hat{s}(k) = \sum_{b=-B_1}^{B_2} \psi(b) d(k-b) \quad (34.11)$$

where  $B = B_1 + B_2 + 1$  is the size of the slope table input i.e., the number of data bits used in calculating the slope. The SLT-based gradient is then,

$$\Delta(k) = e(k)\hat{s}(k) \tag{34.12}$$

where the factor of  $-2$  in Eq. (34.8) can be absorbed in the lookup table. In our analysis we need the slope generating filter coefficients  $\psi(c)$ . These coefficients  $\psi(c)$ s are obtained in the process of numerically generating the signal slopes, which are correlated with the data.

*Phase Detector Properties*

Before computing the output noise jitter of the entire timing loop, the properties of the phase detector must be analyzed. Quantities important for the performance of the phase detector are its *KPD* and output noise standard deviation ratio  $KPD/\sigma_n$ . The *KPD* is the ratio of the mean phase detector output to a constant sampling phase error,  $\tau$ . The *KPD* can thus be thought of as the signal gain of the timing loop where the signal is the sampling phase error. The output noise  $n_o(k)$  is the equivalent noise at the output of the phase detector for a given input noise  $n(k)$  at the phase detector input. The error,  $e(k)$ , at the equalizer output is a combination of contributions from the sampling phase error,  $\tau(k)$  and noise. Let  $n(k)$  represent the noise at the equalizer output (intersymbol interference + filtered equalized noise). We then have,

$$e(k) = \tau(k)s(k) + n(k) \tag{34.13}$$

The phase detector output,  $\Delta(k)$ , is then

$$\Delta(k) = [\tau(k)s(k) + n(k)]\hat{s}(k) = \tau(k)s(k)\hat{s}(k) + n_o(k) \tag{34.14}$$

Figure 34.25 shows in detail the timing loop of Fig. 34.22 with the details of the SLT phase detector and the composition of the error signal from the sampling phase and noise per Eq. (34.13).

Now find the statistical properties of *KPD* and  $n_o$  using  $\mathcal{E}$  as the expectation operator. For a tractable analysis we assume  $n(k)$  is AWG. To easily relate  $\sigma_n$  to the error event rate (EER) at the output of the Viterbi detector, we assume that channel errors are dominated by a minimum distance error event (with distance  $d_{\min}$ ).

$$\sigma_n = \frac{d_{\min}/2}{Q^{-1}(\text{EER})} \tag{34.15}$$

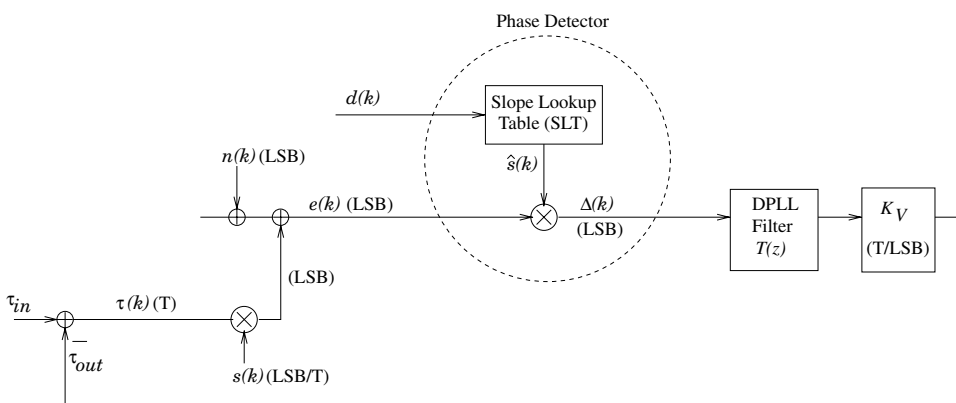

FIGURE 34.25 Timing loop with SLT phase detector.

The EER is the BER divided by the number of bit errors in the dominant error event. In Eq. (34.15)  $Q$  refers to the well-known  $Q$  function defined by

$$Q(x) = \frac{1}{2\pi} \int_x^\infty \exp\left(-\frac{y^2}{2}\right) dy \quad (34.16)$$

*Signal Gain (KPD) of the Phase Detector*

Using the definition of  $KPD$ , for a constant sampling phase error  $\tau$ ,

$$KPD = \frac{\mathcal{E}\{\tau \hat{s}(k)s(k) + n(k)\hat{s}(k)\}}{\tau} = \mathcal{E}\{\hat{s}(k)s(k)\} + \frac{\mathcal{E}\{n(k)\hat{s}(k)\}}{\tau} \quad (34.17)$$

Consider  $\mathcal{E}\{n(k)\hat{s}(k)\}$ , where  $\hat{s}(k)$  is a linear function of the data bits, which can be realistically assumed to be uncorrelated with the noise  $n(k)$ . Therefore, this term is zero and as we should expect, the noise does not contribute to the mean phase detector output. Thus,

$$KPD = \mathcal{E}\{\hat{s}(k)s(k)\} = \sum_{b=-B_1}^{B_2} \sum_{c=-C_1}^{C_2-1} \psi(b)\psi(c)\mathcal{E}\{d(k-b)d(k-c)\} \quad (34.18)$$

If  $d$  is uncoded, hence white, with zero mean,  $\mathcal{E}\{d(k-b)d(k-c)\} = \sigma_d^2$  if  $b = c$  and is 0 if  $b \neq c$ . Consequently, the  $KPD$  is

$$KPD = \sigma_d^2 \sum_{b=-B_1}^{B_2} \psi^2(b) \quad (34.19)$$

where it is assumed that slope table output is based on fewer than  $C_1 + C_2 + 1$  terms to reduce the summation to be from  $b = -B_1$  to  $B_2$ . We note that the  $KPD$  values obtained here are equivalent to the slopes of the  $f(\tau)$  versus  $\tau$  curve plotted in Fig. 34.24.

*Output Noise of the Phase Detector*

Computing the autocorrelation,

$$\mathcal{E}\{n_o(k)n_o(k+l)\} = \mathcal{E}\{n(k)\hat{s}(k)n(k+l)\hat{s}(k+l)\}$$

Because  $\hat{s}(k)$  is a filtered version of  $d(k)$ , which is uncorrelated with  $n$ ,  $n$  and  $\hat{s}$  are uncorrelated. Therefore,

$$\begin{aligned} \mathcal{E}\{n_o(k)n_o(k+l)\} &= \mathcal{E}\{n(k)n(k+l)\}\mathcal{E}\{\hat{s}(k)\hat{s}(k+l)\} \\ &= R_n(l)\mathcal{E}\{\hat{s}(k)\hat{s}(k+l)\} \end{aligned}$$

$$\mathcal{E}\{\hat{s}(k)\hat{s}(k+l)\} = \sum_{b=-B_1}^{B_2} \sum_{b'=-B_1}^{B_2} \psi(b)\psi(b')\mathcal{E}\{d(k-b)d(k+l-b')\} \quad (34.20)$$

With  $d$  being uncoded (hence white) and zero mean,  $\mathcal{E}\{d(k-b)d(k+l-b')\} = \sigma_d^2$  if  $b' = b+l$  and 0 if  $b' \neq b+l$ . Also assuming,  $R_n(l) = \sigma_n^2 \delta[l]$ , i.e.,  $n$  to be white, we need to consider only  $l=0$  in which case we have  $b = b'$ . In that case,

$$\mathcal{E}\{n_o(k)n_o(k+l)\} = \sigma_n^2 \sigma_d^2 \delta[l] \sum_{b=-B_1}^{B_2} \psi^2(b) \quad (34.21)$$

FIGURE 34.26 Timing loop with Mueller–Muller phase detector.

Observe that the noise at the phase detector output is indeed white with standard deviation,

$$\sigma_{n_o} = \sigma_n \sigma_d \sqrt{\sum_{b=-B_1}^{B_2} \psi^2(b)} \quad (34.22)$$

### Mueller and Muller (MM) Timing Loop

Now examine the properties of the MM timing gradient. This gradient is obtained as

$$\Delta(k) = y(k)\hat{y}(k-1) - y(k-1)\hat{y}(k) \quad (34.23)$$

in terms of the equalized signal  $y(k)$  and its delayed version as well as the corresponding estimates of the “ideal” values  $\hat{y}$  for these signals. A block diagram of a MM timing loop using this gradient is shown in Fig. 34.26. It is possible to evaluate this phase detector’s KPD and noise performance. This is accomplished by writing  $y(k)$  as  $\hat{y}(k) + e(k)$ , expanding  $e(k)$  as in Eq. (34.13) from which  $s(k)$  is further expressed in terms of the slope generating filter based on Eq. (34.10). Likewise,  $\hat{y}(k)$  is expressed in terms of the PR coefficients as per Eq. (34.7). The analysis makes the usual assumptions about the data and noise  $n(k)$  being white. The details of the analysis can be found in [29] which yields,

$$KPD = \sigma_d^2 \left( \underbrace{\sum_c \sum_m}_{m-c=-1} \psi(c)h(m) - \underbrace{\sum_c \sum_m}_{m-c=1} \psi(c)h(m) \right) \quad (34.24)$$

where the sum over  $m$  is from 0 to  $P-1$  and that over  $c$  is from  $-C_1$  to  $C_2+1$ .

The autocorrelation,  $R_{n_o}(l)$  for the noise at the output of the phase detector, assuming the data to be white, is also computed in [29]. It is shown that even with AWG noise at the phase detector input, i.e., noise with autocorrelation  $R_n(l) = \sigma_n^2 \delta[l]$ , noise at the phase detector output is not white; however, it is shown that if  $R_n(l) = \sigma_n^2 \delta[l]$  the autocorrelation of  $R_{n_o}(l)$  will be limited to only the first delay terms, i.e.,  $l = 1$  and  $-1$  so we have,

$$R_{n_o}(0) = \sigma_{n_o}^2 = 2\sigma_d^2 \sigma_n^2 \sum_{p=0}^{P-1} h(p)^2 \quad (34.25)$$

and

$$R_{n_o}(1) = R_{n_o}(-1) = -\sigma_d^2 \sigma_n^2 \sum_{\substack{p=0 \\ p-m=2}}^{P-1} \sum_{m=0}^{P-1} h(m)h(p) \quad (34.26)$$

### Performance Comparison of Symbol Rate Timing Loops

So far, the properties of the SLT and MM timing gradients or phase detectors have been examined. If the noise at the phase detector output for both systems were white we could directly compare their performance by comparing their respective *KPD* to  $\sigma_{n_o}$  ratio as a kind of signal-to-noise ratio (SNR) of the phase detector. The ratio would measure a signal gain (experienced by sampling phase errors) to noise gain across the entire bandwidth. If the noise had been white for both systems this ratio would scale similarly for both systems when measured over the effective noise bandwidth determined by the loop filter; however, for the MM loop we observed that the noise at the phase detector output was not white. Therefore, we must examine the timing loop performance at the output of the loop filter not just at the output of the phase detector. Before continuing our analysis let us make some qualitative comments about the loop filter.

#### Qualitative Loop Filter Description

A timing loop is a feedback control loop. Therefore, the stability/loop dynamics are determined by the “gain” (in converting observed amplitude error to a timing update) of the phase detector and the details of the loop filter. If the timing loop were needed to remove the effect of a sampling phase error, a first order DPLL would be sufficient; however, the timing loop must also recover the proper frequency with which to sample the signal. Therefore, the use of a second order DPLL loop filter is needed. This allows the timing loop to continually generate small phase updates to produce a clock, which not only has the correct sampling phase within a symbol interval  $T$  but which also has the correct value for the symbol interval i.e., the correct clock frequency. DPLL here refers to the portion of the overall loop filter transfer function  $T(z)$  without the fixed delay term  $z^{-L}$ . In addition, important to the performance of the loop is its noise performance, i.e., for a given level of input noise, the effect on the jitter in sampling phase updates. The jitter properties are determined by the noise gain of the phase detector as well as the loop filter properties. The loop filters out noise beyond the bandwidth of interest, this bandwidth being determined by how rapidly the loop is designed to react to timing changes. As mentioned earlier, the DPLL loop filter is a second order filter with an additional latency term. Its transfer function is given by:

$$T(z) = z^{-L} \left( \frac{f_g z^{-1}}{1 - z^{-1}} + p_g \right) \left( \frac{z^{-1}}{1 - z^{-1}} \right) \quad (34.27)$$

where  $f_g$  and  $p_g$  are frequency and phase update gains for the second order and first order sections, respectively, while  $L$  is the loop latency. A block diagram of  $T(z)$  is also shown in Fig. 34.27(a).

#### Noise Jitter Analysis of Timing Loop

Linearized  $Z$  domain analysis of the DPLL is now performed by replacing the phase detector with its *KPD* (denoted by  $K_p$  in the equations for readability). In evaluating the SLT and MM DPLLs three sets or combinations of  $p_g$  and  $f_g$  will be used: “LOW”, “MED”, and “HGH” where the LOW gains, are relatively low update gains, which would be used in tracking mode, MED gains are moderate gains, and HGH gains, are high gains, which might be used during acquisition. For the SLT and MM DPLLs the  $p_g$  and  $f_g$  are scaled so that the same settings result in the about same transient response for a given sized phase or frequency disturbance.

**FIGURE 34.27** Linearized model: (a) second-order DPLL loop filter, (b) timing loop with phase detector modeled by its average signal gain.

**FIGURE 34.28** Closed loop frequency response of SLT DPLL for low  $p_g$  and  $f_g$  update gains.

The open loop DPLL transfer function,  $G(z)$ , incorporating the loop filter  $L(z)$  and clock update gain is

$$G(z) = K_V \left( \frac{f_g z^{-1}}{1 - z^{-1}} + p_g \right) z^{-L} \left( \frac{z^{-1}}{1 - z^{-1}} \right)$$

Referring to the timing loop model of Fig. 34.27(b), the closed loop transfer function  $(T_{out}/T_{in}) = H(z)$  is

$$H(z) = \frac{K_p G(z)}{1 + K_p G(z)} \tag{34.28}$$

Note that  $K_p$  has dimensions of LSB/T,  $K_V$  and  $G(z)$  have dimensions of T/LSB and  $H(z)$  is a transfer function with respect to two time quantities. The effective noise bandwidth is then,

$$ENB = 2 \int_0^{0.5} |H(f)|^2 df$$

An example of a closed loop transfer function for the SLT DPLL is shown in Fig. 34.28 for LOW update gains. To find the effect of AWG noise,  $n(k)$ , first convert the  $\sigma_n$  to an effective timing noise by dividing by the rms slope,  $\sigma_s$ , of the signal that is obtained during the numerical generation of the signal slopes

and calculation of the slope generating filter coefficients. Now it can be multiplied by the square root of the  $ENB$  to determine the corresponding noise induced timing jitter  $\sigma_j$  (units of T). Therefore,

$$\sigma_j = \frac{\sigma_n}{\sigma_s} \sqrt{ENB} \quad (34.29)$$

The equivalent model for the above method of analysis is shown in Fig. 34.27(b).

For the SLT-based DPLL, the total jitter is simply the above  $\sigma_j$ . For the MM DPLL the phase detector output noise is colored; however, we know its properties here and can examine its effect from this point onwards. The only difference is that the closed loop transfer function seen by the MM phase detector output noise is,

$$F(z) = \frac{G(z)}{1 + K_p G(z)} \quad (34.30)$$

The noise jitter is then obtained as,

$$\sigma_j = \sqrt{2 \int_0^{0.5} P_n(f) |F(f)|^2 df} \quad (34.31)$$

where  $P_n(f)$  is the noise p.s.d. at the phase detector output.

Figure 34.29 plots the jitter performance of the SLT- and MM-based DPLLs for three sets of  $(p_g, f_g)$ : LOW, MED, HGH. Shown are the output, noise-induced timing jitter of the loop for four channel error event rates. Observe that the MM timing loop's output noise jitter is almost the same but slightly better than that of the SLT-based timing loop.

### Jitter and BER Simulation Results

Simulations on the SLT-based timing loop and the MM loop are run within the simulator framework described in Fig. 34.22. The same DPLL loop filter structure is used for both systems. Simulations are run at a channel bit density bit of 2.8 without noise and SNRs, which correspond with channel EERs of

FIGURE 34.29 Analytically calculated output jitter for SLT and MM timing loops.

**TABLE 34.2** Simulation-Based Timing Loop Output Jitter  $\sigma_j$  (Units of  $T/64$ ) Performance of SLT and MM Timing Loops for Final EERs of Zero (Noiseless),  $10^{-4}$ , and  $10^{-2}$

$p_g, f_g$ GAINS	SLT			MMPD		
	EER 0	EER $10^{-4}$	EER $10^{-2}$	EER 0	EER $10^{-4}$	EER $10^{-2}$
LOW	0.49	1.30	2.18	0.45	1.16	1.86
MED	0.49	1.69	2.99	0.46	1.56	2.51
HGH	0.67	2.67	4.86	0.70	2.67	4.38

**FIGURE 34.30** SLT and MM DPLL reaction to  $0.1875T$  ( $12T/64$ ) phase step. Low  $p_g, f_g$  gains. No noise in this simulation.

$10^{-4}$  and  $10^{-2}$ . The steady-state jitter is examined in the DPLL output phase and the response of the timing loop to a phase step in the data field. Figure 34.30 shows the transient phase response plots of the SLT and MM DPLLs responding to a  $0.1875T$  ( $12T/64$ ) phase step in data field for the same LOW  $p_g$  and  $f_g$  settings. Note that they have very similar responses. Table 34.2 shows the steady-state output jitter of the two timing loops for various combinations of gains and noise levels corresponding to EERs of  $10^{-4}$  and  $10^{-2}$ . The settled DPLL phases show some nonzero jitter without additive noise from quantization effects. Timing jitter at the DPLL output is measured by measuring the standard deviation of the DPLL phase. Again, observe that the two timing loops have very similar jitter numbers although the MM timing loop jitter is slightly lower.

Finally, the Viterbi detector BER performance is examined instead of the timing loop jitter performance for the read channel architecture of Fig. 34.31 employing the MM and SLT timing loops. Observe that the BERs of the two systems are practically indistinguishable.

## Conclusions

An overview of timing recovery methods for PRML magnetic recording channels, including interpolative and traditional symbol rate VCO-based timing recovery methods, was provided. Also reviewed was the MMSE timing recovery from first principles and its formulation in the framework of a SLT-based timing gradient. A framework for analyzing the performance of the timing loops in terms of output noise jitter was provided. The jitter calculation is based on obtaining linearized  $Z$  domain closed loop transfer functions of the timing loop. Also compared was the output timing jitter, due to input noise,

FIGURE 34.31 Simulated BERs of practical read channel using SLT and MM timing loops.

of the SLT and MM timing loops—two commonly used timing loops. The jitter performance of the MM loop is almost the same but very slightly better than that obtained with the SLT-based timing loop; however, the Viterbi BER performance of read channel systems employing the two timing loops are practically indistinguishable.

## 34.4 Head Position Sensing in Disk Drives

---

*Ara Patapoutian*

### Introduction

Data in a disk drive is stored in concentric tracks on one or more disk platters. As the disks spin, a magnetic transducer known as a read/write head, transfers information between the disks and a user [1]. When the user wants to access a given track, the head assembly moves the read/write head to the appropriate location. This positioning of the head is achieved by use of a feedback servo system as shown in Fig. 34.32. First, a position sensor generates a noisy estimate of the head location. Then by comparing the difference between this estimate and the desired location, a controller is able to generate a signal to adjust the *actuator* accordingly.

Two known approaches are used in sensing the head position. An external optical device can be used to estimate the head position by emitting a laser light and then by measuring the reflected beam. This approach is relatively expensive, may need frequent calibrations, and at present is limited to servo writers, which are discussed later. In the second approach, a read head, which is designed primarily to detect the recorded user data pattern, will itself sense position specific magnetic marks recorded on a disk surface. Using statistical signal-processing techniques, the read waveform is decoded into a head position estimate. At present this second approach is preferred for disk drives and is the topic of this article.

In an *embedded servo* scheme, as shown in Fig. 34.33, a portion of each platter, which is divided into multiple wedges, is reserved to provide radial and sometimes angular position information for the read

FIGURE 34.32 Position control loop for a disk drive.

FIGURE 34.33 Data and servo fields on a disk drive.

FIGURE 34.34 A generic composition of a servo field.

head. These reserved wedges are known as *servo fields*, and the number of wedges per surface varies significantly amongst different products. A generic servo wedge provides radial estimates in two steps. On a disk surface, each track is assigned a number known as the *track address*. These addresses are included in a servo field, providing complete radial position information with accuracy of up to a track. In other words, the information provided by a track address is complete but coarse. The positional error signal (PES) complements the track address by providing a more accurate estimate within a track. By combining these two estimates, a complete and accurate head position estimate can be obtained.

A wedge may also contain coarse information regarding angular position if a specific address is assigned to each wedge. The user data field, with its own address mark and timing capability, can complement the wedge address by providing finer angular position estimates.

A typical wedge will have multiple sub-fields, as shown in Fig. 34.34. A periodic waveform, known as a *preamble*, provides ample information to calibrate the amplitude of the waveform and, if necessary, to acquire the timing of the recorded pattern. Frame synchronization, or the start of a wedge, is recognized

by a special sequence known as the *address mark*. This is followed by the track and wedge addresses, and finally by the servo burst that provides information regarding the PES. These multiple sub-fields can be divided into two distinct areas. Since the address mark, track address, and wedge address are all encoded as binary strings, they are referred to as the *digital field*, as shown in Fig. 34.34. By contrast, ignoring quantization effects of the *read channel*, the periodic servo burst field is decoded to a real number representing the analog radial position. Thus, the format designs as well as the demodulation techniques for the digital and burst fields are fundamentally different. The digital field demodulator is known as the *detector* while the servo burst field demodulator is known as the *estimator*.

Despite their differences, the two fields are not typically designed independently of each other. For example, having common sample rates and common front-end hardware simplifies the receiver architecture significantly. Furthermore, it makes sense to use coherent or synchronous detection algorithms with coherent estimation algorithms and vice versa.

Having a reserved servo field comes at the expense of user data capacity. A major optimization goal is to minimize the servo field overhead for a given cost and reliability target. Both the servo format design as well as that of the detectors/estimators in the read channel chip of a disk drive are optimized to minimize this overhead.

This chapter section reviews position sensing formats and demodulators. Because estimation and detection are well-known subjects, presented in multiple textbooks [2,3], issues that are particular to disk drive position sensors are emphasized. Furthermore, rather than the servo control loop design, the statistical signal processing aspects of position sensing are presented. For a general introduction to disk drive servo control design, the reader is referred to [4], where the design of a disk drive servo is presented as a case study of a control design problem. In general, because of the proprietary nature of this technology, the literature regarding head position sensing is limited to a relatively few published articles, with the exception of patents.

When a disk drive is first assembled in a factory, the servo fields have to somehow be recorded on the disk platters. Once a drive leaves the factory, these fields will only be read and never rewritten. Traditionally, an expensive external device, known as the *servo writer*, introduced in the subsection on “Servo Writers,” records the servo fields. In general, the servo writing process constrains and affects the servo field format choices as well as the demodulator performance. In the next section, the digital field format and detection approaches are addressed, while in the subsection on “The Burst Field,” the servo burst format and PES estimation approaches are introduced.

## Servo Writers

After a disk drive is assembled, the function of a servo writer is to record the servo wedges on a drive. While the disks are spinning, an *external* servo writer senses the radial position usually through the head assembly using the reflection of a laser beam. An external mechanical device moves the head assembly. Finally, an external read head locks on a clocking track on a disk to locate the angular position. By knowing both the radial and angular position, as well as controlling the radial position, the servo writer records the wedges, track by track, using the native head of the drive.

Servo writing has been an expensive process. The servo writing time per disk is an important interval that disk manufacturers try to minimize and is proportional to the number of tracks per disk surface, to the spin of the disk drive, and to the number of passes needed to record a track. Since the number of tracks per disk is increasing faster than the spin speed, the servo writer time becomes a parameter that needs to be contained. To this end, the disk drive industry has attempted to minimize both servo writer time and the servo writer cost.

Self-servo writing is a procedure where the wedges are written by the disk drive itself without using any external device [5,6]. Here, the servo writing time is increased but the process is less costly. Many hybrid proposals also use a combination of an external servo writer to record some initial marks and then complete the wedges by using the drive itself. An example of such a process is the printed media approach [7,8], where a master disk “stamps” each disk, and afterward the drive completes writing the wedges.

FIGURE 34.35 Servo writer impairments: erase bands and radial incoherence.

In general, the servo writer cannot record an arbitrary wedge format. For example, it is very difficult for a servo writer that records wedges track-by-track to record a smooth angled transition across the radius. Furthermore, the wedges generated by a servo writer are not ideal. For example, servo writers that record wedges track-by-track create an *erase band* between tracks [9], where due to head and disk media characteristics, no transition is recorded in a narrow band between two adjacent tracks. Similarly, because of uncertainties in the angular position, two written tracks may not be aligned properly causing *radial incoherence* between adjacent tracks. These two impairments are illustrated in Fig. 34.35. In summary, the servo writer architecture affects both the wedge format design as well as the demodulator performance of a disk drive sensor.

## The Digital Field

The digital servo field has many similarities to the disk drive user data field [10] and to a digital communications system [2]. Each track in a digital field is encoded and recorded as a binary string similar to a data field. What differentiates a digital servo field from others is its short block length, and more importantly its off-track detection requirement.

Before discussing these differences, let us start by saying that a magnetic recording channel, for both the data and servo digital fields, is an intersymbol interference (ISI) channel. When read back, the information recorded in a given location modifies the waveform not only at that given location but also in the neighboring locations. Finite length ISI channels can be optimally detected using sequence detectors [11], where at least theoretically, all the field samples are observed before detecting them as a string of ones and zeros. For about a decade now, such sequence detectors have been employed in disk drives to detect the user data field.

The digital servo field length is very short relative to a data field. The present data sector length is around 512 bytes long, whereas the servo digital information string is only a few bytes long. So, whereas the percentage of overhead attributable to a preamble, address marks, and error correcting codes (ECC) is relatively small compared to the user data field, the overhead associated with a digital servo field can easily exceed one hundred percent. For example, it is well known that ECC coding efficiency increases with block length, i.e. codes with very short block lengths have weak error correction capability.

One strategy in minimizing the preamble field length is to use asynchronous detection, which usually trades performance for format, since it does not require exact timing information.

A simple strategy in minimizing the digital field is to write only partial information per wedge [12]. For example, with a smart controller, the absolute track or wedge address may not be needed, since it may be predicted using a state machine; however, such strategies improve format efficiency at the expense of performance robustness and complexity.

## Offtrack Detection

A primary factor that differentiates digital servo fields from other types of detection channels is the requirement to detect data reliably at any radial position, even when the read head is between two adjacent tracks. In contrast, a user data field is expected to be read reliably only if the read head is directly above

X	+	-	+	+	+	-
Y	+	-	-	+	+	-

**FIGURE 34.36** An example of two Gray-coded track addresses. The two addresses are different only in the third location.

that specific track. As will be discussed shortly, such a constraint influences the ECC as well as sequence detection strategies.

A related concern is the presence of radial incoherence, and the erase field introduced during servo writing that are present when the read head straddles two tracks. The detector performance will suffer from such impairments. Formats that tolerate such impairments are desired.

Because the recorded address mark and wedge address does not vary from one track to the next, the emphasis is on track addresses. When the read head is in the middle of two adjacent tracks, with track addresses X and Y, the read waveform is the superposition of the waveforms generated from each of the respective addresses. In general, the resulting waveform cannot be decoded reliably to any one of the two track addresses. A common solution is the use of a Gray code to encode track addresses, as shown in Fig. 34.36, where any two adjacent tracks differ in their binary address representation in only one symbol value. Hence, for the moment ignoring ISI, when the head is midway between adjacent tracks, the detector will decode the address bits correctly except for the bit location where the two adjacent tracks differ, that is, for the two track addresses labeled as X and Y, the decoder will decode the waveform to either track address X or Y, introducing an error of at most one track. By designing a radially periodic servo burst field, with period of at least two track widths, track number ambiguity generated by track addresses is resolved; however, as will be discussed next, Gray codes complicate the use of ECC codes and sequence detectors.

A Gray code restricts two adjacent tracks to differ in only a single position, or equivalently forcing the *Hamming distance* between two adjacent track addresses to be one. Adding an ECC field to the digital fields is desirable since reliable detection of track addresses is needed in the presence of miscellaneous impairments such as electronic and disk media noise, radial incoherence, erase bands, etc.; however, any ECC has a minimum Hamming distance larger than one. That is, it is not possible to have two adjacent track-addresses be Gray and ECC encoded simultaneously. If an ECC field is appended to each track address, it can be used only when the head is directly above a track. A possible alternative is to write the track addresses multiple times with varying radial shifts so that, at any position, the head is mostly directly above a track address [13]. Such a solution improves reliability at the expense of significant format efficiency loss.

Another complication of introducing Gray codes results from the interaction of these codes with the ISI channel. Consider an ISI free channel where the magnetic transitions are written ideally and where the read head is allowed to be anywhere between two adjacent Gray coded track addresses X and Y. As was discussed earlier, the track address reliability, or the probability that the decoded address is neither X nor Y, is independent of the read head position. Next, it is shown that for an ISI channel the detector performance depends on the radial position. In particular, consider the simple ISI channel with pulse response  $1 - D$ , which approximates a magnetic recording channel. For such a channel, events of length two are almost as probable as errors of length one (same distance but different number of neighbors). Now, as the head moves from track X to Y, the waveform modification introduced by addresses X and Y, at that one location where the two tracks differ, can trigger an error of length two. The detector may decode the received waveform to a different track address Z, which may lie far from addresses X or Y. In other words, in an ISI channel, whenever the head is between two tracks X and Y, the probability that the received waveform is decoded to some other address Z increases.

FIGURE 34.37 Signal space representation of three codewords. Configuration (a) ISI free (b) with ISI.

For readers familiar with signal space representation of codewords, the ISI free and  $1 + D$  channels are shown for the three addresses X, Y, and Z with their decision regions in Fig. 34.37. Let  $d_h$  denote to the shortest distance from codeword X to the decision boundaries of codeword Z. As shown in Fig. 34.37, when the head is midway between tracks X and Y, the shortest distance to cross the decision boundaries of codeword Z is reduced by a factor of  $\sqrt{3}$  (or 4.77 dB). Therefore, when the head is in the middle of two tracks, represented by addresses X and Y, the probability that the decoded codeword is Z increases significantly. For an arbitrary ISI channel this reduction factor in shortest distance varies, and it can be shown to be at most  $\sqrt{3}$ .

A trivial solution to address both the ECC and ISI complications introduced by the Gray code is not to use any coding and to write address bits far enough from each other to be able to ignore ISI effects. Then a simple symbol-by-symbol detector is sufficient to detect the address without the need for a sequence detector. Actually this is a common approach taken in many disk drive designs; however, dropping ECC capability affects reliability and forcing the magnetic recording channel to behave as ISI free requires additional format.

Another approach is to use symbol based codes, such as a bi-phase code, rather than sequence-based codes, that is, rather than maximizing the minimum distance between any two codewords, the distance between two symbols is maximized. For example, in a magnetic recording channel, a bi-phase code produces a positive pulse at the middle of the symbol for a symbol “1” and a negative pulse for a symbol “0,” increasing symbol reliability [13,14]. In this example, it can be shown that the ISI related degradations are minimized and the detector performance is improved.

A fundamentally different approach would not make use of a Gray code at all. Instead, codes would be designed from scratch in such a way that for any two addresses X and Y the distance between X and Y would increase, as they are radially located further away from each other.

## The Burst Field

In the previous subsection, track addresses were introduced, which provide head position information to about single-track accuracy. To be able to read the data field reliably, it is essential to position the read head directly upon the desired track within a small fraction of a track. To this end the track number addresses are complemented with the servo burst field, where the analog radial position is encoded in a periodic waveform such as a sinusoid. Three ways to encode a parameter in a sinusoidal waveform are used: amplitude, phase, and frequency [3]. Servo burst fields are also periodic radially. Because the track address already provides an absolute position, such a periodicity does not create any ambiguity.

In a disk platter, information is recorded in one of two stable domains. Hence, a servo burst is recorded as a periodic binary pattern. The read back waveform, at the head output, is periodic and will contain both the fundamental and higher harmonics. The sinusoidal waveform is obtained by retaining only the fundamental harmonic. For a given format budget, it is possible to maximize the power of the read back

**FIGURE 34.38** The amplitude burst format and its position error transfer function as the head moves from center-track  $n$  to center-track  $n + 1$ .

waveform by optimizing the fundamental period [15]. If recorded transitions get too close, ISI destroys most of the signal power. On the other hand, if transitions are far from each other, then the read back pulses are isolated and contain little power.

In this subsection, first the impairment sources are identified. Afterward, various servo burst formats and their performances are discussed [16,17]. Finally, various estimator characteristics and options are reviewed.

### Impairments

Here, impairments in a servo burst field are classified into three categories: servo-writer induced, read head induced, and read channel induced. Not all impairments are present in all servo burst formats.

As was discussed in the subsection on “Servo Writers”, when the servo-writer records wedges track-by-track, erase band as well as radial incoherence may be present between tracks, degrading the performance of some of the servo burst formats. Also, the duty cycle of the recorded periods may be different than the intended 50%. Finally, write process limitations result in nonideal recorded transitions.

The read head element as well as the preamplifier, which magnifies the incoming signal, generate electronic noise, modeled by additive white Gaussian noise (AWGN). Also, in many situations the width of the read head element ends up, being shorter than the servo burst radial width as shown in Fig. 34.38 (a). As will be discussed shortly, for some formats, this creates saturated radial regions where the radial estimates are not reliable [9]. Finally, the rectangular approximation of the read head element shown in Fig. 34.38(a) is not accurate. More specifically, different regions of the read head may respond differently to a magnetic flux. Hence, the read head profile may be significantly different than a rectangle [18,19].

The read channel, while processing the read waveform, induces a third class of errors. Most present estimators are digitally implemented and have to cope with *quantization error*. If only the first harmonic of the received waveform is desired then suppressing higher harmonics may leave residues that may interact with the first harmonic inside the estimator. Furthermore, sampling a waveform with higher harmonic residues creates *aliasing effects*, where higher harmonics fold into the first harmonic. Many read channel estimators require that the phase, frequency, or both phase and frequency of the incoming waveform are known. Any discrepancy results in estimator degradation. Finally, estimator complexity constraints result in suboptimal estimators, further degrading the accuracy of the position estimate.

### Formatting Strategies

At present, the amplitude servo burst format, shown in Fig. 34.38(a), is the most common format used in the disk drive industry. Depending on the radial position of the read head, the overlap between the head and the bursts A and B varies. Through this overlap, or amplitude variation, it is possible to estimate the radial position. First, the waveforms resulting from the overlap of the read head and the burst fields

**FIGURE 34.39** Alternative burst formats where A' and B' are either orthogonal to or of opposite polarity of A and B, respectively.

A and B are transformed into amplitude estimates. These amplitude estimates are then subtracted from each other and scaled to get a positional estimate. As the head moves from track center  $n$  to track center  $(n + 1)$ , the noiseless positional estimate, known as *position error transfer function*, is plotted in Fig. 34.38(b). Here, since the radial width of the servo burst is larger than the read element, any radial position falls into either the *linear* region, where radial estimate is accurate, or in the *saturated* region, where the radial estimate is not accurate [9]. One solution to withstand saturated regions is to include multiple burst pairs, such that any radial position would fall in the linear region of at least one pair of bursts. The obvious drawback of such a strategy is the additional format loss. The amplitude format just presented does not suffer from radial incoherence since two bursts are not recorded radially adjacent to each other.

Because nonrecorded areas do not generate any signal, in Fig. 34.38(a) only 50% of the servo burst format is recorded with transitions or utilized. In an effort to improve the position estimate performance, the whole allocated servo area can be recorded. As a result, at least two alternative formats have emerged, both illustrated by Fig. 34.39.

In the first improved format, burst A is radially surrounded by an *antipodal* or “opposite polarity” burst A'. For example, if burst A is recorded as  $++--++--\dots$  then burst A' is recorded as  $--++--++\dots$ . For readers familiar with digital communications, the difference between the amplitude and antipodal servo burst formats can be compared to the difference between on-off and antipodal signaling. In on-off signaling, a symbol “0” or “1” is transmitted while in antipodal signaling 1 or  $-1$  is transmitted. Antipodal signaling is 6 dB more efficient than on-off signaling. Similarly, it can be shown that the antipodal servo burst format gives a 6-dB advantage with respect to amplitude servo burst format under the AWGN assumption [17].

Instead of recording A' to be the opposite polarity of A, another alternative is to record a pattern A' that is orthogonal to A. For example, it is possible to pick up two sinusoids with different frequencies such that the two waveforms are orthogonal over a finite burst length interval. The resulting format is known as the *dual frequency* format [20]. Inside the read channel, two independent estimates of the head position can be obtained from two estimators, each tuned to one of the two frequencies. The final radial estimate is the average of the two estimates, resulting in a 3-dB improvement with respect to the amplitude format, again under AWGN assumption.

Unlike the amplitude format, these more sophisticated formats are in general more sensitive to other impairments such as erase band and radial incoherence.

A fundamentally different format is presented in Fig. 34.40. Here, the transitions are skewed and the periodic pattern gradually shifts in the angular direction as the radius changes. The radial information is stored in the phase of the period, so it is called the *phase format*. In Fig. 34.40 two burst fields A and B are presented where the transition slopes have the same magnitude but opposite polarities. An estimator makes two phase estimates, one from the sinusoid in field A and another one from the sinusoid in field B. By subtracting the second phase estimate from the first, and then by scaling the result, the radial position estimate can be obtained. Similar to the antipodal format, it can be shown that the phase pattern is 6 dB superior to the amplitude pattern [17] under AWGN. A major challenge for the phase format is successfully recording the skewed transitions on a disk platter without significant presence of radial incoherence and erase band.

FIGURE 34.40 The phase format.

### Position Estimators

Estimating various parameters of a sinusoid is well documented in textbooks [3]. A decade ago position estimators were mostly implemented by analog circuitry, whereas at present, digital implementation is the norm and the one considered in this article [21–25]. One way of classifying estimators is to determine whether the phase and/or the frequency of the incoming waveform are known.

Assume that the amplitude of a noisy sinusoid needs to be determined. If the phase of this waveform is known, a matched filter can be used to generate the amplitude estimate. This is known as coherent estimation. Under certain assumptions and performance criteria such a filter becomes optimal. When the phase of the waveform is not known, but the frequency is known, then two matched filters can be used, one tuned to a sine waveform while the other filter is tuned to a cosine waveform. The outputs of the two filters are squared and added to give the energy estimate of the waveform. This is known as noncoherent estimation and is equivalent to computing the Fourier transform at the first harmonic. Other ad hoc estimators include the peak estimator and digital area estimators [26], which respectively estimate the averaged peak and the mean value of the unsigned waveform. Neither of these estimators requires the phase or the frequency of the waveform.

For the amplitude format, all the estimators mentioned here can be used. For the antipodal format, the phase of the waveform is needed and therefore a single matched filter is the required estimator. For dual frequency format, we need two estimators, each tuned to a different frequency. Since the two waveforms are orthogonal to each other, an estimator tuned to one of the waveforms will not observe the other waveform. Each estimator can utilize a single matched filter for coherent estimation or two matched filters for noncoherent estimation. Finally, for phase estimation, two matched filters are utilized, similar to noncoherent estimation; however, rather than squaring and adding the filter outputs, the inverse tangent function is performed on the ratio of the filter outputs.

## 34.5 Modulation Codes for Storage Systems

---

*Brian Marcus and Emina Šoljanin*

### Introduction

Modulation codes are used to constrain the individual sequences that are recorded in data storage channels, such as magnetic or optical disk or tape drives. The constraints are imposed in order to improve the detection capabilities of the system. Perhaps the most widely known constraints are the runlength limited (RLL( $d,k$ )) constraints, in which ones are required to be separated by at least  $d$  and no more than  $k$  zeros. Such constraints are useful in data recording channels that employ peak detection: waveform peaks, corresponding to data ones, are detected independently of one another. The  $d$ -constraint helps

increase linear density while mitigating intersymbol interference, and the  $k$ -constraint helps provide feedback for timing and gain control.

Peak detection was widely used until the early 1990s. Although it is still used today in some magnetic tape drives and some optical recording devices, most high density magnetic disk drives now use a form of maximum likelihood (Viterbi) sequence detection. The data recording channel is modeled as a linear, discrete-time, communications channel with inter-symbol interference (ISI), described by its transfer function and white Gaussian noise. The transfer function is often given by  $h(D) = (1 - D)(1 + D)^N$ , where  $N$  depends on and increases with the linear recording density.

Broadly speaking, two classes of constraints are of interest in today's high density recording channels: (1) constraints for improving timing and gain control and simplifying the design of the Viterbi detector for the channel and (2) constraints for improving noise immunity. Some constraints serve both purposes.

Constraints in the first class usually take the form of a PRML ( $G, I$ ) constraint: the maximum run of zeros is  $G$  and the maximum run of zeros, within each of the two substrings defined by the even indices and odd indices, is  $I$ . The  $G$ -constraint plays the same role as the  $k$ -constraint in peak detection, while the  $I$ -constraint enables the Viterbi detector to work well within practical limits of memory.

Constraints in the second class eliminate some of the possible recorded sequences in order to increase the minimum distance between those that remain or eliminate the possibility of certain dominant error events. This general goal does not specify how the constraints should be defined, but many such constraints have been constructed; see [20] and the references therein for a variety of examples. Bounds on the capacities of constraints that avoid a given set of error events have been given in [26].

Until recently, the only known constraints of this type were the matched-spectral-null (MSN) constraints. They describe sequences whose spectral nulls match those of the channel and therefore increase its minimum distance. For example, a set of DC-balanced sequences (i.e., sequences of  $\pm 1$  whose accumulated digital sums are bounded) is an MSN constraint for the channel with transfer function  $h(D) = 1 - D$ , which doubles its minimum distance [18].

During the past few years, significant progress has been made in defining high capacity distance enhancing constraints for high density magnetic recording channels. One of the earliest examples of such a constraint is the maximum transition run (MTR) constraint [28], which constrains the maximum run of ones. We explain the main idea behind this type of distance-enhancing codes in the subsection on "Constraints for ISI Channels."

Another approach to eliminating problematic error events is that of parity coding. Here, a few bits of parity are appended to (or inserted in) each block of some large size, typically 100 bits. For some of the most common error events, any single occurrence in each block can be eliminated. In this way, a more limited immunity against noise can be achieved with less coding overhead [5].

Coding for more realistic recording channel models that include colored noise and intertrack interference are discussed in the subsection on "Channels with Colored Noise and Intertrack Interference." The authors point out that different constraints, which avoid the same prescribed set of differences, may have different performance on more realistic channels. This makes some of them more attractive for implementation.

For a more complete introduction to this subject, the reader is referred to any one of the many expository treatments, such as [16,17,24].

## Constrained Systems and Codes

Modulation codes used in almost all contemporary storage products belong to the class of constrained codes. These codes encode random input sequences to sequences that obey the constraint of a labeled directed graph with a finite number of states and edges. The set of corresponding constrained sequences is obtained by reading the labels of paths through the graph. Sets of such sequences are called constrained systems or constraints. [Figures 34.41](#) and [34.42](#) depict graph representations of an RLL constraint and a DC-balanced constraint.

Of special interest are those constraints that do not contain (globally or at certain positions) a finite number of finite length strings. These systems are called systems of finite type (FT). An FT system  $X$

FIGURE 34.41 RLL (1,3) constraint.

FIGURE 34.42 DC-balanced constraint.

over alphabet  $\mathcal{A}$  can always be characterized by a finite list of forbidden strings  $\mathcal{F} = \{w_1, \dots, w_N\}$  of symbols in  $\mathcal{A}$ . Defined this way, FT systems will be denoted by  $X_{\mathcal{F}}^A$ . The RLL constraints form a prominent class of FT constraints, while DC-balanced constraints are typically not FT.

Design of constrained codes begins with identifying constraints, such as those described in the Introduction, that achieve certain objectives. Once the system of constrained sequences is specified, information bits are translated into sequences that obey the constraints via an *encoder*, which usually has the form of a finite-state machine. The actual set of sequences produced by the encoder is called a constrained code and is often denoted  $\mathcal{C}$ . A *decoder* recovers user sequences from constrained sequences. While the decoder is also implemented as a finite-state machine, it is usually required to have a stronger property, called *sliding-block decodability*, which controls error propagation [24].

The maximum rate of a constrained code is determined by *Shannon capacity*. The Shannon capacity or simply *capacity* of a constrained system, denoted by  $C$ , is defined as

$$C = \lim_{n \rightarrow \infty} \frac{\log_2 N(n)}{n}$$

where  $N(n)$  is the number of sequences of length  $n$ . The capacity of a constrained system represented by a graph  $G$  can be easily computed from the *adjacency matrix* (or *state transition matrix*) of  $G$  (provided that the labeling of  $G$  satisfies some mildly innocent properties). The adjacency matrix of  $G$  with  $r$  states and  $a_{ij}$  edges from state  $i$  to state  $j$ ,  $1 \leq i, j \leq r$ , is the  $r \times r$  matrix  $A = A(G) = \{a_{ij}\}_{r \times r}$ . The Shannon capacity of the constraint is given by

$$C = \log_2 \lambda(A)$$

where  $\lambda(A)$  is the largest real eigenvalue of  $A$ .

The *state-splitting algorithm* [1] (see also [24]) gives a general procedure for constructing constrained codes at any rate up to capacity. In this algorithm, one starts with a graph representation of the desired constraint and then transforms it into an encoder via various graph-theoretic operations including splitting and merging of states. Given a desired constraint and a desired rate  $p/q \leq C$ , one or more rounds of state splitting are performed; the determination of which states to split and how to split them is governed by an approximate eigenvector, i.e., a vector  $\mathbf{x}$  satisfying  $A^q \mathbf{x} \geq 2^p \mathbf{x}$ .

Many other very important and interesting approaches are used to constrained code construction—far too many to mention here. One approach combines state-splitting with look-ahead encoding to obtain a very powerful technique which yields superb codes [14]. Another approach involves variable-length and time-varying variations of these techniques [2,13]. Many other effective coding constructions are described in the monograph [17].

**FIGURE 34.43** Two equivalent constraints: (a)  $\mathcal{F} = \{11\}$  NRZI and (b)  $\mathcal{F} = \{101, 010\}$  NRZ.

For high capacity constraints, graph transforming techniques, such as the state-splitting algorithm, may result in encoder/decoder architectures with formidable complexity. Fortunately, a block encoder/decoder architecture with acceptable implementation complexity for many constraints can be designed by well-known enumerative [6], and other combinatorial [32] as well as heuristic techniques [25].

Translation of constrained sequences into the channel sequences depends on the modulation method. Saturation recording of binary information on a magnetic medium is accomplished by converting an input stream of data into a spatial stream of bit cells along a track where each cell is fully magnetized in one of two possible directions, denoted by 0 and 1. Two important modulation methods are commonly used on magnetic recording channels: non-return-to-zero (NRZ) and modified non-return-to-zero (NRZI). In NRZ modulation, the binary digits 0 and 1 in the input data stream correspond to 0 and 1 directions of cell magnetizations, respectively. In NRZI modulation, the binary digit 1 corresponds to a magnetic transition between two bit cells, and the binary digit 0 corresponds to no transition. For example, the channel constraint which forbids transitions in two neighboring bit cells, can be accomplished by either  $\mathcal{F} = \{11\}$  NRZI constraint or  $\mathcal{F} = \{101, 010\}$  NRZ constraint. The graph representation of these two constraints is shown in Fig. 34.43. The NRZI representation is, in this case, simpler.

### Constraints for ISI Channels

This subsection discusses a class of codes known as codes, which avoid specified differences. This is the only class of distance enhancing codes used in commercial magnetic recording systems. Two main reasons for this are: these codes simplify the channel detectors relative to the uncoded channel and even high rate codes in this class can be realized by low complexity encoders and decoders.

#### Requirements

A number of papers have proposed using constrained codes to provide coding gain on channels with high ISI (see, for example, [4,10,20,28]). The main idea of this approach can be described as follows [20]. Consider a discrete-time model for the magnetic recording channel with possibly constrained input  $\mathbf{a} = \{a_n\}$   $\mathcal{C} \subseteq \subseteq \{0,1\}^\infty$ , impulse response  $\{h_n\}$ , and output  $\mathbf{y} = \{y_n\}$  given by

$$y_n = \sum_m a_m h_{n-m} + \eta_n \quad (34.32)$$

where  $h(D) = \sum_n h_n D^n = (1 - D)(1 + D)^3$  ( $E^2$ PR4) or  $h(D) = \sum_n h_n D^n = (1 - D)(1 + D)^4$  ( $E^3$ PR4),  $\eta_n$  are independent Gaussian random variables with zero mean and variance  $\sigma^2$ . The quantity  $1/\sigma^2$  is referred to as the signal-to-noise ratio (SNR). The minimum distance of the uncoded channel (34.32) is

$$d_{\min}^2 = \min_{\epsilon(D) \neq 0} \|h(D)\epsilon(D)\|^2$$

where  $\epsilon(D) = \sum_{i=0}^{l-1} \epsilon_i D^i$ , ( $\epsilon_i \in \{-1, 0, 1\}$ ,  $\epsilon_0 = 1, \epsilon_{l-1} \neq 0$ ) is the polynomial corresponding to a normalized input error sequence  $\epsilon = \{\epsilon_i\}_{i=0}^{l-1}$  of length  $l$ , and the squared norm of a polynomial is defined as the sum of its squared coefficients. The minimum distance is bounded from above by  $\|h(D)\|^2$ , denoted by

$$d_{\text{MFB}}^2 = \|h(D)\|^2 \quad (34.33)$$

This bound is known as the matched-filter bound (MFB) and is achieved when the error sequence of length  $l = 1$ , i.e.,  $\epsilon(D) = 1$ , is in the set

$$\arg \min_{\epsilon(D) \neq 0} \|h(D)\epsilon(D)\|^2 \quad (34.34)$$

For channels that fail to achieve the MFB, i.e., for which  $d_{\text{min}}^2 < \|h(D)\|^2$ , any error sequences  $\epsilon(D)$  for which

$$d_{\text{min}}^2 \leq \|h(D)\epsilon(D)\|^2 < \|h(D)\|^2 \quad (34.35)$$

are of length  $l \geq 2$  and may belong to a constrained system  $X_{\mathcal{L}}^{\{-1,0,1\}}$ , where  $\mathcal{L}$  is an appropriately chosen finite list of forbidden strings.

For code  $\mathcal{C}$ , the set of all admissible nonzero error sequences is written as

$$\mathcal{E}(\mathcal{C}) = \{\epsilon \in \{-1, 0, 1\}^{\infty} \mid \epsilon \neq 0, \epsilon = (\mathbf{a} - \mathbf{b}), \mathbf{a}, \mathbf{b} \in \mathcal{C}\}$$

Given the condition  $\mathcal{E}(\mathcal{C}) \subseteq X_{\mathcal{L}}^{\{-1,0,1\}}$ , the least restrictive finite collection  $\mathcal{F}$  of blocks over the alphabet  $\{0, 1\}$  can be identified so that

$$\mathcal{C} \subseteq X_{\mathcal{F}}^{\{0,1\}} \Rightarrow \mathcal{E}(\mathcal{C}) \subseteq X_{\mathcal{L}}^{\{-1,0,1\}} \quad (34.36)$$

## Definitions

A constrained code is defined by specifying  $\mathcal{F}$ , the list of forbidden strings for code sequences. Prior to that one needs to first characterize error sequences that satisfy (34.35) and then specify  $\mathcal{L}$ , the list of forbidden strings for error sequences. Error event characterization can be done by using any of the methods described by Karabed, Siegel, and Soljanin in [20]. Specification of  $\mathcal{L}$  is usually straightforward.

A natural way to construct a collection  $\mathcal{F}$  of blocks forbidden in code sequences based on the collection  $\mathcal{L}$  of blocks forbidden in error sequences is the following. From the above definition of error sequences  $\epsilon = \{\epsilon_i\}$  we see that  $\epsilon_i = 1$  requires  $a_i = 1$  and  $\epsilon_i = -1$  requires  $a_i = 0$ , i.e.,  $a_i = (1 + \epsilon_i)/2$ . For each block  $\mathbf{w}_{\mathcal{E}} \in \mathcal{L}$ , construct a list  $\mathcal{F}_{\mathbf{w}_{\mathcal{E}}}$  of blocks of the same length  $l$  according to the rule:

$$\mathcal{F}_{\mathbf{w}_{\mathcal{E}}} = \{\mathbf{w}_{\mathcal{C}} \in \{0, 1\}^l \mid w_{\mathcal{C}}^i = (1 + w_{\mathcal{E}}^i)/2 \text{ for all } i \text{ for which } w_{\mathcal{E}}^i \neq 0\}.$$

Then the collection  $\mathcal{F}$  obtained as  $\mathcal{F} = \cup_{\mathbf{w}_{\mathcal{E}} \in \mathcal{L}} \mathcal{F}_{\mathbf{w}_{\mathcal{E}}}$  satisfies requirement (34.36); however, the constrained system  $X_{\mathcal{F}}^{\{0,1\}}$  obtained this way may not be the most efficient. (Bounds on the achievable rates of codes which avoid specified differences were found recently in [26].)

The previous ideas are illustrated in the example of the E<sup>2</sup>PR4 channel. Its transfer function is  $h(D) = (1 - D)(1 + D)^3$ , and its MFB is  $\|(1 - D)(1 + D)^3 \cdot 1\|^2 = 10$ . The error polynomial  $\epsilon(D) = 1 - D + D^2$  is the unique error polynomial for which  $\|(1 - D)(1 + D)^3 \epsilon(D)\|^2 = 6$ , and the error polynomials  $\epsilon(D) = 1 - D + D^2 + D^5 - D^6 + D^7$  and  $\epsilon(D) = \sum_{i=0}^{l-1} (-1)^i D^i$  for  $l \geq 4$  are the only polynomials for which  $\|(1 - D)(1 + D)^3 \epsilon(D)\|^2 = 8$  (see, for example, [20]).

FIGURE 34.44 Possible pairs of sequences for which error event +-+00 may occur.

It is easy to show that these error events are not in the constrained error set defined by the list of forbidden error strings  $\mathcal{L} = \{+-+00, +-+-\}$ , where + denotes 1 and - denotes -1. To see this, note that an error sequence that does not contain the string +-+00 cannot have error polynomials  $\epsilon(D) = 1 - D + D^2$  or  $\epsilon(D) = 1 - D + D^2 + D^5 - D^6 + D^7$ , while an error sequence that does not contain string +-+- cannot have an error polynomial of the form  $\epsilon(D) = \sum_{i=0}^{l-1} (-1)^i D^i$  for  $l \geq 4$ . Therefore, by the above procedure of defining the list of forbidden error strings, we obtain the  $\mathcal{F} = \{+-+\}$  NRZ constraint. Its capacity is about 0.81, and a rate 4/5 code into the constraint was first given in [19].

In [20], the following approach was used to obtain several higher rate constraints. For each of the error strings in  $\mathcal{L}$ , we write all pairs of channel strings whose difference is the error string. To define  $\mathcal{F}$ , look for the longest string(s) appearing in at least one of the strings in each channel pair. For the example above and the +-+00 error string, a case-by-case analysis of channel pairs is depicted in Fig. 34.44. We can distinguish two types (denoted by A and B in the figure) of pairs of code sequences involved in forming an error event. In a pair of type A, at least one of the sequences has a transition run of length 4. In a pair of type B, both sequences have transition runs of length 3, but for one of them the run starts at an even position and for the other at an odd position. This implies that an NRZI constrained system that limits the run of 1s to 3 when it starts at an odd position, and to 2 when it starts at an even position, eliminates all possibilities shown bold-faced in Fig. 34.44. In addition, this constraint eliminates all error sequences containing the string +-+- . The capacity of the constraint is about .916, and rate 8/9 block codes with this constraint have been implemented in several commercial read channel chips. More about the constraint and the codes can be found in [4,10,20,28].

## Channels with Colored Noise and Intertrack Interference

Magnetic recording systems always operate in the presence of colored noise intertrack interference, and data dependent noise. Codes for these more realistic channel models are studied in [27]. The following is a brief outline of the problem.

The data recording and retrieval process is usually modeled as a linear, continuous-time, communications channel described by its Lorentzian step response and additive white Gaussian noise. The most common discrete-time channel model is given by Eq. (34.32). Magnetic recording systems employ channel equalization to the most closely matching transfer function  $h(D) = \sum_n h_n D^n$  of the form  $h(D) = (1 - D)(1 + D)^N$ . This equalization alters the spectral density of the noise, and a better channel model assumes that the  $\eta_n$  in Eq. (34.32) are identically distributed, Gaussian random variables with zero mean, variance  $\sigma^2$ , and normalized cross-correlation  $E\{\eta_n \eta_k\} / \sigma^2 = \rho_{n-k}$ .

In practice, there is always intertrack interference (ITI), i.e., the read head picks up magnetization from an adjacent track. Therefore, the channel output is given by

$$y_n = \sum_m a_m h_{n-m} + \sum_m x_m g_{n-m} + \eta_n \tag{34.37}$$

where  $\{g_n\}$  is the discrete-time impulse response of the head to the adjacent track, and  $\mathbf{x} = \{x_n\} \in \mathcal{C}$  is the sequence recorded on that track. Assuming that the noise is white.

In the ideal case (34.32), the probability of detecting  $\mathbf{b}$  given that  $\mathbf{a}$  was recorded is equal to  $Q(d(\boldsymbol{\epsilon})/\sigma)$ , where  $d(\boldsymbol{\epsilon})$  is the distance between  $\mathbf{a}$  and  $\mathbf{b}$  given by

$$d^2(\boldsymbol{\epsilon}) = \sum_n \left( \sum_m \epsilon_m h_{n-m} \right)^2 \quad (34.38)$$

Therefore, a lower bound, and a close approximation for small  $\sigma$ , to the minimum probability of an error-event in the system is given by  $Q(d_{\min,C}/\sigma)$ , where

$$d_{\min,C} = \min_{\boldsymbol{\epsilon} \in \mathcal{E}_c} d(\boldsymbol{\epsilon})$$

is the channel minimum distance of code  $\mathcal{C}$ . We refer to

$$d_{\min} = \min_{\boldsymbol{\epsilon} \in \{-1,0,1\}^n} d(\boldsymbol{\epsilon}) \quad (34.39)$$

as the minimum distance of the uncoded channel, and to the ratio  $d_{\min,C}/d_{\min}$  as the gain in distance of code  $\mathcal{C}$  over the uncoded channel.

In the case of colored noise, the probability of detecting  $\mathbf{b}$  given that  $\mathbf{a}$  was recorded equals to  $Q(\Delta(\boldsymbol{\epsilon})/\sigma)$ , where  $\Delta(\boldsymbol{\epsilon})$  is the distance between  $\mathbf{a}$  and  $\mathbf{b}$  given by

$$\Delta^2(\boldsymbol{\epsilon}) = \frac{\left[ \sum_n \left( \sum_m \epsilon_m h_{n-m} \right)^2 \right]^2}{\sum_n \sum_k \left( \sum_m \epsilon_m h_{n-m} \right) \rho_{n-k} \left( \sum_m \epsilon_m h_{k-m} \right)}$$

Therefore, a lower bound to the minimum probability of an error-event in the system is given by  $Q(\Delta_{\min,C}/\sigma)$ , where

$$\Delta_{\min,C} = \min_{\boldsymbol{\epsilon} \in \mathcal{E}_c} \Delta(\boldsymbol{\epsilon})$$

In the case of ITI (Eq. 34.37), an important factor is the probability of detecting sequence  $\mathbf{b}$  given that sequence  $\mathbf{a}$  was recorded on the track being read and sequence  $\mathbf{x}$  was recorded on an adjacent track. This probability is

$$Q(\delta(\boldsymbol{\epsilon}, \mathbf{x})/\sigma)$$

where  $\delta(\boldsymbol{\epsilon}, \mathbf{x})$  is the distance between  $\mathbf{a}$  and  $\mathbf{b}$  in the *presence* of  $\mathbf{x}$  given by [30]

$$\delta^2(\boldsymbol{\epsilon}, \mathbf{x}) = \frac{1}{\left[ \sum_n \left( \sum_m \epsilon_m h_{n-m} \right)^2 \right]} \left[ \sum_n \left( \sum_m \epsilon_m h_{n-m} \right)^2 + \sum_n \left( \sum_m x_m g_{n-m} \right) \left( \sum_m \epsilon_m h_{n-m} \right) \right]^2$$

Therefore, a lower bound to the minimum probability of an error-event in the system is proportional to  $Q(\delta_{\min,C}/\sigma)$ , where

$$\delta_{\min,C} = \min_{\boldsymbol{\epsilon} \neq 0, \mathbf{x} \in \mathcal{C}} \delta(\boldsymbol{\epsilon}, \mathbf{x})$$

Distance  $\delta_{\min,C}$  can be bounded as follows [30]:

$$\delta_{\min,C} \geq (1 - \mathcal{M})d_{\min,C} \quad (34.40)$$

where  $\mathcal{M} = \max_{n,x \in \mathcal{C}} \sum_m x_m g_{n-m}$ , i.e.,  $\mathcal{M}$  is the maximum absolute value of the interference. Note that  $\mathcal{M} = \sum_n |g_n|$ . We will assume that  $\mathcal{M} < 1$ . The bound is achieved if and only if there exists an  $\boldsymbol{\epsilon}$ ,  $d(\boldsymbol{\epsilon}) = d_{\min,C}$ , for which  $\sum_m \epsilon_m h_{n-m} \in \{-1, 0, 1\}$  for all  $n$ , and there exists an  $\mathbf{x} \in \mathcal{C}$  such that  $\sum_m x_m g_{n-m} = +\mathcal{M}$  whenever  $\sum_m \epsilon_m h_{n-m} = \pm 1$ .

## An Example

Certain codes provide gain in minimum distance on channels with ITI and colored noise, but not on the AWGN channel with the same transfer function. This is best illustrated using the example of the partial response channel with the transfer function  $h(D) = (1 - D)(1 + D)^2$  known as EPR4. It is well known that for the EPR4 channel  $d_{\min}^2 = 4$ . Moreover, as discussed in the subsection on ‘‘Constraints for ISI Channels,’’ the following result holds:

**Proposition 1.** *Error events  $\boldsymbol{\epsilon}(D)$  such that*

$$d^2(\boldsymbol{\epsilon}) = d_{\min}^2 = 4$$

*take one of the following two forms:*

$$\boldsymbol{\epsilon}(D) = \sum_{j=0}^{k-1} D^{2j}, \quad k \geq 1$$

*or*

$$\boldsymbol{\epsilon}(D) = \sum_{i=0}^{l-1} (-1)^i D^i, \quad l \geq 3$$

Therefore, an improvement of error-probability performance can be accomplished by codes which eliminate the error sequences  $\boldsymbol{\epsilon}$  containing the strings  $-1 + 1 - 1$  and  $+1 - 1 + 1$ . Such codes were extensively studied in [20].

In the case of ITI (Eq. 34.37), it is assumed that the impulse response to the reading head from an adjacent track is described by  $g(D) = \alpha H(D)$ , where the parameter  $\alpha$  depends on the track to head distance. Under this assumption, the bound (34.40) gives  $\delta_{\min}^2 \geq d_{\min}^2 (1 - 4\alpha)^2$ . The following result was shown in [30]:

**Proposition 2.** *Error events  $\boldsymbol{\epsilon}(D)$  such that*

$$\min_{\mathbf{x} \in \mathcal{C}} \delta^2(\boldsymbol{\epsilon}, \mathbf{x}) = \delta_{\min}^2 = d_{\min}^2 (1 - 4\alpha)^2 = 4(1 - 4\alpha)^2$$

*take the following form:*

$$\boldsymbol{\epsilon}(D) = \sum_{i=0}^{l-1} (-1)^i D^i, \quad l \geq 5$$

*For all other error sequences for which  $d^2(\boldsymbol{\epsilon}) = 4$ , we have  $\min_{\mathbf{x} \in \mathcal{C}} \delta^2(\boldsymbol{\epsilon}, \mathbf{x}) = 4(1 - 3\alpha)^2$ .*

Therefore, an improvement in error-probability performance of this channel can be accomplished by limiting the length of strings of alternating symbols in code sequences to four. For the NRZI type of recording, this can be achieved by a code that limits the runs of successive ones to three. Note that the set of minimum distance error events is smaller than in the case with no ITI. Thus, performance improvement can be accomplished by higher rate codes that would not provide any gain on the ideal channel.

Channel equalization to the EPR4 target introduces cross-correlation among noise samples for a range of current linear recording densities (see [27] and references therein). The following result was obtained in [27]:

**Proposition 3.** *Error events  $\epsilon(D)$  such that*

$$\Delta^2(\epsilon) = \Delta_{\min}^2$$

*take the following form:*

$$\epsilon(D) = \sum_{i=0}^{l-1} (-1)^i D^i, \quad l \geq 3, \quad l \text{ odd}$$

Again, the set of minimum distance error events is smaller than in the ideal case (white noise), and performance improvement can be provided by codes which would not give any gain on the ideal channel. For example, since all minimum distance error events have odd parity, a single parity check code can be used.

## Future Directions

### Soft-Output Decoding of Modulation Codes

Detection and decoding in magnetic recording systems is organized as a concatenation of a channel detector, an inner decoder, and an outer decoder, and as such should benefit from techniques known as erasure and list decoding. To declare erasures or generate lists, the inner decoder (or channel detector) needs to assess symbol/sequence reliabilities. Although the information required for this is the same one necessary for producing a single estimate, some additional complexity is usually required. So far, the predicted gains for erasure and list decoding of magnetic recording channels with additive white Gaussian noise were not sufficient to justify increasing the complexity of the channel detector and inner and outer decoder; however, this is not the case for systems employing new magneto-resistive reading heads, for which an important noise source, thermal asperities, is to be handled by passing erasure flags from the inner to the outer decoder.

In recent years, one more reason for developing simple soft-output channel detectors has surfaced. The success of turbo-like coding schemes on memoryless channels has sparked the interest in using them as modulation codes for ISI channels. Several recent results show that the improvements in performance turbo codes offer when applied to magnetic recording channels at moderate linear densities are even more dramatic than in the memoryless case [12,29]. The decoders for turbo and low-density parity check codes (LDPC) either require or perform much better with soft input information which has to be supplied by the channel detector as its soft output. The decoders provide soft outputs which can then be utilized by the outer Reed–Solomon (RS) decoder [22]. A general soft-output sequence detection was introduced in [11], and it is possible to get information on symbol reliabilities by extending those techniques [21,31].

### Reversed Concatenation

Typically, the modulation encoder is the inner encoder, i.e., it is placed downstream of an error-correction encoder (ECC) such as an RS encoder; this configuration is known as standard concatenation (Fig. 34.45). This is natural since otherwise the ECC encoder might well destroy the modulation properties before

FIGURE 34.45 Standard concatenation.

FIGURE 34.46 Reversed concatenation.

passing across the channel; however, this scheme has the disadvantage that the modulation decoder, which must come before the ECC decoder, may propagate channel errors before they can be corrected. This is particularly problematic for modulation encoders of very high rate, based on very long block size. For this reason, a good deal of attention has recently focused on a reversed concatenation scheme, where the encoders are concatenated in the reversed order (Fig. 34.46). Special arrangements must be made to ensure that the output of the ECC encoder satisfies the modulation constraints. Typically, this is done by insisting that this encoder be systematic and then re-encoding the parity information using a second modulation encoder (the “parity modulation encoder”), whose corresponding decoder is designed to limit error propagation; the encoded parity is then appended to the modulation-encoded data stream (typically a few merging bits may need to be inserted in between the two streams in order to ensure that the entire stream satisfies the constraint). In this scheme, after passing through the channel the modulation-encoded data stream is split from the modulation-encoded parity stream, and the latter is then decoded via the parity modulation decoder before being passed on to the ECC decoder. In this way, many channel errors can be corrected before the data modulation decoder, thereby mitigating the problem of error propagation. Moreover, if the data modulation encoder has high rate, then the overall scheme will also have high rate because the parity stream is relatively small.

Reversed concatenation was introduced in [3] and later in [23]. Recent interest in the subject has been spurred on by the introduction of a lossless compression scheme, which improves the efficiency of reversed concatenation [15], and an analysis demonstrating the benefits in terms of reduced levels of interleaving [8]; see also [9]. Research on fitting soft decision detection into reversed concatenation can be found in [7,33].

## 34.6 Data Detection

---

*Miroslav Despotović and Vojin Šenk*

### Introduction

Digital magnetic recording systems transport information from one time to another. In communication society jargon, it is said that recording and reading information back from a (magnetic) medium is equivalent to sending it through a time channel. There are differences between such channels. Namely, in communication systems, the goal is a user error rate of  $10^{-5}$  or  $10^{-6}$ . Storage systems, however, often require error rates of  $10^{-12}$  or better. On the other hand, the common goal is to send the greatest possible amount of information through the channel used. For storage systems, this is tantamount to increasing recording density, keeping the amount redundancy as low as possible, i.e., keeping the bit rate per recorded pulse as high as possible. The perpetual push for higher bit rates and higher storage densities spurs a steady increment of the amplitude distortion of many types of transmission and storage channels.

When recording density is low, each transition written on the magnetic medium results in a relatively isolated peak of voltage, and peak detection method is used to recover written information; however, when PW50 (pulse width at half maximum response) becomes comparable with the channel bit period, the peak detection channel cannot provide reliable data detection, due to intersymbol interference (ISI). This interference arises because the effects of one readback pulse are not allowed to die away completely before the transmission of the next. This is an example of a so-called baseband transmission system, i.e., no carrier modulation is used to send data. Impulse dispersion and different types of induced noise at the receiver end of the system introduce combination of several techniques (equalization, detection, and timing recovery) to restore data. This chapter section gives a survey of most important detection techniques in use today assuming ideal synchronization.

Increasing recording density in new magnetic recording products necessarily demands enhanced detection techniques. First detectors operated at densities at which pulses were clearly separated, so that very simple, symbol-by-symbol detection technique was applied, the so-called *peak detector* [30]. With increased density, the overlap of neighboring dispersed pulses becomes so severe (i.e., large intersymbol interference—ISI) that peak detector could not combat with such heavy pulse shape degradation. To accomplish this task, it was necessary to master signal processing technology to be able to implement more powerful *sequence detection* techniques. This chapter section will both focus on this type of detection already applied in commercial products and give advanced procedures for searching the detection trellis to serve as a tutorial material for research on next generation products.

### Partial-Response Equalization

In the classical peak detection scheme, an equalizer is inserted whose task is just to remove all the ISI so that an isolated pulse is acquired, but the equalization will also enhance and colorize the noise (from readback process) due to spectral mismatch. The noise enhancement obtained in this manner will increase

FIGURE 34.47 Maximum-likelihood sequence detector.

with recording density and eventually become intolerable. Namely, since such a full equalization is aimed at slimming the individual pulse, so that it does not overlap with adjacent pulses, it is usually too aggressive and ends up with huge noise power.

Let us now review the question of recording density, also known as packing density. It is often used to specify how close two adjacent pulses stay to each other and is defined as  $PW50/T$  (see Chapter 34.1 for definition). Whatever tricks are made with peak detection systems, they barely help at  $PW50/T$  ratios above 1.

Section 34.6 discusses two receiver types that run much less rapidly out of steam. These are the partial-response equalizer (PRE) and the decision-feedback equalizer (DFE). Both are rooted in old telegraph tricks and, just as is the case with peak detector, they take instantaneous decisions with respect to the incoming data. Section 34.6 will focus mainly on these issues, together with sequence detection algorithms that accompany partial-response (PR) equalization.

What is PR equalization? It is the act of shaping the readback magnetic recording signal to look like the target signal specified by the PR. After equalization the data are detected using a sequence detector. Of course, quantization by an analog-to-digital converter (ADC) occurs at some point before the sequence detector.

The common readback structure consists of a linear filter, called a whitened matched filter, a symbol-rate sampler (ADC), a PRE, and a sequence detector, Fig. 34.47. The PRE in this scheme can also be put before the sampler, meaning that it is an analog, not a digital equalizer. Sometimes part of the equalizer is implemented in the analog, the other part in the digital domain. In all cases, analog signal, coming from the magnetic head, should have a certain and constant level of amplification. This is done in a variable gain amplifier (VGA). To keep a signal level, VGA gets a control signal from a clock and gain recovery system. In the sequel, we will assume that VGA is already (optimally) performed. In the design of equalizers and detectors, low power dissipation and high speed are both required. The error performances need to be maintained as well. So far, most systems seek for the implementations in the digital domain, as is the case in Fig. 34.47, but it has been shown that ADC may contribute to the high-frequency noise during the PR target equalization, causing a long settling time in clock recovery loop, as well as degrading performance [33]. In addition, the ADC is also usually the bottleneck for the low-power high-speed applications. On the other hand, the biggest problem for an analog system is the imperfection of circuit elements. The problems encountered with analog systems include nonideal gain, mismatch, nonlinear hold step, offset, etc.

Let us now turn to the blocks shown in Fig. 34.47. The first of them, the whitened matched filter, has the following properties [7]:

*Simplicity:* a single filter producing single sample at the output is all that is needed. The response of the filter is either chosen to be causal and hence realizable, or noncausal, meaning some delay has to be introduced, yielding better performance.

*Sufficiency:* the filter is information lossless, in the sense that its sampled outputs are a set of sufficient statistics for estimation of the input sequence.

*Whiteness:* the noise components of the sampled outputs are independent identically distributed Gaussian random variables.

The whiteness and sufficiency property follow from the fact that the set of waveforms at the output of the matched filter is an orthonormal basis for the signal space.

The next block is PRE. What is PR? Essential to PR techniques is that the PR sequence is obtained from the channel sequence via a simple linear filter. More specifically, the impulse response of this filter is such that the overall response is modeled as having only a few small integer-valued coefficients, the condition actually considered crucial for the system to be called PR. This condition subsequently yields relatively simple sequence detectors. The correlative level coding [3], also known as PR [31] is adopted in digital communication applications for long time. Kobayashi [9] suggested in 1971 that this type of channels can be treated as a linear finite state machine, and thus can be represented by the state diagram and its time instant labeled counterpart, trellis diagram. Consequently, its input is best inferred using some trellis search technique, the best of them (if we neglect complexity issues) being the Viterbi algorithm [2] (if one is interested in maximizing the likelihood of the whole sequence; otherwise, a symbol-by-symbol detector is needed). Kobayashi also indicated that the magnetic recording channel could be regarded as the PR channel due to the inherent differentiation property in the readback process [8]. This is both present in inductive heads and in magnetoresistive (MR) heads, though the latter are directly sensitive to magnetization and not to its change (this is due to the fact that the head has to be shielded). In other words, the pulse will be read only when the transition of opposite magnet polarities is sensed.

Basic to the PR equalization is the fact that a controlled amount of ISI is not suppressed by the equalizer, but rather left for a sequence detector to handle. The nature of the controlled ISI is defined by a PR. A proper match of this response to the channel permits noise enhancement to remain small even when amplitude distortion is severe. In other words, PR equalization can provide both well-controlled ISI and spectral match.

PR equalization is based on two assumptions:

- The shape of readback signal from an isolated transition is exactly known and determined.
- The superposition of signals from adjacent transitions is linear.

Furthermore, it is assumed that the channel characteristics are fixed and known, so that equalization need not be adaptive. The resulting PR channel can be characterized using  $D$ -transform of the sequences that occur,  $X(D) = I(D)H(D)$  [7] where  $H(D) = \sum_{i=0}^{M-1} h_i D^i$ ,  $D$  represents the delay factor in  $D$ -transform and  $M$  denotes the order of the PR signals. When modeling differentiation,  $H(D) = 1 - D$ . The finite state machine (FSM) of this PR channel is known as the dicode system since there are only two states in the transition diagram.

The most unclear signal transformation in Fig. 34.47 is equalization. What does it mean that the pulse of voltage should look like the target signal specified by the PR (the so-called PR target)? To answer this question let us consider the popular Class IV PR, or PRIV system.

For magnetic recording systems with  $PW50/T$  approximately equal to 2, comparatively little equalization is required to force the equalized channel to match a class-4 PR (PR4) channel where  $H(D) = (1 - D)(1 + D) = 1 - D^2$ . Comparing to the Lorentzian model of Chapter 34.1, PR4 channel shows more emphasis in the high frequency domain. The equalizer with the PR4 as the equalization target thus suppresses the low frequency components and enhances the high frequency ones, degrading the performance of all-digital detectors since the quantization noise, that is mainly placed at higher frequencies, is boosted up.

The isolated pulse shape in a PR4 system is shown in Fig. 34.48. The transition is written at time instant  $t = 0$ , where  $T$  is the channel bit period. The shape is oscillating and the pulse values at integer number of bit periods before the transition are exactly zeros. Obviously, it is this latter feature that should give us future advantage; however, at  $t = 0$  and at  $t = T$ , i.e., one bit period later, the values of the pulse are equal to “1”. The pulse of voltage reaches its peak amplitude of 1.273 at one half of the bit period. Assume that an isolated transition is written on the medium and the pulse of voltage shown in Fig. 34.48 comes to the PRML system. The PR4 system requires that the samples of this pulse should correspond to the bit periods. Therefore, samples of the isolated PR4 pulse will be 00...011000 ... (of course, “1” is used for convenience, and in reality it corresponds to some ADC level).

Because the isolated transition has two nonzero samples, when the next transition is written, the pulses will interfere. Thus, writing two pulses adjacent to each other will introduce superposition between them,

FIGURE 34.48 Capacity of PR4 channel.

FIGURE 34.49 Capacity of EPR4 channel.

usually called a dipulse response, as shown in Fig. 34.49. Here, the samples are [...,0,0,1,0,-1,0,0,...], resulting from

$$\begin{array}{r}
 0\ 0\ 1\ 1\ 0\ 0\ 0 \\
 +\ 0\ 0\ 0\ 0\ -1\ -1\ 0\ 0 \\
 \hline
 0\ 0\ 1\ 0\ -1\ 0\ 0
 \end{array}
 \begin{array}{l}
 \text{from the first transition} \\
 \text{from the second transition}
 \end{array}$$

Now, there is no concern about linear ISI; once the pulses can be reduced to the predetermined simple shape, the data pattern is easily recovered because superposition of signals from adjacent transitions is known.

In the above example, we see that sample “1” is suppressed by “-1” from the next transition. It is a simple matter to check that all possible linear combinations of the samples result in only three possible values  $\{-1, 0, +1\}$  (naturally, it is that all parts of the system are working properly, i.e., equalization, gain, and timing recovery, and that the signal is noise free). A positive pulse of voltage is always followed by a negative pulse and vice versa, so that the system can be regarded as an alternative mark inversion (AMI) code.

The higher bit capacity of the PR4 channel can best be understood from Fig. 34.48. It is observed that PR4 channel provides a 50% enhancement in the recording density as compared with the peak detection (fully equalized) one, since the latter requires isolation of single bits from each other. In the next figure, we see that the EPR4 channel (explained later) adds another 33% to this packing density. PR4 has another advantage over all the other PR systems; since  $H(D) = 1 - D^2$ , the current symbol is correlated to the second previous one, allowing the system to be modeled as two interleaved dicode channels, implying the use of simple dicode detectors for even and odd readback samples. RLL coding is necessary in this case, since nonideal tracking and timing errors result in a residual intermediate term (linear in  $D$ ) that induces correlation between two interleaved sequences, and thus degrades systems that rely on decoupled detection of each of them.

RLL codes are widely used in conjunction with PR equalization in order to eliminate certain data strings that would render tracking and synchronization difficult. If PR4 target is used, a special type of RLL coding is used, characterized by  $(0, G/I)$ . Here,  $G$  and  $I$  denote the maximum number of consecutive zeros in the overall data string, and in the odd/even substrings, respectively. The latter parameter ensures proper functioning of the clock recovery mechanism if deinterleaving of the PR4 channel into two independent dicode channels is performed. The most popular is the  $(0, 4/4)$  code, whose data rate is  $7/8$ , i.e., whose data loss is limited to 12.5%.

Other PR targets are used besides PR4. The criterion of how to select the appropriate PR target is based on spectral matching, to avoid introducing too much equalization noise. For instance, for  $PW50/T \approx 2.25$ , it is better to model ISI pattern as the so-called EPR4 (i.e. extended class-4 partial response) channel with  $H(D) = (1 + D)^2(1 - D) = 1 + D - D^2 - D^3$ . As the packing density goes up, more low frequency components are being introduced (low compared to  $1/T$ , that also increases as  $T$  is shortened, in reality those frequencies are higher than those met for lower recording densities, respectively greater  $T$ ). This is the consequence of the fact that intersymbol interference blurs the boundary between individual pulses, flattening the overall response (in time domain). The additional  $1 + D$  term in the target PR effectively suppresses the unwanted high frequencies. EPR4 enables even higher capacities of the magnetic recording systems than PR4, observing the difference of 33% in the recording density displayed in Fig. 34.49; however, a practical implementation of EPR4 is much more complex than is the case with PR4. First, the deinterleaving idea used for PR4 cannot be implemented. Second, the corresponding state diagram (and consequently trellis) now has eight states instead of four (two if deinterleaving is used). Furthermore, its output is five-leveled, instead of ternary for the PR4 and the dicode channel, so that a 4.4 dB degradation is to be expected with a threshold detector. Naturally, if sequence detector is used, such as Viterbi algorithm (VA), this loss does not exist, but its elimination is obtained at the expense of a significantly increased complexity of the detector. Furthermore, if such a detector can be used, EPR4 has a performance advantage over PR4 due to less equalization noise enhancement, cf. Fig. 34.50.

Let us reconsider the PR equalizer shown in Fig. 34.47. Following the approach from Reference 44, its aim is to transform the input spectrum  $Y'(e^{j2\pi\Omega})$  into a spectrum  $Y(e^{j2\pi\Omega}) = Y'(e^{j2\pi\Omega})|C(e^{j2\pi\Omega})|^2$ , where  $C(e^{j2\pi\Omega})$  is the transfer function of the equalizer. The spectrum  $Y(e^{j2\pi\Omega}) = I(e^{j2\pi\Omega})|H(e^{j2\pi\Omega})|^2 + N(e^{j2\pi\Omega})$  where  $H(D)$  is the PR target. For instance, duobinary PR target ( $H(D) = 1 + D$ ) enhances low frequencies and suppresses those near the Nyquist frequency  $\Omega = 0.5$ , whereas dicode  $H(D) = (1 - D)$  does the opposite: it suppresses low frequencies and enhances those near  $\Omega = 0.5$ .

In principle, the spectral zeros of  $H(e^{j2\pi\Omega})$  can be undone via a linear (recursive) filter, but this would excessively enhance any noise components added. The schemes for tracking the input sequence to the system based on the PR target equalized one will be reviewed later in this chapter section. For instance,

FIGURE 34.50 Equalization noise enhancement in PR channels.

FIGURE 34.51 (a) PR4 recursive restoration of information sequence and (b) precoder derived from it.

for a PR4 system, a second-order recursive filter can in principle be used to transform its input into an estimate of the information sequence, Fig. 34.51.

Unfortunately, if an erroneous estimate is produced at any moment, all subsequent estimates will be in error (in fact, they will no longer be in the alphabet  $\{-1, 0, 1\}$ , enabling error monitoring and simple forms of error correction [31]). To avoid this catastrophic error propagation, resort can be taken to a precoder.

Let us analyze the functioning of this precoder in the case of the PR4 channel  $(1 - D^2)$  (generalization to other PR channels is trivial). Its function is to transform  $i_n$  into a binary sequence  $d_n = i_n d_{n-2}$  to which the PR transformation is applied, Fig. 34.51(b). This produces a ternary sequence

$$x_n = (d * h)_n = d_n - d_{n-2} = i_n d_{n-2} - d_{n-2} = (i_n - 1)d_{n-2}$$

Because  $d_{n-2}$  cannot be zero,  $x_n$  is zero iff  $i_n - 1 = 0$ , i.e.,  $i_n = 1$ . Thus, the estimate  $\hat{i}_n$  of  $i_n$  can be formed by means of the memoryless mapping (MM)

$$\hat{i}_n = \begin{cases} 1, & x_n = 0 \\ 0, & \text{else} \end{cases}$$

This decoding rule does not rely on past data estimates and thereby avoids error propagation altogether. In practice, the sequences  $i_n$  and  $d_n$  are in the alphabet  $\{0, 1\}$  rather than  $\{-1, 1\}$ , and the multiplication in Fig. 34.51(b) becomes a modulo-2 addition (where 0 corresponds to 1, and 1 to  $-1$ ).

The precoder does not affect the spectral characteristics of an uncorrelated data sequence. For correlated data, however, precoding need not be spectrally neutral. It is instructive to think of the precoder as a first-order recursive filter with a pole placed so as to cancel the zero of the partial response. The filter uses a modulo-2 addition instead of a normal addition and as a result the cascade of filter and PR, while memoryless, has a nonbinary output. The MM serves to repair this “deficiency.”

FIGURE 34.52 Feedback detector.

Catastrophic error propagation can be avoided without precoder by forcing the output of the recursive filter of Fig. 34.52 to be binary (Fig. 34.52(a)). An erroneous estimate  $\hat{i}_{n-2} = -i_{n-2}$  leads to a digit

$$\hat{i}_n = x_n + \hat{i}_{n-2} = i_n - i_{n-2} + \hat{i}_{n-2} = i_n - 2i_{n-2}$$

whose polarity is obviously determined by  $i_{n-2}$ . Thus, the decision  $\hat{i}_n$  that is taken by the slicer in Fig. 34.52(a) will be correct if  $i_n$  happens to be the opposite of  $i_{n-2}$ . If data is uncorrelated, this will happen with probability 0.5, and error propagation will soon cease, since the average number of errors in a burst is  $1 + 0.5 + (0.5)^2 + \dots = 2$ . Error propagation is thus not a serious problem.

The feedback detector of Fig. 34.52 is easily generalized to arbitrary partial response  $H(D)$ . For purposes of normalization,  $H(D)$  is assumed to be causal and monic (i.e.,  $h_n = 0$  for  $n < 0$  and  $h_0 = 1$ ). The nontrivial taps  $h_1, h_2, \dots$  together form the “tail” of  $H(D)$ . This tail can be collected in  $P(D)$ , with  $p_n = 0$  for  $n \leq 0$  and  $p_n = h_n$  for  $n \geq 1$ . Hence,  $h_n = \delta_n + p_n$ , where the Kronecker delta function  $\delta_n$  represents the component  $h_0 = 1$ . Hence

$$x_n = (i * h)_n = (i * (\delta + p))_n = i_n + (i * p)_n.$$

The term  $(i * p)_n$  depends exclusively on past digits  $i_{n-1}, i_{n-2}, \dots$  that can be replaced by decisions  $\hat{i}_{n-1}, \hat{i}_{n-2}, \dots$ . Therefore, an estimate  $\hat{i}_n$  of the current digit  $i_n$  can be formed according to  $\hat{i}_n = x_k(\hat{i} * p)_n$  as in Fig. 34.52(b). As before, a slicer quantizes  $\hat{i}_n$  into binary decisions  $\hat{i}_n$  so as to avoid catastrophic error propagation. The average length of bursts of errors, unfortunately, increases with the memory order of  $H(D)$ . Even so, error propagation is not normally a serious problem [21]. In essence, the feedback detector avoids noise enhancement by exploiting past decisions. This viewpoint is also central to decision-feedback equalization, to be explained later.

Naturally, all this can be generalized to nonbinary data; but in magnetic recording, so far, only binary data are used (the so-called saturation recording). The reasons for this are elimination of hysteresis and the stability of the recorded sequence in time.

Let us consider now the way the PR equalizer from Fig. 34.47 is constructed. In Fig. 34.53, a discrete-time channel with transfer function  $F(e^{j2\pi\Omega})$  transforms  $i_n$  into a sequence  $y_n = (i * f)_n + u_n$ , where  $u_n$  is the additive noise with power spectral density  $U(e^{j2\pi\Omega})$ , and  $y_n$  represents the sampled output of a whitened matched filter. We might interpret  $F(e^{j2\pi\Omega})$  as comprising two parts: a transfer function  $H(e^{j2\pi\Omega})$  that captures most of the amplitude distortion of the channel (the PR target) and a function

FIGURE 34.53 Interpretation of PR equalization.

$F_r(e^{j2\pi\Omega}) = F(e^{j2\pi\Omega})/H(e^{j2\pi\Omega})$  that accounts for the remaining distortion. The latter distortion has only a small amplitude component and can thus be undone without much noise enhancement by a linear equalizer with transfer function

$$C(e^{j2\pi\Omega}) = \frac{1}{F_r(e^{j2\pi\Omega})} = \frac{H(e^{j2\pi\Omega})}{F(e^{j2\pi\Omega})}$$

This is precisely the PR equalizer we sought for. It should be stressed that the subdivision in Fig. 34.53 is only conceptual. The equalizer output is a noisy version of the “output” of the first filter in Fig. 34.53 and is applied to the feedback detector of Fig. 34.52, to obtain decision variables  $\hat{i}'_n$  and  $\hat{i}_n$ . The precoder and MM of Fig. 34.51 are, of course, also applicable and yield essentially the same performance.

The choice of the coefficients of the PRE in Fig. 34.47 is the same as for full-response equalization and is explained in the subsection on “Adaptive Equalization and Timing Recovery.” Interestingly, zero-forcing here is not as bad as is the case with full-response signaling and yields approximately the same result as minimum mean-square equalization. To evaluate the performance of the PRE, let us assume that all past decisions that affect  $\hat{i}_n$  are correct and that the equalizer is zero forcing (see “Adaptive Equalization and Timing Recovery” for details). The only difference between  $\hat{i}'_n$  and  $\hat{i}_n$  is now the filtered noise component ( $u * c$ )<sub>n</sub> with variance

$$\sigma_{\text{ZFPRE}}^2 = \int_{-0.5}^{0.5} U(e^{j2\pi\Omega}) |C(e^{j2\pi\Omega})|^2 d\Omega = \int_{-0.5}^{0.5} \frac{U(e^{j2\pi\Omega}) |H(e^{j2\pi\Omega})|^2}{|F(e^{j2\pi\Omega})|^2} d\Omega$$

Because  $|H(e^{j2\pi\Omega})|$  was selected to be small wherever  $|F(e^{j2\pi\Omega})|$  is small, the integrand never becomes very large, and the variance will be small. This is in marked contrast with full-response equalization. Here,  $H(e^{j2\pi\Omega}) = 1$  for all  $\Omega$ , and the integrand in the above formula can become large at frequencies where  $|F(e^{j2\pi\Omega})|$  is small. Obviously, the smallest possible noise enhancement occurs if  $H(e^{j2\pi\Omega})$  is selected so that the integrand is independent of frequency, implying that the noise at the output of the PRE is white. This is, in general, not possible if  $H(e^{j2\pi\Omega})$  is restricted to be PR (i.e., small memory-order, integer-valued). The generalized feedback detector of Fig. 34.52, on the other hand, allows a wide variety of causal responses to be used, and here  $|H(e^{j2\pi\Omega})|$  can be chosen at liberty. Exploitation of this freedom leads to decision feedback equalization (DFE).

## Decision Feedback Equalization

This subsection reviews the basics of decision feedback detection. It is again assumed that the channel characteristics are fixed and known, so that the structure of this detector need not be adaptive. Generalizing to variable channel characteristics and adaptive detector structure is tedious, but straightforward.

A DFE detector shown in Fig. 34.54, utilizes the noiseless decision to help remove the ISI. There are two types of ISI: *precursor* ISI (ahead of the detection time) and *postcursor* (behind detection time). Feed-forward equalization (FFE) is needed to eliminate the precursor ISI, pushing its energy into the postcursor domain. Supposing all the decisions made in the past are correct, DFE reproduces exactly the modified

FIGURE 34.54 Decision feedback equalizer.

FIGURE 34.55 Precursor and postcursor ISI elimination with DFE (a) sampled channel response, (b) after feed-forward filter and (c) slicer output.

postcursor ISI (with extra postcursor ISI produced by the FFE during the elimination of precursor ISI), thus eliminating it completely, Fig. 34.55. If the length of the FFE can be made infinitely long, it should be able to completely suppress the precursor ISI, redistributing its energy into the postcursor region, where it is finally cancelled by feedback decision part. No spectrum inverse is needed for this process, so noise boosting is much less than is the case with linear equalizers.

The final decision of the detector is made by the memoryless slicer, Fig. 34.54. The reason why a slicer can perform efficient sequence detection can be explained with the fact that memory of the DFE system is located in two equalizers, so that only symbol-by-symbol detection can suffice. In terms of performance, the DFE is typically much closer to the maximum likelihood sequence detector than to the LE. If the equalization target is not the main cursor, but a PR system, a sequence detection algorithm can be used afterwards. A feasible way to implement this with minimum additional effort is the tree search algorithm used instead of VA [6]. The simple detection circuitry of a DFE, consisting of two equalizers and one slicer, makes implementation possible. The DFE may be regarded as a generalization of the PRE. In the DFE, the trailing portion of the ISI is not suppressed by a forward equalizer but rather canceled by a feedback filter that is excited by past decisions. Fortunately, error propagation is typically only a minor

FIGURE 34.56 Block diagram of a RAM-based DFE.

problem and it can, in fact, be altogether avoided through a technique that is called Tomlinson/Harashima precoding.

Performance differences between zero-forcing and minimum mean-square equalizers tend to be considerably smaller in the DFE case than for the LE, and as a result it becomes more difficult to reap SNR benefits from the modulation code. It can be proved that DFE is the optimum receiver with no detection delay. If delay is allowed, it is better to use trellis-based detection algorithms.

### RAM-Based DFE Detection

Decision feedback equalization or RAM-based DFE is the most frequent alternative to PRML detection. Increase of bit density leads to significant nonlinear ISI in the magnetic recording channel. Both the linear DFE [12,26] and PRML detectors do not compensate for the nonlinear ISI. Furthermore, the implementation complexity of a Viterbi detector matched to the PR channel grows exponentially with the degree of channel polynomial. Actually, in order to meet requirements for a high data transfer rate, high-speed ADC is also needed. In the RAM-based DFE [19,24], the linear feedback section of the linear DFE is replaced with a look-up table. In this way, detector decisions make up a RAM address pointing to the memory location that contains an estimate of the post cursor ISI for the particular symbol sequence. This estimate is subtracted from the output of the forward filter forming the equalizer output. Look-up table size is manageable and typically is less than 256 locations. The major disadvantage of this approach is that it requires complicated architecture and control to recursively update ISI estimates based on equalizer error.

### Detection in a Trellis

A trellis-based system can be simply described as a FSM (Finite State Machine) whose structure may be displayed with the aid of a graph, tree, or trellis diagram. A FSM maps input sequences (vectors) into output sequences (vectors), not necessarily of the same length. Although the system is generally nonlinear and time-varying, linear fixed trellis based systems are usually met. For them,

$$F(a \cdot \mathbf{i}_{[0,\infty)}) = a \cdot F(\mathbf{i}_{[0,\infty)})$$

$$F(\mathbf{i}'_{[0,\infty)} + \mathbf{i}''_{[0,\infty)}) = F(\mathbf{i}'_{[0,\infty)}) + F(\mathbf{i}''_{[0,\infty)})$$

where  $a$  is a constant,  $\mathbf{i}_{[0,\infty)}$  is any input sequence and  $F(\mathbf{i}_{[0,\infty)})$  is the corresponding output sequence. It is assumed that input and output symbols belong to a subset of a field. Also, for any  $d > 0$ , if  $\mathbf{x}_{[0,\infty)} = F(\mathbf{i}_{[0,\infty)})$  and  $\mathbf{i}'_l = \mathbf{i}_{l-d}$ ,  $\mathbf{i}'_{[0,d)} = \mathbf{0}_{[0,d)}$  then  $F(\mathbf{i}'_{[0,\infty)}) = \mathbf{x}'_{[0,\infty)}$ , where  $\mathbf{x}'_l = \mathbf{x}_{l-d}$ ,  $\mathbf{x}'_{[0,d)} = \mathbf{0}_{[0,d)}$ . It is easily verified that  $F(\cdot)$  can be represented by the convolution, so that  $\mathbf{x} = \mathbf{i} * \mathbf{h}$ , where  $\mathbf{h}$  is the system impulse

response (this is also valid for different lengths of  $\mathbf{x}$  and  $\mathbf{i}$  with a suitable definition of  $\mathbf{h}$ ). If  $\mathbf{h}$  is of finite duration,  $M$  denotes the system memory length.

Let us now consider a feedforward FSM with memory length  $M$ . At any time instant (depth or level)  $l$ , the FSM output  $\mathbf{x}_l$  depends on the current input  $\mathbf{i}_l$  and  $M$  previous inputs  $\mathbf{i}_{l-1}, \dots, \mathbf{i}_{l-M}$ . The overall functioning of the system can be mapped on a trellis diagram, whereon a node represents one of  $q^M$  encoder states ( $q$  is the cardinality of the input alphabet including the case when the input symbol is actually a subsequence), while a branch connecting two nodes represents the FSM output associated to the transition between the corresponding system states.

A trellis, which is a visualization of the state transition diagram with a time element incorporated, is characterized by  $q$  branches stemming from and entering each state, except in the first and last  $M$  branches (respectively called head and tail of the trellis). The branches at the  $l$ th time instant are labeled by sequences  $\mathbf{x}_l \in X$ . A sequence of  $l$  information symbols,  $\mathbf{i}_{(0,l)}$  specifies a path from the root node to a node at the  $l$ th level and, in turn, this path specifies the output sequence  $\mathbf{x}_{(0,l)} = \mathbf{x}_0 \bullet \mathbf{x}_1 \bullet \dots \bullet \mathbf{x}_{l-1}$ , where  $\bullet$  denotes concatenation of two sequences.

The input can, but need not, be separated in frames of some length. For framed data, where the length of each input frame equals  $L$  branches (thus  $L$   $q$ -ary symbols) the length of the output frame is  $L + M$  branches ( $L + M$  output symbols), where the  $M$  known symbols (usually all zeros) are added at the end of the sequence to force the system into the desired terminal state. It is said that such systems suffer a fractional rate loss by  $L/(L + M)$ . Clearly, this rate loss has no asymptotic significance.

In the sequel, the detection of the input sequence,  $\mathbf{i}_{(0,\infty)}$ , will be analyzed based on the corrupted output sequence  $\mathbf{y}_{(0,\infty)} = \mathbf{x}_{(0,\infty)} + \mathbf{u}_{(0,\infty)}$ . Suppose there is no feedback from the output to the input, so that

$$P[y_n | x_0, \dots, x_{n-1}, x_n, y_0, \dots, y_{n-1}] = P[y_n | x_n]$$

and

$$P[y_1, \dots, y_N | x_1, \dots, x_N] = \prod_{n=1}^N P[y_n | x_n]$$

Usually,  $\mathbf{u}_{(0,\infty)}$  is a sequence that represents additive white Gaussian noise sampled and quantized to enable digital processing.

The task of the detector that minimizes the sequence error probability is to find a sequence which maximizes the joint probability of input and output channel sequences

$$P[\mathbf{y}_{(0,L+M)}, \mathbf{x}_{(0,L+M)}] = P[\mathbf{y}_{(0,L+M)} | \mathbf{x}_{(0,L+M)}] P[\mathbf{x}_{(0,L+M)}]$$

Since usually the set of all probabilities  $P[\mathbf{x}_{(0,L+M)}]$  is equal, it is sufficient to find a procedure that maximizes  $P[\mathbf{y}_{(0,L+M)} | \mathbf{x}_{(0,L+M)}]$ , and a decoder that always chooses as its estimate one of the sequences that maximize it or

$$\begin{aligned} \mu(\mathbf{y}_{(0,L+M)} | \mathbf{x}_{(0,L+M)}) &= A \log_2 P[\mathbf{y}_{(0,L+M)} | \mathbf{x}_{(0,L+M)}] \\ -f(\mathbf{y}_{(0,L+M)}) &= A \sum_{l=0}^{L+M} \log_2 (P[\mathbf{y}_l | \mathbf{x}_l] - f(\mathbf{y}_l)) \end{aligned}$$

(where  $A \geq 0$  is a suitably chosen constant, and  $f(\cdot)$  is any function) is called a maximum-likelihood decoder (MLD). This quantity is called a metric,  $\mu$ . This type of metric suffers one significant disadvantage because it is suited only for comparison between paths of the same length. Some algorithms, however,

employ a strategy of comparing paths of different length or assessing likelihood of such paths with the aid of some thresholds. The metric that enables comparison for this type of algorithms is called the Fano metric. It is defined as

$$\begin{aligned}\mu_F(\mathbf{y}_{[0,l]}|\mathbf{x}_{[0,l]}) &= A \log_2 \frac{P[\mathbf{y}_{[0,l]}, \mathbf{x}_{[0,l]}]}{P[\mathbf{y}_{[0,l]}]} \\ &= A \sum_{n=0}^l \left( \log_2 \frac{P[\mathbf{y}_n|\mathbf{x}_n]}{P[\mathbf{y}_n]} - R \right)\end{aligned}$$

If the noise is additive, white, and Gaussian (an assumption that is not entirely true, but that usually yields systems of good performances), the probability distribution of its sample is

$$p[\mathbf{y}_n|\mathbf{x}_n] = \frac{1}{\sqrt{2\pi\sigma^2}} \exp\left(-\frac{(\mathbf{y}_n - \mathbf{x}_n)^2}{2\sigma^2}\right)$$

The ML metric to be used in conjunction with such a noise is the logarithm of this density, and thus proportional to  $-(\mathbf{y}_n - \mathbf{x}_n)^2$ , i.e., to the negative squared Euclidean distance of the readback and supposed written signal. Thus, maximizing likelihood amounts to minimizing the squared Euclidean distance of the two sequences, leading to minimizing the squared Euclidean distance between two sampled sequences given by  $\sum_n (\mathbf{y}_n - \mathbf{x}_n)^2$ .

The performance of a trellis-based system, as is the case with PR systems, depends on the detection algorithm employed and on the properties of the system itself. The distance spectrum is the property of the system that constitutes the main factor of the event error probability of a ML (optimum) detector, if the distance is appropriately chosen for the coding channel used.<sup>45</sup> For PR channels with additive white Gaussian noise, it is the squared Euclidean distance that has to be dealt with. Naturally, since the noise encountered is neither white, nor entirely Gaussian, this is but an approximation to the properly chosen distance measure.

As stated previously, the aim of the search procedure is to find a path with the highest possible likelihood, i.e., metric. There are several possible classifications of detecting procedures. This classification is in-line with systematization made in coding theory, due to fact that algorithms developed for decoding in a trellis are general so that it could be applied to problem of detection in any trellis-based system as well. According to detector's strategies in extending the most promising path candidates we classify them into breadth-first, metric-first, and depth-first, bidirectional algorithms, and into sorting and nonsorting depending on whether the procedure performs any kind of path comparison (sifting or sorting) or not. Moreover, detecting algorithms can be classified into searches that *minimize* the *sequence* or *symbol* error rate.

The usual measure of algorithm efficiency is its complexity (arithmetic and storage) for a given probability of error. In the strict sense, arithmetic or computational complexity is the number of arithmetic operations per detected symbol, branch, or frame; however, it is a usual practice to track only the number of node computations, which makes sense because all such computations require approximately the same number of basic machine instructions. A node computation (or simply computation) is defined as the total number of nodes extended (sometimes it is the number of metrics computed) per detected branch or information frame  $\mathbf{i}_{[0,L+M]}$ . One single computation consists of determining the state in which the node is computing the metrics of all its successors. For most practical applications with finite frame length, it is usually sufficient to observe node computations since a good prediction of search duration can be precisely predicted. Nevertheless, for asymptotic behavior it is necessary to track the sorting requirements too. Another important aspect of complexity is storage (memory or space), which is the amount of auxiliary storage that is required for detecting memory, processors working in parallel, etc. Thus, space complexity of an algorithm is the size (or number) of resources that must be reserved for

its use, while the computational, or more precisely time complexity, reflects the number of accesses to this resources taking into account that any two operations done in parallel by the spatially separated processors should be counted as one. The product of these two, the time-space complexity, is possibly the best measure of the algorithm cost for it is insensitive to time-space tradeoff such as parallelization or the use of precomputed tables, although it also makes sense to keep the separate track of these two. Finally, for selecting which algorithm to use, one must consider additional details that we omit here, but which can sometimes cause unexpected overall performance or complicate the design of a real-time detector. They include complexity of the required data structure, buffering needs, and applicability of available hardware components.

**Basic Breadth-First Algorithms**

**The Viterbi Algorithm (VA)**

The VA was introduced in 1967 as a method of decoding convolutional codes. Forney showed in 1972 [7] that the VA solves the maximum-likelihood sequence detection (MLSD) problem in the presence of ISI and additive white noise. Kobayashi and Tang [8] recognized that this algorithm is possible to apply in magnetic recording systems for detection purposes. Strategy to combine Viterbi detector with PR equalization in magnetic recording channel resulted with many commercial products.

The VA is an optimal decoding algorithm in the sense that it always finds the nearest path to the noisy modification of the FSM output sequence  $\mathbf{x}_{[0, L+M]}$ , and it is quite useful when FSM has a short memory. The key to Viterbi (maximum-likelihood, ML) decoding lies in the *Principle of Nonoptimality* [17]. If the paths  $\mathbf{i}'_{[0,l]}$  and  $\mathbf{i}''_{[0,l]}$  terminate at the same state of the trellis and

$$\mu(\mathbf{y}_{[0,l]}, \mathbf{x}'_{[0,l]}) > \mu(\mathbf{y}_{[0,l]}, \mathbf{x}''_{[0,l]})$$

then  $\mathbf{i}''_{[0,l]}$  cannot be the first  $l$  branches of one of the paths  $\mathbf{i}_{[0, L+M]}$  that maximize the overall sequence metric. This principle which some authors call the *Principle of Optimality* literally specifies the most efficient MLD procedure for decoding/detecting in the trellis.

To apply VA as an ML sequence detector for a PR channel, we need to define the channel trellis describing the amount of controlled ISI. Once we define the PR channel polynomial, it is an easy task. An example of such trellis for PR4 channel with  $P(D) = 1 - D^2$  is depicted in Fig. 34.57. The trellis for this channel consists of four states according to the fact that channel input is binary and channel memory is 2, so that there are four possible state values (00, 10, 01, 11). Generally, if the channel input sequence can take  $q$  values, and the PR channel forms the ISI from the past  $M$  input symbols, then the PR channel can be described by a trellis with  $q^M$  states. Branches joining adjacent states are labeled with the pair of expected noiseless symbols in the form channel\_output/channel\_input. Equalization to  $P(D) = 1 - D^2$  results in ternary channel output, taking values  $\{0, \pm 1\}$ . Each noiseless output channel sequence is obtained by reading the sequence of labels along some path through the trellis.

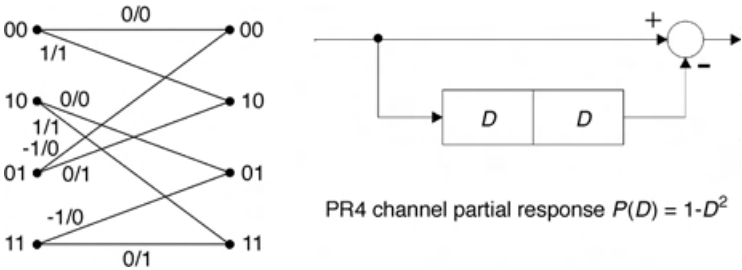

FIGURE 34.57 PR4 channel trellis.

Now the task of detecting  $\mathbf{i}_{[0,\infty)}$  is to find  $\mathbf{x}_{[0,\infty)}$  that is closest to  $\mathbf{y}_{[0,\infty)}$  in the Euclidean sense. Recall that we stated as an assumption that channel noise is AWGN, while in magnetic recording systems after equalization the noise is colored so that the minimum-distance detector is not an optimal one, and additional post-processing is necessary, which will be addressed later in this chapter.

The Viterbi algorithm is a classical application of dynamic programming. Structurally, the algorithm contains  $q^M$  lists, one for each state, where the paths whose states correspond to the label indices are stored, compared, and the best one of them retained. The algorithm can be described recursively as follows:

1. *Initial condition:* Initialize the starting list with the root node (the known initial state) and set its metric to zero,  $l = 0$ .
2. *Path extension:* Extend all the paths (nodes) by one branch to yield new candidates,  $l = l + 1$ , and find the sum of the metric of the predecessor node and the branch metric of the connecting branch (ADD). Classify these candidates into corresponding  $q^M$  lists (or less for  $l < M$ ). Each list (except in the head of the trellis) contains  $q$  paths.
3. *Path selection:* For each end-node of extended paths determine the maximum/minimum\* of these sums (COMPARE) and assign it to the node. Label the node with the best path metric to it, selecting (SELECT) that path for the next step of the algorithm (discard others). If two or more paths have the same metric, i.e., if they are equally likely, choose the best one at random. Find the best of all the survivor paths,  $\mathbf{x}'_{[0,l)}$ , and its corresponding information sequence  $\mathbf{i}'_{[0,l)}$  and release the bit  $\mathbf{i}'_{l-\delta}$ . Go to step 2.

In the description of the algorithm we emphasized three Viterbi-characteristic operations—add, compare, select (ADC)—that are performed in every recursion of the algorithm. So today’s specialized signal processors have this operation embedded optimizing its execution time. Consider now the amount of “processing” done at each depth  $l$ , where all of the  $q^M$  states of the trellis code are present. For each state it is necessary to compare  $q$  paths that merge in that state, discard all but the best path, and then compute and send the metrics of  $q$  of its successors to the depth  $l + 1$ .

Consequently, the computational complexity of the VA exponentially increases with  $M$ . These operations can be easily parallelized, but then the number of parallel processors rises as the number of node computations decreases. The total time-space complexity of the algorithm is fixed and increases exponentially with the memory length.

The sliding window VA decodes infinite sequences with delay of  $\delta$  branches from the last received one. In order to minimize its memory requirements ( $\delta + 1$  trellis levels), and achieve bit error rate only insignificantly higher than with finite sequence VA,  $\delta$  is chosen as  $\delta \approx 4M$ . In this way, the Viterbi detector introduces a fixed decision delay.

### Example

Assume that a recorded channel input sequence  $\mathbf{x}$ , consisting of  $L$  equally likely binary symbols from the alphabet  $\{0, 1\}$ , is “transmitted” over PR4 channel. The channel is characterized by the trellis of Fig. 34.57, i.e., all admissible symbol sequences correspond to the paths traversing the trellis from  $l = 0$  to  $l = L$ , with one symbol labeling each branch, Fig. 34.58. Suppose that the noisy sequence of samples at the channel output is  $\mathbf{y} = 0.9, 0.2, -0.6, -0.3, 0.6, 0.9, 1.2, 0.3, \dots$ . If we apply a simple symbol-by-symbol detector to this sequence, the fifth symbol will be erroneous due to the hard quantization rule for noiseless channel output estimate

$$\hat{y}_k = \begin{cases} -1 & y_k < -0.5 \\ 1 & y_k > 0.5 \\ 0 & \text{otherwise} \end{cases}$$

\*It depends on whether the metric or the distance is accumulated.

FIGURE 34.58 Viterbi algorithm detection on the PR4 trellis.

The Viterbi detector will start to search the trellis accumulating branch distance from sequence  $\mathbf{y}$ . In the first recursion of the algorithm, there are two paths of length 1 at the distance

$$d(\mathbf{y},0) = (0.9 - 0)^2 = 0.81$$

$$d(\mathbf{y},1) = (0.9 - 1)^2 = 0.01$$

from  $\mathbf{y}$ . Next, each of the two paths of length 1 are extended in two ways forming four paths of length 2 at squared Euclidean distance from the sequence  $\mathbf{y}$

$$d(\mathbf{y},(0,0)) = 0.81 + (0.2 - 0)^2 = 0.85$$

$$d(\mathbf{y},(0,1)) = 0.81 + (0.2 - 1)^2 = 1.45$$

$$d(\mathbf{y},(1,0)) = 0.01 + (0.2 - 0)^2 = 0.05$$

$$d(\mathbf{y},(1,1)) = 0.01 + (0.2 - 1)^2 = 0.65$$

and this accumulated distance of four paths labels the four trellis states. In the next loop of the algorithm each of the paths is again extended in two ways to form eight paths of length 3, two paths to each node at level (depth) 3.

Node 00

$$d(\mathbf{y},(0,0,0)) = 0.85 + (-0.6 - 0)^2 = 1.21$$

$$d(\mathbf{y},(1,0,-1)) = 0.05 + (-0.6 + 1)^2 = 0.21 \quad \text{surviving path}$$

Node 10

$$d(\mathbf{y},(0,0,1)) = 0.85 + (-0.6 - 1)^2 = 3.41$$

$$d(\mathbf{y},(1,0,0)) = 0.05 + (-0.6 - 0)^2 = 0.41 \quad \text{surviving path}$$

Node 01

$$d(\mathbf{y},(0,1,0)) = 1.45 + (-0.6 - 0)^2 = 1.81$$

$$d(\mathbf{y},(1,1,-1)) = 0.65 + (-0.6 + 1)^2 = 0.81 \quad \text{surviving path}$$

FIGURE 34.59 Implementation of  $1-D^2$  Viterbi detector with two half-rate,  $1-D$  detectors.

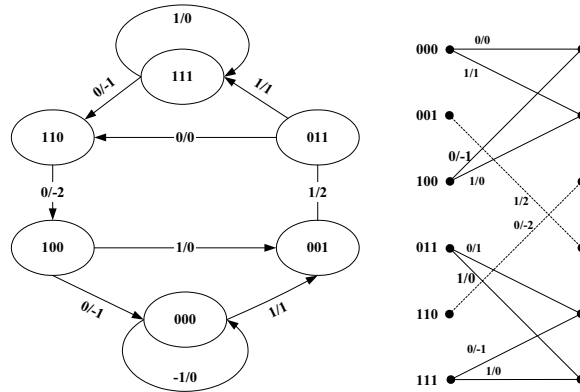

FIGURE 34.60 (1,7) coded PR4 channel.

Node 11

$$d(\mathbf{y},(0,1,1)) = 1.45 + (-0.6 - 1)^2 = 4.01$$

$$d(\mathbf{y},(1,1,0)) = 0.65 + (-0.6 - 0)^2 = 1.01 \quad \text{surviving path}$$

Four paths of length 3 are selected as the surviving most likely paths to the four trellis nodes. The procedure is repeated and the detected sequence is produced after a delay of  $4M = 8$  trellis sections. Note, Fig. 34.58, that the symbol-by-symbol detector error is now corrected. Contrary to this example, a 4-state PR4ML detector is implemented with two interleaved 2-state dicode,  $(1 - D)$ , detectors each operating at one-half the symbol rate of one full-rate PR4 detector [35]. The sequence is interleaved, such that the even samples go to the first and the odd to the second dicode detector, Fig. 34.59, so the delay  $D$  in the interleaved detectors is actually twice the delay of the PR4 detector. A switch at the output resamples the data to get them out in the correct order.

For other PR channels this type of decomposition is not possible, so that their complexity can become great for real-time processing. In order to suppress some of the states in the corresponding trellis diagram of those PR systems, thus simplifying the sequence detection process, some data loss has to be introduced. For instance, in conjunction with precoding (1,7) code prohibits two states in PR4 trellis: [101] and [010]. This can be used to reduce the 8-state PR4 trellis to 6-state trellis depicted in Fig. 34.60 and the number of add-compare-select units in the VA detector to 4. The data rate loss is 33% in this case. Using the (2,7) code eliminates two more states, paying the complexity gain by a 50% data rate loss.

Because VA involves addition, multiplication, compare and select functions, which require complex circuitry at the read side, simplifications of the receiver for certain PRs were sought. One of them is the dynamic threshold technique [22]. This technique implies generating a series of thresholds. The readback samples are compared with them, just as for the threshold detector, and are subsequently included in their modification. While preserving the full function of the ML detector, this technique saves a substantial fraction of the necessary hardware. Examples of dynamic threshold detectors are given in [30] and [6].

**Noise-Predictive Maximum Likelihood Detectors (NPMLD)**

Maximum likelihood detection combined with PR equalization is a dominant type of detection electronics in today’s digital magnetic recording devices. As described earlier, in order to simplify hardware realization of the receiver, the degree of the target PR polynomial is chosen to be small with integer coefficients to restrict complexity of Viterbi detection trellis. On the other hand, if the recording density is increased, to produce longer ISI, equalization to the same PR target will result in substantial noise enhancement and detector performance degradation. Straightforward solution is to increase the duration of the target PR polynomial decreasing the mismatch between channel and equalization target. Note that this approach leads to undesirable increase in detector complexity fixing the detector structure in a sense that its target polynomial cannot be adapted to changing channel density.

The (NPML) detector [20,32] is an alternative data detection method that improves reliability of the PRML detector. This is achieved by embedding a noise prediction/whitening process into the branch metric computation of a Viterbi detector. Using reduced-state sequence-estimation [43] (see also the description of the generalized VA in this chapter), which limits the number of states in the detector trellis, compensates for added detector complexity.

A block diagram of a NPML system is shown in Fig. 34.61. The input to the channel is binary sequence,  $\mathbf{i}$ , which is written on the disk at a rate of  $1/T$ . In the readback process data are recovered via a lowpass filter as an analog signal  $y(t)$ , which can be expressed as  $y(t) = \sum_n i_n h(t - nT) + u(t)$ , where  $h(t)$  denotes the pulse response and  $u(t)$  is the additive white Gaussian noise. The signal  $y(t)$  is sampled periodically at times  $t = nT$  and shaped into the PR target response by the digital equalizer. The NPML detector then performs sequence detection on the PR equalized sequence  $\mathbf{y}$  and provides an estimate of the binary information sequence  $\mathbf{i}$ . Digital equalization is performed to fit the overall system transfer function to some PR target, e.g., the PR4 channel.

The output of the equalizer  $y_n + i_n + \sum_{i=1}^M f_i x_{n-i} + w_n$  consists of the desired response and an additive total distortion component  $w_n$ , i.e., the colored noise and residual interference. In conventional PRML detector, an estimate of the recorded sequence is done by the minimum-distance criteria as described for the Viterbi detector. If the mismatch between channel and PR target is significant, the power of distortion component  $w_n$  can degrade the detector performance. The only additional component compared to the Viterbi detector, NPML noise-predictor, reduces the power of the total distortion by

FIGURE 34.61 Block diagram of NPVA detector.

FIGURE 34.62 NPML metric computation for PR4 trellis.

whitening the noise prior to the Viterbi detector. The whitened total distortion component of the PR equalized output  $y_n$  is

$$w_n - \hat{w}_n = w_n - \sum_{i=1}^N w_{n-i} p_i$$

where the  $N$ -coefficient MMSE predictor transfer polynomial is  $P(D) = p_1 D^1 + p_2 D^2 + \dots + p_N D^N$ . Note that an estimate of the current noise sample  $\hat{w}_n$  is formed based on estimates of previous  $N$  noise samples. Assuming the PR4 equalization of sequence  $\mathbf{y}$ , the metric of the Viterbi detector can be modified in order to compensate for distortion component. In this case, the equalizer output is  $y_n = x_n - x_{n-2} + w_n$  and the NPML distance is

$$\begin{aligned} & \left[ \left( y_n - \sum_{i=1}^N w_{n-i} p_i \right) - (x_n(S_k) - x_{n-2}(S_j)) \right]^2 \\ & = \left[ \left( y_n - \sum_{i=1}^N (y_{n-i} - \hat{x}_{n-i}(S_j) - \hat{x}_{n-i-2}(S_j)) p_i \right) - (x_n(S_k) - x_{n-2}(S_j)) \right]^2 \end{aligned}$$

where  $\hat{x}_{n-i}(S_j)$ ,  $\hat{x}_{n-i-2}(S_j)$  represent past decisions taken from the Viterbi survivor path memory associated with state  $S_j$ . The last expression gives the flavor of this technique, but it is not suitable for implementation so that the interested reader can find details in [20] how to modify this equation for RAM look-up realization. Furthermore, in the same paper, a description of the general procedure to compute the predictor coefficients based on the autocorrelation of the total distortion  $w_n$  at the output of a finite-length PR equalizer is given.

### Postprocessor

As explained earlier, Viterbi detector improves the performance of a read channel by tracing the correct path through the channel trellis [8]. Further performance improvement can be achieved by using soft output Viterbi algorithm (SOVA) [14]. Along with the bit decisions, SOVA produces the likelihood of these decisions, that combined create *soft information*. In principle, soft information can be passed to hard drive controller and used in RS decoder that resides there, but at the present time soft decoding of RS codes is still too complex to be implemented at 1 Gb/s speeds. Alternatively, much shorter inner code is used. Because of the nonlinear operations on bits performed by the modulation decoder logic, the inner code is used in inverse concatenation with modulation encoder in order to simplify calculation of bit likelihood. Due to the channel memory and noise coloration, Viterbi detector produces some error patterns more often than others [5], and the inner code is designed to correct these so-called *dominant error sequences* or *error events*. The major obstacle for using soft information is the speed limitations and hardware complexity required to implement SOVA. Viterbi detector is already a bottleneck and the most complex block in a read channel chip, occupying most of the chip area, and the architectural challenges in implementing even more complex SOVA would be prohibitive. Therefore, a postprocessor architecture is used [18]. The postprocessor is a block that resides after Viterbi detector and comprises the block for calculating error event likelihood and an inner-soft error event correcting decoder.

The postprocessor is designed by using the knowledge on the set of dominant error sequences  $E = \{e_i\}_{1 \leq i}$  and their occurrence probabilities  $P = (p_i)_{1 \leq i}$ . The index  $i$  is referred to as an *error type*, while the position of the *error event end* within a codeword is referred as an *error position*. The relative frequencies of error events will strongly depend on recording density [36]. The detection is based on the fact that we can calculate the likelihoods of each of dominant error sequences at each point in time. The parity bits detect the errors, and provide localization in error type and time. The likelihoods are then used to choose the most likely error events for corrections.

The error event likelihoods are calculated as the difference in the squared Euclidean distances between the signal and the convolution of maximum likelihood sequence estimate and the channel PR, versus that between the signal and the convolution of an alternative data pattern and the channel PR. During each clock cycle, the best  $M$  of them are chosen, and the syndromes for these error events are calculated. Throughout the processing of each block, a list is maintained of the  $N$  most likely error events, along with their associated error types, positions and syndromes. At the end of the block, when the list of candidate error events is finalized, the likelihoods and syndromes are calculated for each of  $\binom{N}{L}$  combinations of  $L$ -set candidate error events that are possible. After disqualifying those  $L$ -sets of candidates, which overlap in the time domain, and those candidates and  $L$ -sets of candidates, which produce a syndrome which does not match the actual syndrome, the candidate or  $L$ -set of candidates, which remains and which has the highest likelihood is chosen for correction. Finding the error event position and type completes decoding.

The decoder can make two types of errors: it fails to correct if the syndrome is zero, or it makes a wrong correction if the syndrome is nonzero, but the most likely error event or combination of error events does not produce the right syndrome. A code must be able to detect a single error from the list of dominant error events and should minimize the probability of producing zero syndrome when more than one error event occurs in a codeword. Consider a linear code given by an  $(n - k) \times n$  parity check matrix  $H$ . We are interested in capable of correcting or detecting dominant errors. If all errors from a list were contiguous and shorter than  $m$ , a cyclic  $n - k = m$  parity bit code could be used to correct a single error event [16]; however, in reality, the error sequences are more complex, and occurrence probabilities of error events of lengths 6, 7, 8 or more are not negligible. Furthermore, practical reasons (such as decoding delay, thermal asperities, etc.) dictate using short codes, and consequently, in order to keep the code rate high, only a relatively small number of parity bits is allowed, making the design of error event detection codes nontrivial. The code redundancy must be used carefully so that the code is optimal for a given  $E$ .

The parity check matrix of a code can be created by a recursive algorithm that adds one column of  $H$  at a time using the criterion that after adding each new column, the code error-event-detection capabilities are still satisfied. The algorithm can be described as a process of building a directed graph whose vertices are labeled by the portions of parity check matrix long enough to capture the longest error event, and whose edges are labeled by column vectors that can be appended to the parity check matrix without violating the error event detection capability [4]. To formalize code construction requirements, for each error event from  $E$ , denote by  $s_{i,l}$  a syndrome of error vector  $\sigma_l(e_i)$  ( $s_{i,l} = \sigma_l(e_i) \cdot H^T$ ), where  $\sigma_l(e_i)$  is an  $l$ -time shifted version of error event  $e_i$ . The code should be designed in such a way that any shift of any dominant error sequence produces a nonzero syndrome, i.e., that  $s_{i,l} \neq 0$  for any  $1 \leq i \leq I$  and  $1 \leq l \leq n$ . In this way, a single error event can be detected (relying on error event likelihoods to localize the error event). The correctable shifts must include negative shifts as well as shifts larger than  $n$  in order to cover those error events that straddle adjacent codewords, because the failure to correct straddling events significantly affects the performance. A stronger code could have a parity check matrix that guarantees that syndromes of any two-error event-error position pairs  $((i_1, l_1), (i_2, l_2))$  are different, i.e.,  $s_{i_1, l_1} \neq s_{i_2, l_2}$ . This condition would result in a single error event correction capability. The codes capable of correcting multiple error events can be defined analogously. We can even strengthen this property and require that for any two shifts and any two dominant error events, the Hamming distance between any pair of syndromes is larger than  $\delta$ ; however, by strengthening any of these requirements the code rate decreases.

If  $L_i$  is a length of the  $i$ th error event, and if  $L$  is the length of the longest error event from  $E$  ( $L = \max_{1 \leq i \leq I} \{L_i\}$ ), then it is easy to see that for a code capable of detecting an error event from  $E$  that ends at position  $j$ , the linear combination of error events and the columns of  $H$  from  $j - L + 1$  to  $j$  has to be nonzero. More precisely, for any  $i$  and any  $j$  (ignoring the codeword boundary effects)

$$\sum_{1 \leq m \leq L_i} e_{i,m} \cdot h_{j-L_i+m}^T \neq 0$$

where  $e_{i,m}$  is the  $m$ th element of the error event  $e_i$ , and  $h_j$  is the  $j$ th column of  $H$ .

## Advanced Algorithms and Algorithms under Investigation

This subsection gives a brief overview of less complex procedures for searching the trellis. It is intended to give background information that can be used in future development if it shows up that NPVA detectors and postprocessing are not capable of coping with ever-increasing storage densities and longer PRs needed for them. In such cases, a resort has to be made to some sort of reduced complexity suboptimal algorithms, whose performance is close to optimal. Explained algorithms are not yet implemented in commercial products, but all of them are a natural extension of already described procedures for searching the trellis.

### Other Breadth-First Algorithms

#### *The M-Algorithm*

Since most survivors in the VA usually possess much smaller metrics than does the best one, all the states or nodes kept are not equally important. It is intuitively reasonable to assume that unpromising survivors can be omitted with a negligible probability of discarding the best one. The  $M$ -algorithm [10] is one such modification of the VA; all candidates are stored in a single list and the best  $M \leq q^M$  survivors are selected from the list in each cycle. The steps of the  $M$ -algorithm are:

1. *Initial condition:* Initialize the list with the root node and set its metric to zero.
2. *Path extension:* Extend all the paths of length  $l$  by one branch and classify all contenders (paths of length  $l + 1$ ) into the list. If two or more paths enter the same state keep the best one.
3. *Path selection:* From the remaining paths find the best  $M$  candidates and delete the others. If  $l = L + M$ , take the only survivor and transfer its corresponding information sequence to the output (terminated case, otherwise use the sliding window variation). Otherwise, go to step 2.

Defined in this way, the  $M$ -algorithm performs trellis search, while, when the state comparison in step 2 is omitted, it searches the tree, saving much time on comparisons but with slightly increased error probability. When applied to decoding/detecting infinitely long sequences, it is usual that comparisons performed in step 2 are substituted with the so-called ambiguity check [10] and a release of one decoded branch. In each step this algorithm performs  $M$  node computations, and employing any sifting procedure (since the paths need not be sorted) perform  $\sim Mq$  metric comparisons. If performed, the Viterbi-type discarding of step 2 requests  $\sim M^2q$  state and metric comparisons. This type of discarding can be performed with  $\sim M \log_2 M$  comparisons (or even linearly) but than additional storage must be provided. The space complexity grows linearly with the information frame length  $L$  and parameter  $M$ .

#### *The Generalized Viterbi Algorithm*

In contrast to the VA, which is a multiple-list single survivor algorithm, the  $M$ -algorithm is a single-list multiple-survivor algorithm. The natural generalization to a multiple-list multiple-survivor algorithm was first suggested by Hashimoto [39]. Since all the lists are not equally important, this algorithm, originally called the generalized Viterbi algorithm (GVA), utilizes only  $q^{M_1}$  lists (labels), where  $M_1 \leq M$ . In each list from all  $q^{M-M_1+1}$  paths, it retains the best  $M_1$  candidates. The algorithm can be described as follows:

1. *Initial condition:* Initialize the starting label with the root node and set its metric to zero.
2. *Path extension:* Extend all the paths from each label by one branch and classify all successors into the appropriate label. If two or more paths enter the same state keep the best one.
3. *Path selection:* From the remaining paths of each label find the best  $M_1$  and delete the others. If  $l = L + M$ , take the only survivor and transfer its information sequence to the output (for the terminated case, otherwise use the sliding window variant). Go to step 2.

When  $M_1 = M$ , and  $M_1 = 1$ , the GVA reduces to the VA, and for  $M_1 = 0$ ,  $M_1 = M$  it reduces to the  $M$ -algorithm. Like the  $M$ -algorithm, GVA in each step performs  $M_1$  node computations per label, and employing any sifting procedure  $\sim M_1 q$  metric comparisons. If performed, the Viterbi-type discarding of step 2 requests  $\sim M_1^2 q$  or less state and metric comparisons per label.

## Metric-First Algorithms

Metric-first and depth-first sequential detection is a name for a class of algorithms that compare paths according to their Fano metric (one against another or with some thresholds) and on that basis decide which node to extend next, which to delete in metric first procedures or whether to proceed with current branch or go back. These algorithms generally extend fewer nodes for the same performance, but have increased sorting requirements.

Sequential detecting algorithms have a variable computation characteristic that results in large buffering requirements, and occasionally large detecting delays and/or incomplete detecting of the received sequence. Sometimes, when almost error-free communication is required or when retransmission is possible, this variable detecting effort can be an advantage. For example, when a detector encounters an excessive number of computations, it indicates that a frame is possibly very corrupted meaning that the communication is insufficiently reliable and can ultimately cause error patterns in detected sequence. In such situations the detector gives up detecting and simply requests retransmission. These situations are commonly called erasures, and detecting incomplete. A complete decoder such as the Viterbi detector/decoder would be forced to make an estimate, which may be wrong. The probability of buffer overflow is several orders of magnitude larger than the probability of incorrect decision when the decoder operates close to the so-called (computational) cutoff rate.

The performance of sequential detecting has traditionally been evaluated in terms of three characteristics: the probability of sequence error, the probability of failure (erasure), and the Pareto exponent associated with detecting effort.

### The Stack Algorithm

The stack (or ZJ) algorithm was for the first time suggested by Zigangirov [1] and later independently by Jelinek [1]. As its name indicates, the algorithm contains a stack (in fact, a list) of already searched paths of varying lengths, ordered according to their metric values. At each step, the path at the top of the stack (the best one) is replaced by its  $q$  successors extended by one branch, with correspondingly augmented metrics. The check whether two or more paths are in the same state is not performed. This algorithm has its numerous variations and we first consider the basic version that is closest to Zigangirov's:

1. *Initial condition:* Initialize the stack with the root node and set its Fano metric to zero (or some large positive number to avoid arithmetic with negative numbers, but low enough to avoid overflow).
2. *Path extension:* Extend the best path from the stack by one branch, delete it, sort all successors, and then merge them with the stack so that it is ordered according to the path metrics.
3. *Path selection:* Retain the best  $Z$  paths according to the Fano metric. If the top path has the length  $l = L + M$  branches, transfer its information sequence to the output (terminated case; otherwise, a sliding window version has to be used); otherwise, go to step 2.

It is obvious that this algorithm does not consider path merging since the probability that the paths of the same depth and the same state can be stored in the stack simultaneously is rather small. Nonetheless, some authors [1] propose that a following action should be added to the step 2: If any of the  $2^K$  new paths merges with a path already in the stack, keep the one with the higher metric.

The stack algorithm is based on the nonselection principle [17]. If the paths  $\mathbf{i}'_{[0,L+M]}$  and  $\mathbf{i}''_{[0,L+M]}$  through the tree diverge at depth  $j$  and

$$\min \{ u(\mathbf{x}'_{[0,l]}, \mathbf{y}_{[0,l]}) \}_{l \in [j+1, L+M]} > \min \{ u(\mathbf{x}''_{[0,l]}, \mathbf{y}_{[0,l]}) \}_{l \in [j+1, L+M]}$$

then  $\mathbf{i}''_{[0,L+M]}$  cannot be the path at the top of the stack when the stack algorithm stops.

The computational complexity of the stack algorithm is almost unaffected by the code memory length, but well depends on the channel performance. Its computational complexity is a random variable and so is its stack size if not otherwise limited. The upper bound on the computational complexity is given by

$$P[C \geq \eta] < A\eta^{-\rho} \quad 0 < \rho \leq 1$$

where  $A$  is a constant and  $\rho$  is a power that goes to unity as  $R \rightarrow R_0 < R_C$  and to zero as  $R \rightarrow R_C$ , where  $R_C$  is the channel capacity and  $R_0$  is the cutoff rate [17]. The distribution described previously is called a Pareto distribution, and  $\rho$  a Pareto exponent.

Omit depth-first algorithms, such as the Fano algorithm, from consideration here, because they are not interesting for PR detection.

### **Bidirectional Algorithms**

Another class of algorithms are those that exploit bidirectional decoding/detection which is designed for framed data. Almost all unidirectional procedures have their bidirectional supplements since Forney showed that detecting could start from the end of the sequence provided that the trellis contains a tail. All bidirectional algorithms employ two searches from both sides. The forward search is performed using the original trellis code while the backward one employs the reverse code. The reverse trellis code is obtained from the original code by time reversing.

#### ***The Bidirectional Stack Algorithm***

This algorithm was independently proposed by Šenk and Radivojac [40–42], and Kallel and Li [38]. It uses two stacks F (forward) and B (backward, that uses the reverse code). It is based on notions of tunnel, tentative decision, and discarding criteria. The tunnel is the unique sequence  $T$  ( $0 \leq T \leq M$ ) branches long that connect two states in the trellis. The tentative decision is the sequence  $L + M$  branches long that connects the known initial and terminal trellis states (direction does not matter here) that has the highest accumulated metric of all the sequences of that length analyzed so far. A set of discarding criteria is a means to tell beforehand whether a partly explored path is likely to be a part of the finally detected sequence or not (in the latter case, the path may be eliminated from the subsequent search). Because the version [30] of the algorithm is a special case of [41] (when  $T = 0$ ), the steps of the BSA are:

1. Place the root node into F stack, and the unique terminal node into B stack, associating them the zero metric. Make one of these stacks active (e.g., the F one).
2. Choose the node with the largest metric (of length, say,  $l$ ) from the active stack and eliminate it from the stack. Link it via a tunnel (if a tunnel is possible, i.e., if the states match) to each of the existing paths in the other stack whose lengths are  $L - l + M - T$  (if a tunnel is  $M$  branches long, then the best path from the active stack can be linked to all the paths from the other stack whose lengths are  $L - l$ ). The total length of the paths obtained in this way is  $l + T + (L - l + M - T) = L + M$  branches. Store the best one into the tentative decision register. If there is already a path in the register, keep the better. Prune the paths remaining in both stacks according to any of discarding criteria used. If both stacks are emptied in this way, output the tentative decision as the decoder's final decision and terminate the algorithm. Otherwise, evaluate the metrics of all the successors of the processed path, and eliminate all of them that do not conform to the discarding criteria established.
3. Sort the remaining successors into the active stack according to their metrics applying any tie-breaking rule. Change the active stack and return to step 2.

After each tentative decision, several discarding criteria can be applied. In [41] Šenk and Radivojac applied the nonselection principle and the maximum-likelihood criterion described. The algorithm can be easily performed by two processors, although one node computation lasts longer than in the original stack algorithm. Simulations showed [41] that the Pareto exponent of the BSA in the moment when the final decision is obtained is approximately doubled, but the discarding criteria used did not provide the

termination at the same time. However, the algorithm may be stopped after the assigned time for its execution has elapsed, and in such cases the erasure probability is substantially decreased.

Two additional bidirectional algorithms are worth mentioning. Belzile and Haccoun [11] investigated the bidirectional  $M$ -algorithm. Since the  $M$ -algorithm inherently avoids erasures by its breadth-first nature it still suffers from the correct path loss in its unidirectional version. Another interesting algorithm is the bidirectional multiple stack algorithm [23]. It additionally decreases the erasure probability of the MSA without compromising the error performance.

## Algorithms That Minimize Symbol Error Rate

### The BCJR Algorithm

So far, the algorithms that minimize the error probability of information sequence  $\mathbf{i}_{[0,L+M]}$  have been considered. They accomplish it by searching for the “closest” sequence  $\mathbf{x}_{[0,L+M]}$  according to the metric chosen; however, these algorithms do not necessarily minimize the symbol or bit error rate. The BCJR algorithm was independently proposed by Bahl et al. [25] and McAdam et al. [27], but a more detailed description can be found in [25]. The algorithm is a special case of a more general problem of estimating the *a posteriori* probabilities of the states and transitions of a Markov source observed through a DMC, i.e., the probabilities

$$P\left[s_l = i, s_{l+1} = j | \mathbf{y}_{[0,L+M]}\right] \quad (34.41)$$

or equivalently

$$\sigma_l(i, j) = P\left[s_l = i, s_{l+1} = j, \mathbf{y}_{[0,L+M]}\right] \quad (34.42)$$

where  $s_l$  is the state of the trellis during  $l$ th branch. Introducing

$$\begin{aligned} \alpha_l(i) &= P'[s_l = i, \mathbf{y}_{[0,l]}] \\ \beta_l(i) &= P[\mathbf{y}_{[l,L+M]} | s_l = i] \\ \gamma_l(i, j) &= P[s_{l+1} = j, y_l | s_l = i] \end{aligned} \quad (34.43)$$

it is not hard [25] to show that

$$\begin{aligned} \alpha_{l+1}(j) &= \sum_{i=0}^{2^{KM}-1} \alpha_l(i) \gamma_l(i, j) \\ \beta_l(j) &= \sum_{i=0}^{2^{KM}-1} \beta_{l+1}(i) \gamma_l(i, j) \\ \gamma_l(i, j) &= \sum_{x_l} P[x_l | s_l = i, s_{l+1} = j] P[S_{l+1} = j | s_l = i] P[y_l | x_l] \\ \sigma_l(i, j) &= \alpha_l(i) \gamma_l(i, j) \beta_l(j) \end{aligned} \quad (34.44)$$

The known initial conditions are  $\alpha_0(i=0) = 1$ ,  $\alpha_0(i \neq 0) = 0$ ,  $\beta_{L+M}(i=0) = 1$ ,  $\beta_{L+M}(i \neq 0) = 0$ . Assuming that the initial and terminating state in the trellis is the all zero state, the steps of the algorithm are

1. Initialize  $\alpha_0(i)$ , and  $\beta_{L+M}(i)$ , for  $i = 0, 1, \dots, q^M - 1$  according to (34.44).
2. As soon as  $y_l$  is received, compute  $\alpha_l(i)$  and  $\gamma_l(i, j)$ . Store  $\alpha_l(i, j)$  for all  $l$  and  $i$ .
3. When the complete sequence  $\mathbf{y}_{[0,L+M]}$  is received, compute  $\beta_l(i)$  using (34.44), and immediately the probabilities  $\sigma_l(i, j)$ . Group those  $\sigma_l(i, j)$  that have the same information sequence  $\mathbf{i}_p$ , and choose the largest as the decoder estimate.

The basic problem with the algorithm is that it requires both large storage and great number of computations. All the values of  $\alpha_l(i)$  must be stored, which requires almost  $(L + M)q^{KM}$  memory locations. The number of multiplications required for determining the  $\alpha_l(i)$  and  $\beta_l(i)$  for each  $l$  is  $q^{M+1}$ , and there are  $q^M$  additions of  $q^K$  numbers as well. The computation of  $\gamma_l(i, j)$  is not costly and can be accomplished by a table look-up. Finally, the computation of all  $\sigma_l(i, j)$  requires  $q^{(M+1)+1}$  multiplications for each  $l$ , and  $q - 1$  comparisons in choosing the largest  $i_l$ . Consequently, this is an algorithm with exponential complexity and in practice can be applied only when  $M$  and  $L$  are short. Nevertheless, it is used for iterative decoding where such requirements can be fulfilled, such as for turbo codes. The main advantage of the algorithm in such cases is its ability to estimate  $P[s_{l+1} = j | s_l = i]$ , which for the possible transitions equals  $q^{-1}$  only in the first iteration.

### The SOVA Algorithm

The soft-output Viterbi algorithm (SOVA) [15] is a modification of the VA that was designed with the aim of estimating the reliability of every detected bit by the VA. It is applicable only when  $q = 2$ . The VA is used here in its sliding window form, which detects infinite sequences with delay of  $\delta$  branches from the last received one.

The reliability (or soft value) of a bit  $i$ ,  $L(i)$ , is defined as  $L(i) = \ln(P[i = 0]/P[i = 1])$ . The SOVA further extends the third step in order to obtain this value, in the following way:

*Path selection (extension):* Let  $i_{[0, l-j]}^{(j)}$ ,  $j \in \{0, 1, \dots, \delta - 1\}$  be the information sequences which merge with  $i'_{[0, l]}$  at depths  $l - j$ . Their paths have earlier been discarded due to their lower metrics. Let the corresponding metric differences in the merging states be denoted  $\Delta_j$ , and let  $J = \{j: i'_{l-\delta}^{(j)} \neq i'_{l-\delta}\}$ . Then  $L(i'_{l-\delta}) \approx (1 - 2i'_{l-\delta}) \min_{j \in J} \Delta_j$ .

Because VA detecting metric can be modified in a way to take into account a priori knowledge of input bit probabilities, the SOVA can be used as soft input-soft output (SISO) block in turbo decoding schemes.

## 34.7 An Introduction to Error-Correcting Codes

---

*Mario Blaum*

### Introduction

When digital data are transmitted over a noisy channel, it is important to have a mechanism allowing recovery against a limited number of errors. Normally, a user string of 0s and 1s, called bits, is encoded by adding a number of redundant bits to it. When the receiver attempts to reconstruct the original message sent, it starts by examining a possibly corrupted version of the encoded message, and then makes a decision. This process is called the decoding.

The set of all possible encoded messages is called an error-correcting code. The field was started in the late 1940s by the work of Shannon and Hamming, and since then thousands of papers on the subject have been published. Several very good books are available to touch different aspects of error-correcting codes, for instance, [1,3–5,7,8], to mention just a few.

The purpose of Section 34.7 is to give an introduction to the theory and practice of error-correcting codes. In particular, it will be shown how to encode and decode the most widely used codes, Reed–Solomon (RS) codes.

In principle, it will be assumed that the information symbols are bits, i.e., 0s and 1s. The set  $\{0, 1\}$  has a field structure under the exclusive-OR ( $\oplus$ ) and product operations. This field is denoted as  $GF(2)$ , which means Galois field of order 2.

Roughly, two types of error-correcting codes are used—codes of block type and codes of convolutional type. Codes of block type encode a fixed number of bits, say  $k$  bits, into a vector of length  $n$ . So, the information string is divided into blocks of  $k$  bits each. Convolutional codes take the string of information bits globally and slide a window over the data in order to encode. A certain amount of memory is needed by the encoder; however, Section 3.7 concentrates on block codes only. For more on convolutional codes, see [3,8].

As stated previously,  $k$  information bits are encoded into  $n$  bits. So, we have a 1-1 function  $f$ ,

$$f: GF(2)^k \rightarrow GF(2)^n$$

The function  $f$  defines the encoding procedure. The set of  $2^k$  encoded vectors of length  $n$  is called a code of length  $n$  and dimension  $k$ , and we denote it as an  $[n, k]$  code. Codewords are called the elements of the code while words are called the vectors of length  $n$  in general. The ratio  $k/n$  is called the *rate* of the code.

The error-correcting power of a code is characterized by a parameter called the minimum (Hamming) distance of the code. Formally:

**Definition 1** Given two vectors of length  $n$ , say  $\underline{a}$  and  $\underline{b}$ , we call the Hamming distance between  $\underline{a}$  and  $\underline{b}$  the number of coordinates in which they differ (notation,  $d_H(\underline{a}, \underline{b})$ ).

Given a code  $\mathcal{C}$  of length  $n$  and dimension  $k$ , let

$$d = \min \{d_H(\underline{a}, \underline{b}) : \underline{a} \neq \underline{b}, \underline{a}, \underline{b} \in \mathcal{C}\}$$

$d$  is the minimum (Hamming) distance of the code  $\mathcal{C}$ , and  $\mathcal{C}$  is an  $[n, k, d]$  code.

It is easy to verify that  $d_H(\underline{a}, \underline{b})$  satisfies the axioms of distance, i.e.,

1.  $d_H(\underline{a}, \underline{b}) = d_H(\underline{b}, \underline{a})$ ,
2.  $d_H(\underline{a}, \underline{b}) = 0$  if and only if  $\underline{a} = \underline{b}$ ,
3.  $d_H(\underline{a}, \underline{c}) \leq d_H(\underline{a}, \underline{b}) + d_H(\underline{b}, \underline{c})$ .

A sphere of radius  $r$  and center  $\underline{a}$  are called the set of vectors that are at distance at most  $r$  from  $\underline{a}$ . The relation between  $d$  and the maximum number of errors that code  $\mathcal{C}$  can correct is given by the following lemma:

**Lemma 1** The maximum number of errors that an  $[n, k, d]$  code can correct is  $\lfloor (d-1)/2 \rfloor$ , where  $\lfloor x \rfloor$  denotes the largest integer smaller than or equal to  $x$ .

*Proof:* Assume that vector  $\underline{a}$  was transmitted but a possibly corrupted version of  $\underline{a}$ , for instance  $\underline{r}$ , was received. Moreover, assume that no more than  $\lfloor (d-1)/2 \rfloor$  errors have occurred.

Consider the set of  $2^k$  spheres of radius  $\lfloor (d-1)/2 \rfloor$  whose centers are the codewords in  $\mathcal{C}$ . By the definition of  $d$ , all these spheres are disjoint. Hence,  $\underline{r}$  belongs to one and only one sphere: the one whose center is codeword  $\underline{a}$ . So, the decoder looks for the sphere in which  $\underline{r}$  belongs, and outputs the center of that sphere as the decoded vector. Subsequently, whenever the number of errors is at most  $\lfloor (d-1)/2 \rfloor$ , this procedure will give the correct answer.

Moreover,  $\lfloor (d-1)/2 \rfloor$  is the maximum number of errors that the code can correct. For let  $\underline{a}, \underline{b} \in \mathcal{C}$  such that  $d_H(\underline{a}, \underline{b}) = d$ . Let  $\underline{u}$  be a vector such that  $d_H(\underline{a}, \underline{u}) = 1 + \lfloor (d-1)/2 \rfloor$  and  $d_H(\underline{b}, \underline{u}) = d - 1 - \lfloor (d-1)/2 \rfloor$ . We easily verify that  $d_H(\underline{b}, \underline{u}) \leq d_H(\underline{a}, \underline{u})$ , so, if  $\underline{a}$  is transmitted and  $\underline{u}$  is received (i.e.,  $1 + \lfloor (d-1)/2 \rfloor$  errors have occurred), the decoder cannot decide that the transmitted codeword was  $\underline{a}$ , since codeword  $\underline{b}$  is at least as close to  $\underline{u}$  as  $\underline{a}$ .  $\square$

**Example 1** Consider the following 1-1 relationship between  $GF(2)^2$  and  $GF(2)^5$  defining the encoding:

$$\begin{aligned} 00 &\leftrightarrow 00000 \\ 10 &\leftrightarrow 00111 \\ 01 &\leftrightarrow 11100 \\ 11 &\leftrightarrow 11011 \end{aligned}$$

The four vectors in  $GF(2)^5$  constitute a  $[5, 2, 3]$  code  $\mathcal{C}$ . From Lemma 1,  $\mathcal{C}$  can correct one error.

For instance, assume that we receive the vector  $\underline{r} = 10100$ . The decoder looks into the four spheres of radius 1 (each sphere has six elements) around each codeword, finding that  $\underline{r}$  belongs in the sphere with center 11100. If we look at the table above, the final output of the decoder is the information block 01.  $\square$

Example 1 shows that the decoder has to make at most 24 checks before arriving to the correct decision. When large codes are involved, as is the case in applications, this decoding procedure is not practical, since it amounts to an exhaustive search over a huge set of vectors.

One of the goals in the theory of error-correcting codes is finding codes with rate and minimum distance as large as possible. The possibility of finding codes with the right properties is often limited by bounds that constrain the choice of parameters  $n$ ,  $k$ , and  $d$ . Some of these bounds are given in the next subsection.

Let us point out that error-correcting codes can be used for detection instead of correction of errors. The simplest example of an error-detecting code is given by a parity code: a parity is added to a string of bits in such a way that the total number of bits is even (a more sophisticated way of saying this is that the sum modulo 2 of the bits has to be 0). For example, 0100 is encoded as 01001. If an error occurs, or, more generally, an odd number of errors, these errors will be detected since the sum modulo 2 of the

received bits will be 1. Notice that two errors will be undetected. In general, if an  $[n, k, d]$  code is used for detection only, the decoder checks whether the received vector is in the code or not. If it is not, then errors are detected. It is easy to see that an  $[n, k, d]$  code can detect up to  $d - 1$  errors. Also, one can choose to correct less than  $\lfloor (d - 1)/2 \rfloor$  errors, say  $s$  errors, by taking disjoint spheres of radius  $s$  around codewords, and using the remaining capacity to detect errors. In other words, correct up to  $s$  errors or detect up to  $s + t$  errors when more than  $s$  errors occur.

Another application of error-correcting codes is in erasure correction. An erased bit is a bit that cannot be read, so the decoder has to decide if it was a 0 or a 1. An erasure is normally denoted with the symbol “?”. For instance, 01?0 means that we cannot read the third symbol. Obviously, it is easier to correct erasures than to correct errors, since in the case of erasures we already know the location, we simply have to find what the erased bit was. It is not hard to prove that an  $[n, k, d]$  code can correct upto  $d - 1$  erasures. One may also want to simultaneously correct errors and erasures. In fact, a code  $\mathcal{C}$  with minimum distance  $d$  can correct  $s$  errors together with  $t$  erasures whenever  $2s + t \leq d - 1$ .

### Linear Codes

The previous subsection showed that a binary code of length  $n$  is a subset of  $GF(2)^n$ . Notice that, being  $GF(2)$  a field,  $GF(2)^n$  has a structure of vector space over  $GF(2)$ . A code  $\mathcal{C}$  is linear if it is a subspace of  $GF(2)^n$ , i.e.

1.  $\underline{0} \in \mathcal{C}$ ,
2.  $\forall \underline{a}, \underline{b} \in \mathcal{C}, \underline{a} \oplus \underline{b} \in \mathcal{C}$ .

The symbol  $\underline{0}$  denotes the all-zero vector. In general, vectors will be denoted with underlined letters, otherwise letters denote scalars.

In the first subsection, it was assumed that a code had  $2^k$  elements,  $k$  being the dimension; however, a code of length  $n$  can be defined as any subset of  $GF(2)^n$ .

Many interesting combinatorial questions can be asked regarding nonlinear codes. Probably, the most important question is the following: Given the length  $n$  and the minimum distance  $d$ , what is the maximum number of codewords that a code can have? For more about nonlinear codes, the reader is referred to [4]. From now on, we assume that all codes are linear. Linear codes are in general easier to encode and decode than their nonlinear counterparts; hence they are more suitable for implementation in applications.

In order to find the minimum distance of a linear code, it is enough to find its minimum *weight*. The (Hamming) weight of a vector  $\underline{u}$  is the distance between  $\underline{u}$  and the zero vector. In other words, the weight of  $\underline{u}$ , denoted  $w_H(\underline{u})$ , is the number of nonzero coordinates of the vector  $\underline{u}$ . The minimum weight of a code is the minimum between all the weights of the nonzero codewords. The proof of the following lemma is left as an exercise.

**Lemma 2** Let  $\mathcal{C}$  be a linear  $[n, k, d]$  code. Then, the minimum distance and the minimum weight of  $\mathcal{C}$  are the same.

Next, two important matrices are introduced that define a linear error-correcting code. A code  $\mathcal{C}$  is now a subspace, so the dimension  $k$  of  $\mathcal{C}$  is the cardinality of a basis of  $\mathcal{C}$ . Consider then an  $[n, k, d]$  code  $\mathcal{C}$ . A  $k \times n$  matrix  $G$  is a *generator* matrix of a code  $\mathcal{C}$  if the rows of  $G$  are a basis of  $\mathcal{C}$ . Given a generator matrix, the encoding process is simple. Explicitly, let  $\underline{u}$  be an information vector of length  $k$  and  $G$  a  $k \times n$  generator matrix, then  $\underline{u}$  is encoded into the  $n$ -vector  $\underline{v}$  given by

$$\underline{v} = \underline{u}G \tag{34.45}$$

**Example 2** Let  $G$  be the  $2 \times 5$  matrix

$$G = \begin{pmatrix} 0 & 0 & 1 & 1 & 1 \\ 1 & 1 & 1 & 0 & 0 \end{pmatrix}$$

It is easy to see that  $G$  is a generator matrix of the  $[5, 2, 3]$  code described in Example 1. □

Notice that, although a code may have many generator matrices, the encoding depends on the particular matrix chosen, according to Eq. (34.45). We say that  $G$  is a *systematic* generator matrix if  $G$  can be written as

$$G = (I_k | V) \quad (34.46)$$

where  $I_k$  is the  $k \times k$  identity matrix and  $V$  is a  $k \times (n - k)$  matrix. A systematic generator matrix has the following advantage: given an information vector  $\underline{u}$  of length  $k$ , the encoding given by Eq. (34.45) outputs a codeword  $(\underline{u}, \underline{w})$ , where  $\underline{w}$  has length  $n - k$ . In other words, a systematic encoder adds  $n - k$  redundant bits to the  $k$  information bits, so information and redundancy are clearly separated. This also simplifies the decoding process, since, after decoding, the redundant bits are simply discarded. For that reason, most encoders used in applications are systematic.

A permutation of the columns of a generator matrix gives a new generator matrix defining a new code. The codewords of the new code are permutations of the coordinates of the codewords of the original code, therefore, the two codes are *equivalent*. Notice that equivalent codes have the same distance properties, so their error correcting capabilities are exactly the same.

By permuting the columns of the generator matrix in Example 2, the following generator matrix  $G'$  is obtained:

$$G' = \begin{pmatrix} 1 & 0 & 0 & 1 & 1 \\ 0 & 1 & 1 & 1 & 0 \end{pmatrix} \quad (34.47)$$

The matrix  $G'$  defines a systematic encoder for a code that is equivalent to the one given in Example 1. For instance, the information vector 11 is encoded into 11 101.

The second important matrix related to a code is the so-called *parity check* matrix. An  $(n - k) \times n$  matrix  $H$  is a parity check matrix of an  $[n, k]$  code  $\mathcal{C}$  if and only if, for any  $\underline{c} \in \mathcal{C}$ ,

$$\underline{c}H^T = \underline{0} \quad (34.48)$$

where  $H^T$  denotes the transpose of matrix  $H$  and  $\underline{0}$  is a zero vector of length  $n - k$ . The parity check matrix  $H$  is in systematic form if

$$H = (W | I_{n-k}) \quad (34.49)$$

where  $I_{n-k}$  is the  $(n - k) \times (n - k)$  identity matrix and  $W$  is an  $(n - k) \times k$  matrix.

Given a systematic generator matrix  $G$  of a code  $\mathcal{C}$ , it is easy to find the systematic parity check matrix  $H$  (and conversely). Explicitly, if  $G$  is given by Eq. (34.46),  $H$  is given by

$$H = (V^T | I_{n-k}) \quad (34.50)$$

The proof of this fact is left to the reader.

For example, the systematic parity check matrix of the code, whose systematic generator matrix is given by Eq. (34.47), is

$$H = \begin{pmatrix} 0 & 1 & 1 & 0 & 0 \\ 1 & 1 & 0 & 1 & 0 \\ 1 & 0 & 0 & 0 & 1 \end{pmatrix} \quad (34.51)$$

Next is an important property of parity check matrices.

**Lemma 3** Let  $\mathcal{C}$  be a linear  $[n, k, d]$  code and  $H$  a parity check matrix. Then, any  $d - 1$  columns of  $H$  are linearly independent.

*Proof:* Numerate the columns of  $H$  from 0 to  $n - 1$ . Assume that columns  $0 \leq i_1 < i_2 < \dots < i_m \leq n - 1$  are linearly dependent, where  $m \leq d - 1$ . Without loss of generality, assume that the sum of these columns is equal to the column vector zero. Let  $\underline{y}$  be a vector of length  $n$  whose nonzero coordinates are in locations  $i_1, i_2, \dots, i_m$ . Then,

$$\underline{y}H^T = \underline{0}$$

hence  $\underline{y}$  is in  $\mathcal{C}$ . But  $\underline{y}$  has weight  $m \leq d - 1$ , contradicting the fact that  $\mathcal{C}$  has minimum distance  $d$ .  $\square$

**Corollary 1** For any linear  $[n, k, d]$  code, the minimum distance  $d$  is the smallest number  $m$  such that there is a subset of  $m$  linearly dependent columns.

*Proof:* It follows immediately from Lemma 3.  $\square$

**Corollary 2 (Singleton Bound)** For any linear  $[n, k, d]$  code,

$$d \leq n - k + 1$$

*Proof:* Notice that, because  $H$  is an  $(n - k) \times n$  matrix, any  $n - k + 1$  columns are going to be linearly dependent, so if  $d > n - k + 1$  we would contradict Corollary 1.  $\square$

Codes meeting the Singleton bound are called maximum distance separable (MDS). In fact, except for trivial cases, binary codes are not MDS. In order to obtain MDS codes, we will define codes over larger fields, like the so-called Reed Solomon codes, to be described later in the chapter.

A second bound is also given relating the redundancy and the minimum distance of an  $[n, k, d]$  code the so-called Hamming or volume bound. Let us denote by  $V(r)$  the number of elements in a sphere of radius  $r$  whose center is an element in  $GF(2)^n$ . It is easy to verify that

$$V(r) = \sum_{i=0}^r \binom{n}{i} \quad (34.52)$$

We then have:

**Lemma 4 (Hamming bound)** Let  $\mathcal{C}$  be a linear  $[n, k, d]$  code, then

$$n - k \geq \log_2 V(\lfloor (d - 1)/2 \rfloor) \quad (34.53)$$

*Proof:* Notice that the  $2^k$  spheres with the  $2^k$  codewords as centers and radius  $\lfloor (d - 1)/2 \rfloor$  are disjoint. The total number of vectors contained in these spheres is  $2^k V(\lfloor (d - 1)/2 \rfloor)$ . This number has to be smaller than or equal to the total number of vectors in the space, i.e.,

$$2^n \geq 2^k V(\lfloor (d - 1)/2 \rfloor) \quad (34.54)$$

Inequality (34.53) follows immediately from Eq. (34.54).  $\square$

A *perfect* code is a code for which inequality Eq. (34.53) is in effect equality. Geometrically, a perfect code is a code for which the  $2^k$  spheres of radius  $\lfloor (d - 1)/2 \rfloor$  and the codewords as centers cover the whole space.

Not many perfect codes exist. In the binary case, the only nontrivial linear perfect codes are the Hamming codes (to be presented in the next subsection) and the [23,12,7] Golay code. For details, the reader is referred to [4].

## Syndrome Decoding, Hamming Codes, and Capacity of the Channel

This subsection studies the first important family of codes, the so-called Hamming codes. As will be shown, Hamming codes can correct up to one error.

Let  $\mathcal{C}$  be an  $[n, k, d]$  code with parity check matrix  $H$ . Let  $\underline{u}$  be a transmitted vector and  $\underline{r}$  a possibly corrupted received version of  $\underline{u}$ . We say that the syndrome of  $\underline{r}$  is the vector  $\underline{s}$  of length  $n - k$  given by

$$\underline{s} = \underline{r}H^T \quad (34.55)$$

Notice that, if no errors occurred, the syndrome of  $\underline{r}$  is the zero vector. The syndrome, however, tells us more than a vector being in the code or not. For instance, as before, that  $\underline{u}$  was transmitted and  $\underline{r}$  was received, where  $\underline{r} = \underline{u} \oplus \underline{e}$ ,  $\underline{e}$  an error vector. Notice that,

$$\underline{s} = \underline{r}H^T = (\underline{u} \oplus \underline{e})H^T = \underline{u}H^T \oplus \underline{e}H^T = \underline{e}H^T$$

because  $\underline{u}$  is in  $\mathcal{C}$ . Hence, the syndrome does not depend on the received vector but on the error vector. In the next lemma, we show that to every error vector of weight  $\leq (d - 1)/2$  corresponds a unique syndrome.

**Lemma 5** Let  $\mathcal{C}$  be a linear  $[n, k, d]$  code with parity check matrix  $H$ . Then, there is a 1-1 correspondence between errors of weight  $\leq (d - 1)/2$  and syndromes.

*Proof:* Let  $\underline{e}_1$  and  $\underline{e}_2$  be two distinct error vectors of weight  $\leq (d - 1)/2$  with syndromes  $\underline{s}_1 = \underline{e}_1H^T$  and  $\underline{s}_2 = \underline{e}_2H^T$ . If  $\underline{s}_1 = \underline{s}_2$ , then  $\underline{s} = (\underline{e}_1 \oplus \underline{e}_2)H^T = \underline{s}_1 \oplus \underline{s}_2 = \underline{0}$ , hence  $\underline{e}_1 \oplus \underline{e}_2 \in \mathcal{C}$ . But  $\underline{e}_1 \oplus \underline{e}_2$  has weight  $\leq d - 1$ , a contradiction.  $\square$

Lemma 5 gives the key for a decoding method that is more efficient than exhaustive search. We can construct a table with the 1-1 correspondence between syndromes and error patterns of weight  $\leq (d - 1)/2$  and decode by look-up table. In other words, given a received vector, we first find its syndrome and then we look in the table to which error pattern it corresponds. Once we obtain the error pattern, we add it to the received vector, retrieving the original information. This procedure may be efficient for small codes, but it is still too complex for large codes.

**Example 3** Consider the code whose parity matrix  $H$  is given by (34.51). We have seen that this is a [5, 2, 3] code. We have six error patterns of weight  $\leq 1$ . The 1-1 correspondence between these error patterns and the syndromes can be immediately verified to be

$$\begin{aligned} 00000 &\leftrightarrow 000 \\ 10000 &\leftrightarrow 011 \\ 01000 &\leftrightarrow 110 \\ 00100 &\leftrightarrow 100 \\ 00010 &\leftrightarrow 010 \\ 00001 &\leftrightarrow 001 \end{aligned}$$

For instance, assume that we receive the vector  $\underline{r} = 10111$ . We obtain the syndrome  $\underline{s} = \underline{r}H^T = 100$ . Looking at the table above, we see that this syndrome corresponds to the error pattern  $\underline{e} = 00100$ . Adding this error pattern to the received vector, we conclude that the transmitted vector was  $\underline{r} \oplus \underline{e} = 10011$ .  $\square$

Given a number  $r$  of redundant bits, we say that a  $[2^r - 1, 2^r - r - 1, 3]$  Hamming code is a code having an  $r \times (2^r - 1)$  parity check matrix  $H$  such that its columns are all the different nonzero vectors of length  $r$ .

A Hamming code has minimum distance 3. This follows from its definition and Corollary 1. Notice that any two columns in  $H$ , being different, are linearly independent. Also, if we take any two different columns and their sum, these three columns are linearly dependent, proving our assertion.

A natural way of writing the columns of  $H$  in a Hamming code, is by considering them as binary numbers on base 2 in increasing order. This means, the first column is 1 on base 2, the second column is 2, and so on. The last column is  $2^r - 1$  on base 2, i.e.,  $(1, 1, \dots, 1)^T$ . This parity check matrix, although nonsystematic, makes the decoding very simple.

In effect, let  $\underline{r}$  be a received vector such that  $\underline{r} = \underline{v} \oplus \underline{e}$ , where  $\underline{v}$  was the transmitted codeword and  $\underline{e}$  is an error vector of weight 1. Then, the syndrome is  $\underline{s} = \underline{e}H^T$ , which gives the column corresponding to the location in error. This column, as a number on base 2, tells us exactly where the error has occurred, so the received vector can be corrected.

**Example 4** Consider the  $[7, 4, 3]$  Hamming code  $\mathcal{C}$  with parity check matrix

$$H = \begin{pmatrix} 0 & 0 & 0 & 1 & 1 & 1 & 1 \\ 0 & 1 & 1 & 0 & 0 & 1 & 1 \\ 1 & 0 & 1 & 0 & 1 & 0 & 1 \end{pmatrix} \quad (34.56)$$

Assume that vector  $\underline{r} = 1100101$  is received. The syndrome is  $\underline{s} = \underline{r}H^T = 001$ , which is the binary representation of the number 1. Hence, the first location is in error, so the decoder estimates that the transmitted vector was  $\underline{v} = 0100101$ .  $\square$

We can obtain 1-error correcting codes of any length simply by shortening a Hamming code. This procedure works as follows: assume that we want to encode  $k$  information bits into a 1-error correcting code. Let  $r$  be the smallest number such that  $k \leq 2^r - r - 1$ . Let  $H$  be the parity check matrix of a  $[2^r - 1, 2^r - r - 1, 3]$  Hamming code. Then construct a matrix  $H'$  by eliminating some  $2^r - r - 1 - k$  columns from  $H$ . The code whose parity check matrix is  $H'$  is a  $[k + r, k, d]$  code with  $d \geq 3$ , hence it can correct one error. We call it a shortened Hamming code. For instance, the  $[5, 2, 3]$  code whose parity check matrix is given by (34.51) is a shortened Hamming code.

In general, if  $H$  is the parity check matrix of a code  $\mathcal{C}$ ,  $H'$  is a matrix obtained by eliminating a certain number of columns from  $H$  and  $\mathcal{C}'$  is the code with parity check matrix  $H'$ , we say that  $\mathcal{C}'$  is obtained by shortening  $\mathcal{C}$ .

A  $[2^r - 1, 2^r - r - 1, 3]$  Hamming code can be extended to a  $[2^r, 2^r - r - 1, 4]$  Hamming code by adding to each codeword a parity bit, that is, the exclusive-OR of the first  $2^r - 1$  bits. The new code is called an extended Hamming code.

So far, we have not talked about probabilities of errors. Assume that we have a binary symmetric channel (BSC), i.e., the probability of a 1 becoming a 0 or of a 0 becoming a 1 is  $p < .5$ . Let  $P_{\text{err}}$  be the probability of error after decoding using a code, i.e., the output of the decoder does not correspond to the originally transmitted information vector. A fundamental question is the following: given a BSC with bit error probability  $p$ , does it exist a code of high rate that can arbitrarily lower  $P_{\text{err}}$ ? The answer, due to Shannon, is yes, provided that the code has rate below a parameter called the capacity of the channel, as defined next.

**Definition 2** Given a BSC with probability of bit error  $p$ , we say that the capacity of the channel is

$$C(p) = 1 + p \log_2 p + (1 - p) \log_2(1 - p) \quad (34.57)$$

**Theorem 1 (Shannon)** For any  $\epsilon > 0$  and  $R < C(p)$ , there is an  $[n, k]$  binary code of rate  $k/n \geq R$  with  $P_{\text{err}} < \epsilon$ .

For a proof of Theorem 1 and some of its generalizations, the reader is referred to [5], or even to Shannon's original paper [6].

Theorem 1 has enormous theoretical importance. It shows that reliable communication is not limited in the presence of noise, only the rate of communication is. For instance, if  $p = .01$ , the capacity of the channel is  $C(.01) = .9192$ . Hence, there are codes of rate  $\geq .9$  with  $P_{\text{err}}$  arbitrarily small. It also tells us not to look for codes with rate  $.92$  making  $P_{\text{err}}$  arbitrarily small.

The proof of Theorem 1, though, is based on probabilistic methods and the assumption of arbitrarily large values of  $n$ . In practical applications,  $n$  cannot be too large. The theorem does not tell us how to construct efficient codes, it just asserts their existence. Moreover, when we construct codes, we want them to have efficient encoding and decoding algorithms. In the last few years, coding methods approaching the Shannon limit have been developed, the so-called *turbo codes*. Although great progress has been made towards practical implementations of turbo codes, in applications like magnetic recording their complexity is still a problem. A description of turbo codes is beyond the scope of this introduction. The reader is referred to [2].

## Codes over Bytes and Finite Fields

So far, we have considered linear codes over bits. Next we want to introduce codes over larger symbols, mainly over bytes. A byte of size  $v$  is a vector of  $v$  bits. Mathematically, bytes are vectors in  $GF(2)^v$ . Typical cases in magnetic and optical recording involve 8-bit bytes. Most of the general results in the previous sections for codes over bits easily extend to codes over bytes. It is trivial to multiply bits, but we need a method to multiply bytes. To this end, the theory of finite fields has been developed. Next we give a brief introduction to the theory of finite fields. For a more complete treatment, the reader is referred to chapter 4 of [4].

We know how to add two binary vectors, we simply exclusive-OR them componentwise. What we need now is a rule that allows us to multiply bytes while preserving associative, distributive, and multiplicative inverse properties, i.e., a product that gives to the set of bytes of length  $v$  the structure of a field. To this end, we will define a multiplication between vectors that satisfies the associative and commutative properties, it has a 1 element, each nonzero element is invertible and it is distributive with respect to the sum operation.

Recall the definition of the ring  $Z_m$  of integers modulo  $m$ :  $Z_m$  is the set  $\{0, 1, 2, \dots, m-1\}$ , with a sum and product of any two elements defined as the residue of dividing by  $m$  the usual sum or product. It is not difficult to prove that  $Z_m$  is a field if and only if  $m$  is a prime number. Using this analogy, we will give to  $(GF(2))^v$  the structure of a field.

Consider the vector space  $(GF(2))^v$  over the field  $GF(2)$ . We can view each vector as a polynomial of degree  $\leq v-1$  as follows: the vector  $\underline{a} = (a_0, a_1, \dots, a_{v-1})$  corresponds to the polynomial  $a(\alpha) = a_0 + a_1\alpha + \dots + a_{v-1}\alpha^{v-1}$ .

The goal is to give to  $(GF(2))^v$  the structure of a field. We will denote such a field by  $GF(2^v)$ . The sum in  $GF(2^v)$  is the usual sum of vectors in  $(GF(2))^v$ . We need now to define a product.

Let  $f(x)$  be an irreducible polynomial (i.e., it cannot be expressed as the product of two polynomials of smaller degree) of degree  $v$  whose coefficients are in  $GF(2)$ . Let  $a(\alpha)$  and  $b(\alpha)$  be two elements of  $GF(2^v)$ . We define the product between  $a(\alpha)$  and  $b(\alpha)$  in  $GF(2^v)$  as the unique polynomial  $c(\alpha)$  of degree  $\leq v-1$  such that  $c(\alpha)$  is the residue of dividing the product  $a(\alpha)b(\alpha)$  by  $f(\alpha)$  (the notation  $g(x) \equiv h(x) \pmod{f(x)}$  means that  $g(x)$  and  $h(x)$  have the same residue after dividing by  $f(x)$ , i.e.,  $g(\alpha) = h(\alpha)$ ).

The sum and product operations defined above give to  $GF(2^v)$  a field structure. The role of the irreducible polynomial  $f(x)$  is the same as the prime number  $m$  when  $Z_m$  is a field. In effect, the proof that  $GF(2^v)$  is a field when  $m$  is irreducible is essentially the same as the proof that  $Z_m$  is a field when  $m$  is prime. From now on, we denote the elements in  $GF(2^v)$  as polynomials in  $\alpha$  of degree  $\leq v-1$  with coefficients in  $GF(2)$ . Given two polynomials  $a(x)$  and  $b(x)$  with coefficients in  $GF(2)$ ,  $a(\alpha)b(\alpha)$  denotes

**TABLE 34.3** The Finite Field  $GF(8)$  Generated by  $1 + x + x^3$

Vector	Polynomial	Power of $\alpha$	Logarithm
000	0	0	$-\infty$
100	1	1	0
010	$\alpha$	$\alpha$	1
001	$\alpha^2$	$\alpha^2$	2
110	$1 + \alpha$	$\alpha^3$	3
011	$\alpha + \alpha^2$	$\alpha^4$	4
111	$1 + \alpha + \alpha^2$	$\alpha^5$	5
101	$1 + \alpha^2$	$\alpha^6$	6

the product in  $GF(2^v)$ , while  $a(x)b(x)$  denotes the regular product of polynomials. Notice that, for the irreducible polynomial  $f(x)$ , in particular,  $f(\alpha) = 0$  in  $GF(2^v)$ , since  $f(x) \equiv 0 \pmod{f(x)}$ .

So, the set  $GF(2^v)$  given by the irreducible polynomial  $f(x)$  of degree  $v$  is the set of polynomials of degree  $\leq v - 1$ , where the sum operation is the regular sum of polynomials, and the product operation is the residue of dividing by  $f(x)$  the regular product of two polynomials.

**Example 5** Construct the field  $GF(8)$ . Consider the polynomials of degree  $\leq 2$  over  $GF(2)$ . Let  $f(x) = 1 + x + x^3$ . Since  $f(x)$  has no roots over  $GF(2)$ , it is irreducible (notice that such an assessment can be made only for polynomials of degree 2 or 3). Let us consider the powers of  $\alpha$  modulo  $f(\alpha)$ . Notice that  $\alpha^3 = \alpha^3 + f(\alpha) = 1 + \alpha$ . Also,  $\alpha^4 = \alpha\alpha^3 = \alpha(1 + \alpha) = \alpha + \alpha^2$ . Similarly, we obtain  $\alpha^5 = \alpha\alpha^4 = \alpha(\alpha + \alpha^2) = \alpha^2 + \alpha^3 = 1 + \alpha + \alpha^2$ , and  $\alpha^6 = \alpha\alpha^5 = \alpha + \alpha^2 + \alpha^3 = 1 + \alpha^2$ . Finally,  $\alpha^7 = \alpha\alpha^6 = \alpha + \alpha^3 = 1$ .

Note that every nonzero element in  $GF(8)$  can be obtained as a power of the element  $\alpha$ . In this case,  $\alpha$  is called a *primitive* element and the irreducible polynomial  $f(x)$  that defines the field is called a *primitive* polynomial. It can be proven that it is always the case that the multiplicative group of a finite field is cyclic, so there is always a primitive element.

A convenient description of  $GF(8)$  is given in Table 34.3. The first column in Table 34.3 describes the element of the field in vector form, the second one as a polynomial in  $\alpha$  of degree  $\leq 2$ , the third one as a power of  $\alpha$ , and the last one gives the logarithm (also called Zech logarithm): it simply indicates the corresponding power of  $\alpha$ . As a convention, we denote by  $-\infty$  the logarithm corresponding to the element 0.  $\square$

It is often convenient to express the elements in a finite field as powers of  $\alpha$ ; when we multiply two of them, we obtain a new power of  $\alpha$  whose exponent is the sum of the two exponents modulo  $2^v - 1$ . Explicitly, if  $i$  and  $j$  are the logarithms of two elements in  $GF(2^v)$ , then their product has logarithm  $i + j \pmod{2^v - 1}$ . In the example above, if we want to multiply the vectors 101 and 111, we first look at their logarithms. They are 6 and 5, respectively, so the logarithm of the product is  $6 + 5 \pmod{7} = 4$ , corresponding to the vector 011.

In order to add vectors, the best way is to express them in vector form and add coordinate to coordinate in the usual way.

## Cyclic Codes

In the same way we defined codes over the binary field  $GF(2)$ , we can define codes over any finite field  $GF(2^v)$ . Now, a code of length  $n$  is a subset of  $(GF(2^v))^n$ , but since we study only linear codes, we require that such a subset is a vector space. Similarly, we define the minimum (Hamming) distance and the generator and parity check matrices of a code. Some properties of binary linear codes, like the Singleton bound, remain the same in the general case. Others, such as the Hamming bound, require some modifications.

Consider a linear code  $\mathcal{C}$  over  $GF(2^v)$  of length  $n$ . We say that  $\mathcal{C}$  is cyclic if, for any codeword  $(c_0, c_1, \dots, c_{n-1}) \in \mathcal{C}$ , then  $(c_{n-1}, c_0, c_1, \dots, c_{n-2}) \in \mathcal{C}$ . In other words, the code is invariant under cyclic shifts to the right.

If we write the codewords as polynomials of degree  $< n$  with coefficients in  $GF(2^v)$ , this is equivalent to say that if  $c(x) \in \mathcal{C}$ , then  $xc(x) \bmod (x^n - 1) \in \mathcal{C}$ . Hence, if  $c(x) \in \mathcal{C}$ , then, given any polynomial  $w(x)$ , the residue of dividing  $w(x)c(x)$  by  $x^n - 1$  is in  $\mathcal{C}$ . In particular, if the degree of  $w(x)c(x)$  is smaller than  $n$ , then  $w(x)c(x) \in \mathcal{C}$ .

From now on, we write the elements of a cyclic code  $\mathcal{C}$  as polynomials modulo  $x^n - 1$ .

**Theorem 2**  $\mathcal{C}$  is an  $[n, k]$  cyclic code over  $GF(2^v)$  if and only if there is a (monic) polynomial  $g(x)$  of degree  $n - k$  such that  $g(x)$  divides  $x^n - 1$  and each  $c(x) \in \mathcal{C}$  is a multiple of  $g(x)$ , i.e.,  $c(x) \in \mathcal{C}$  if and only if  $c(x) = w(x)g(x)$ ,  $\deg(w) < k$ . We call  $g(x)$  a generator polynomial of  $\mathcal{C}$ .

*Proof:* Let  $g(x)$  be a monic (i.e., lead coefficient is 1) polynomial in  $\mathcal{C}$  such that  $g(x)$  has minimal degree. If  $\deg(g) = 0$  (i.e.,  $g = 1$ ), then  $\mathcal{C}$  is the whole space  $(GF(2^v))^n$ , so assume  $\deg(g) \geq 1$ . Let  $c(x)$  be any element in  $\mathcal{C}$ . We can write  $c(x) = w(x)g(x) + r(x)$ , where  $\deg(r) < \deg(g)$ . Because  $\deg(wg) < n$ ,  $g \in \mathcal{C}$  and  $\mathcal{C}$  is cyclic, in particular,  $w(x)g(x) \in \mathcal{C}$ . Hence,  $r(x) = c(x) - w(x)g(x) \in \mathcal{C}$ . If  $r \neq 0$ , we would contradict the fact that  $g(x)$  has minimal degree, hence,  $r = 0$  and  $c(x)$  is a multiple of  $g(x)$ .

Similarly, we can prove that  $g(x)$  divides  $x^n - 1$ . Let  $x^n - 1 = h(x)g(x) + r(x)$ , where  $\deg(r) < \deg(g)$ . In particular,  $h(x)g(x) \equiv -r(x) \pmod{(x^n - 1)}$ , hence,  $r(x) \in \mathcal{C}$ . Since  $g(x)$  has minimal degree,  $r = 0$ , so  $g(x)$  divides  $x^n - 1$ .

Conversely, assume that every element in  $\mathcal{C}$  is a multiple of  $g(x)$  and  $g$  divides  $x^n - 1$ . It is immediate that the code is linear and that it has dimension  $k$ . Let  $c(x) \in \mathcal{C}$ , hence,  $c(x) = w(x)g(x)$  with  $\deg(w) < k$ . Also, since  $g(x)$  divides  $x^n - 1$ ,  $x^n - 1 = h(x)g(x)$ . Assume that  $c(x) = c_0 + c_1x + c_2x^2 + \dots + c_{n-1}x^{n-1}$ , then,  $xc(x) \equiv c_{n-1} + c_0x + \dots + c_{n-2}x^{n-1} \pmod{x^n - 1}$ . We have to prove that  $c_{n-1} + c_0x + \dots + c_{n-2}x^{n-1} = q(x)g(x)$ , where  $q(x)$  has degree  $\leq k - 1$ . Notice that

$$\begin{aligned} c_{n-1} + c_0x + \dots + c_{n-2}x^{n-1} &= c_{n-1} + c_0x + \dots + c_{n-2}x^{n-1} + c_{n-1}x^n - c_{n-1}x^n \\ &= c_0x + \dots + c_{n-2}x^{n-1} + c_{n-1}x^n - c_{n-1}(x^n - 1) \\ &= xc(x) - c_{n-1}(x^n - 1) \\ &= xw(x)g(x) - c_{n-1}h(x)g(x) \\ &= (xw(x) - c_{n-1}h(x))g(x) \end{aligned}$$

proving that the element is in the code. □

**Theorem 2** gives a method to find all cyclic codes of length  $n$ , simply take all the (monic) factors of  $x^n - 1$ . Each one of them is the generator polynomial of a cyclic code.

**Example 6** Consider the  $[7, 4]$  cyclic code over  $GF(2)$  generated by  $g(x) = 1 + x + x^3$ . We can verify that  $x^7 - 1 = g(x)(1 + x)(1 + x^2 + x^3)$ ; hence,  $g(x)$  indeed generates a cyclic code.

In order to encode an information polynomial over  $GF(2)$  of degree  $\leq 3$  into a codeword, we multiply it by  $g(x)$ .

Say that we want to encode  $\underline{u} = (1, 0, 0, 1)$ , which in polynomial form is  $u(x) = 1 + x^3$ . Hence, the encoding gives  $c(x) = u(x)g(x) = 1 + x + x^4 + x^6$ . In vector form, this gives  $\underline{c} = (1 \ 1 \ 0 \ 0 \ 1 \ 0 \ 1)$ .

It can be easily verified that the  $[7, 4]$  code given in this example has minimum distance 3 and is equivalent to the Hamming code of Example 4. In other words, the codewords of the code given in this example are permutations of the codewords of the  $[7, 4, 3]$  Hamming code given in Example 4. □

The encoding method of a cyclic code with generator polynomial  $g$  is then very simple: we multiply the information polynomial by  $g$ . However, this encoder is not systematic. A systematic encoder of a cyclic code is given by the following algorithm:

**Algorithm 1 (Systematic Encoding Algorithm for Cyclic Codes)** Let  $\mathcal{C}$  be a cyclic  $[n, k]$  code over  $GF(2^v)$  with generator polynomial  $g(x)$ . Let  $u(x)$  be an information polynomial,  $\deg(u) < k$ . Let  $r(x)$  be the residue of dividing  $x^{n-k}u(x)$  by  $g(x)$ . Then  $u(x)$  is encoded into the polynomial  $c(x) = u(x) - x^k r(x)$ .

We leave as an exercise proving that Algorithm 2 produces indeed a codeword in  $\mathcal{C}$ .

**Example 7** Consider the  $[7,4]$  cyclic code over  $GF(2)$  of Example 6. If we want to encode systematically the information vector  $\underline{u} = (1, 0, 0, 1)$  (or  $u(x) = 1 + x^3$ ), we have to obtain first the residue of dividing  $x^3 u(x) = x^3 + x^6$  by  $g(x)$ . This residue is  $r(x) = x + x^2$ . Hence, the output of the encoder is  $c(x) = u(x) - x^4 r(x) = 1 + x^3 + x^5 + x^6$ . In vector form, this gives  $\underline{c} = (1\ 0\ 0\ 1\ 0\ 1\ 1)$ .  $\square$

## Reed Solomon Codes

Throughout this subsection, the codes considered are over the field  $GF(2^v)$ . Let  $\alpha$  be a primitive element in  $GF(2^v)$ , i.e.,  $\alpha^{2^v-1} = 1$ ,  $\alpha^i \neq 1$  for  $i \neq 0 \pmod{2^v-1}$ . A Reed–Solomon (RS) code of length  $n = 2^v - 1$  and dimension  $k$  is the cyclic code generated by

$$g(x) = (x - \alpha)(x - \alpha^2) \cdots (x - \alpha^{n-k-1})(x - \alpha^{n-k})$$

Each  $\alpha^i$  is a root of unity,  $x - \alpha^i$  divides  $x^n - 1$ , hence,  $g$  divides  $x^n - 1$  and the code is cyclic.

An equivalent way of describing a RS code is as the set of polynomials over  $GF(2^v)$  of degree  $\leq n - 1$  with roots  $\alpha, \alpha^2, \dots, \alpha^{n-k}$ , i.e.,  $F$  is in the code if and only if  $\deg(F) \leq n - 1$  and  $F(\alpha) = F(\alpha^2) = \dots = F(\alpha^{n-k}) = 0$ .

This property allows us to find a parity check matrix for a RS code. Say that  $F(x) = F_0 + F_1 x + \dots + F_{n-1} x^{n-1}$  is in the code. Let  $1 \leq i \leq n - k$ , then

$$F(\alpha^i) = F_0 + F_1 \alpha^i + \dots + F_{n-1} \alpha^{i(n-1)} = 0 \quad (34.58)$$

In other words, Eq. (34.58) tells us that codeword  $(F_0, F_1, \dots, F_{n-1})$  is orthogonal to the vectors  $(1, \alpha^i, \alpha^{2i}, \dots, \alpha^{i(n-1)})$ ,  $1 \leq i \leq n - k$ . Hence, these vectors are the rows of a parity check matrix for the RS code. A parity check matrix of an  $[n, k]$  RS code over  $GF(2^v)$  is then

$$H = \begin{pmatrix} 1 & \alpha & \alpha^2 & \dots & \alpha^{n-1} \\ 1 & \alpha^2 & \alpha^4 & \dots & \alpha^{2(n-1)} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 1 & \alpha^{n-k} & \alpha^{(n-k)2} & \dots & \alpha^{(n-k)(n-1)} \end{pmatrix} \quad (34.59)$$

In order to show that  $H$  is in fact a parity check matrix, we need to prove that the rows of  $H$  are linearly independent. The next lemma provides an even stronger result.

**Lemma 6** Any set of  $n - k$  columns in matrix  $H$  defined by Eq. (34.59) is linearly independent.

*Proof:* Take a set  $0 \leq i_1 < i_2 < \dots < i_{n-k} \leq n - 1$  of columns of  $H$ . Denote  $\alpha^{i_j}$  by  $\alpha_j$ ,  $1 \leq j \leq n - k$ . Columns  $i_1, i_2, \dots, i_{n-k}$  are linearly independent if and only if their determinant is nonzero, i.e., if and only if

$$\det \begin{pmatrix} \alpha_1 & \alpha_2 & \dots & \alpha_{n-k} \\ (\alpha_1)^2 & (\alpha_2)^2 & \dots & (\alpha_{n-k})^2 \\ \vdots & \vdots & \ddots & \vdots \\ (\alpha_1)^{n-k} & (\alpha_2)^{n-k} & \dots & (\alpha_{n-k})^{n-k} \end{pmatrix} \neq 0 \quad (34.60)$$

Let

$$V(\alpha_1, \alpha_2, \dots, \alpha_{n-k}) = \det \begin{pmatrix} 1 & 1 & \dots & 1 \\ \alpha_1 & \alpha_2 & \dots & \alpha_{n-k} \\ \vdots & \vdots & \ddots & \vdots \\ (\alpha_1)^{n-k-1} & (\alpha_2)^{n-k-1} & \dots & (\alpha_{n-k})^{n-k-1} \end{pmatrix} \quad (34.61)$$

We call the determinant  $V(\alpha_1, \alpha_2, \dots, \alpha_{n-k})$  a *Vandermonde determinant*—it is the determinant of an  $(n-k) \times (n-k)$  matrix whose rows are the powers of vector  $\alpha_1, \alpha_2, \dots, \alpha_{n-k}$ , the powers running from 0 to  $n-k-1$ . By properties of determinants, if we consider the determinant in (34.60), we have

$$\det \begin{pmatrix} \alpha_1 & \alpha_2 & \dots & \alpha_{n-k} \\ (\alpha_1)^2 & (\alpha_2)^2 & \dots & (\alpha_{n-k})^2 \\ \vdots & \vdots & \ddots & \vdots \\ (\alpha_1)^{n-k} & (\alpha_2)^{n-k} & \dots & (\alpha_{n-k})^{n-k} \end{pmatrix} = \alpha_1 \alpha_2 \dots \alpha_{n-k} V(\alpha_1, \alpha_2, \dots, \alpha_{n-k}) \quad (34.62)$$

Hence, by Eqs. (34.60) and (34.62), since the  $\alpha_j$ 's are nonzero, it is enough to prove that  $V(\alpha_1, \alpha_2, \dots, \alpha_{n-k}) \neq 0$ . A well-known result in literature states that

$$V(\alpha_1, \alpha_2, \dots, \alpha_{n-k}) = \prod_{1 \leq i < j \leq n-k} (\alpha_j - \alpha_i) \quad (34.63)$$

Because  $\alpha$  is a primitive element in  $GF(2^v)$ , its powers  $\alpha^l$ ,  $0 \leq l \leq n-1$  are distinct. In particular, the  $\alpha_i$ 's,  $1 \leq i \leq n-k$  are distinct; hence, the product in the right-hand side of (34.63) is nonzero.  $\square$

**Corollary 3** An  $[n, k]$  RS code has minimum distance  $d = n - k + 1$ .

*Proof:* Let  $H$  be the parity check matrix of the RS code defined by (34.59). Notice that, since any  $n-k$  columns in  $H$  are linearly independent,  $d \geq n - k + 1$  by Lemma 3.

On the other hand,  $d \leq n - k + 1$  by the Singleton bound (Corollary 2), so we have equality.  $\square$

Because RS codes meet the Singleton bound with equality, they are MDS (see second subsection).

**Example 8** Consider the  $[7,3,5]$  RS code over  $GF(8)$ , where  $GF(8)$  is given by Table 34.3. The generator polynomial is

$$g(x) = (x - \alpha)(x - \alpha^2)(x - \alpha^3)(x - \alpha^4) = \alpha^3 + \alpha x + x^2 + \alpha^3 x^3 + x^4$$

Assume that we want to encode the 3-byte vector  $u = 101\ 001\ 111$ . Writing the bytes as powers of  $\alpha$  in polynomial form, we have  $u(x) = \alpha^6 + \alpha^2 x + \alpha^5 x^2$ .

In order to encode  $u(x)$ , we perform

$$u(x)g(x) = \alpha^2 + \alpha^4 x + \alpha^2 x^2 + \alpha^6 x^3 + \alpha^6 x^4 + \alpha^4 x^5 + \alpha^5 x^6$$

In vector form the output of the encoder is given by 001 011 001 101 101 011 111. If we encode  $u(x)$  using a systematic encoder (Algorithm 1), the output of the encoder is

$$\alpha^6 + \alpha^2 x + \alpha^5 x^2 + \alpha^6 x^3 + \alpha^5 x^4 + \alpha^4 x^5 + \alpha^4 x^6$$

which, in vector form, is 101 001 111 101 111 011 011.  $\square$

Next we make some observations:

- The definition given above for an  $[n, k]$  RS code states that  $F(x)$  is in the code if and only if it has as roots the powers  $\alpha, \alpha^2, \dots, \alpha^{n-k}$  of a primitive element  $\alpha$ ; however, it is enough to state that  $F$  has as roots a set of *consecutive* powers of  $\alpha$ , say,  $\alpha^m, \alpha^{m+1}, \dots, \alpha^{m+n-k-1}$ , where  $0 \leq m \leq n-1$ . Although our definition (i.e.,  $m = 1$ ) gives the most usual setting for RS codes, often engineering reasons may determine different choices of  $m$ . It is easy to verify that with the more general definition of RS codes, the minimum distance remains  $n - k + 1$ .
- Given an  $[n, k]$  RS code, there is an easy way to shorten it and obtain an  $[n-l, k-l]$  code for  $l < k$ . In effect, if we have only  $k-l$  bytes of information, we add  $l$  zeros in order to obtain an information string of length  $k$ . We then find the  $n-k$  redundant bytes using a systematic encoder. When writing, of course, the  $l$  zeros are not written, so we have an  $[n-l, k-l]$  code, called a shortened RS code. It is immediately verified that shortened RS codes are also MDS.

We have defined RS codes, proven that they are MDS and showed how to encode them systematically. The next step, to be developed in the next sections, is decoding them.

## Decoding of RS Codes: The Key Equation

Through this subsection,  $\mathcal{C}$  denotes an  $[n, k]$  RS code (unless otherwise stated). Assume that a codeword  $F(x) = \sum_{i=0}^{n-1} F_i x^i$  in  $\mathcal{C}$  is transmitted and a word  $R(x) = \sum_{i=0}^{n-1} R_i x^i$  is received; hence,  $F$  and  $R$  are related by an error vector  $E(x) = \sum_{i=0}^{n-1} E_i x^i$ , where  $R(x) = F(x) + E(x)$ . The decoder will attempt to find  $E(x)$ .

Let us start by computing the syndromes. For  $1 \leq j \leq n-k$ , we have

$$S_j = R(\alpha^j) = \sum_{i=0}^{n-1} R_i \alpha^{ij} = \sum_{i=0}^{n-1} E_i \alpha^{ij} \quad (34.64)$$

Before proceeding further, consider Eq. (34.64) in a particular case.

Take the  $[n, n-2]$  1-byte correcting RS code. In this case, we have two syndromes  $S_1$  and  $S_2$ . So, if exactly one error has occurred, say in location  $i$ , by Eq. (34.64), we have

$$S_1 = E_i \alpha^i \quad \text{and} \quad S_2 = E_i \alpha^{2i} \quad (34.65)$$

Hence,  $\alpha^i = S_2/S_1$ , so we can determine the location  $i$  in error. The error value is  $E_i = (S_1)^2/S_2$ .

**Example 9** Consider the  $[7,5,3]$  RS code over  $GF(8)$ , where  $GF(8)$  is given by [Table 34.3](#).

Assume that we want to decode the received vector

$$r = (101 \ 001 \ 110 \ 001 \ 011 \ 010 \ 100)$$

which, in polynomial form, is

$$R(x) = \alpha^6 + \alpha^2 x + \alpha^3 x^2 + \alpha^2 x^3 + \alpha^4 x^4 + \alpha x^5 + x^6$$

Evaluating the syndromes, we obtain  $S_1 = R(\alpha) = \alpha^2$  and  $S_2 = R(\alpha^2) = \alpha^4$ . Thus,  $S_2/S_1 = \alpha^2$ , meaning that location 2 is in error. The error value is  $E_2 = (S_1)^2/S_2 = (\alpha^2)^2/\alpha^4 = 1$ , which, in vector form, is 100. The output of the decoder is then

$$c = (101 \ 001 \ 010 \ 001 \ 011 \ 010 \ 100)$$

which, in polynomial form, is

$$C(x) = \alpha^6 + \alpha^2 x + \alpha x^2 + \alpha^2 x^3 + \alpha^4 x^4 + \alpha x^5 + x^6 \quad \square$$

Let  $\mathcal{E}$  be the subset of  $\{0, 1, \dots, n-1\}$  of locations in error, i.e.,  $\mathcal{E} = \{l : E_l \neq 0\}$ . With this notation, (34.64) becomes

$$S_j = \sum_{i \in \mathcal{E}} E_i \alpha^{ij}, \quad 1 \leq j \leq n-k \quad (34.66)$$

The decoder will find the error set  $\mathcal{E}$  and the error values  $E_i$  when the error correcting capability of the code is not exceeded. Thus, if  $s$  is the number of errors and  $2s \leq n-k$ , the system of equations given by (34.66) has a unique solution. However, this is a nonlinear system, and it is very difficult to solve it directly.

In order to find the set of locations in error  $\mathcal{E}$  and the corresponding error values  $\{E_i : i \in \mathcal{E}\}$ , we define two polynomials. The first one is called the *error locator polynomial*, which is the polynomial that has roots the values  $\alpha^{-i}$ , where  $i \in \mathcal{E}$ . We denote this polynomial by  $\sigma(x)$ . Explicitly,

$$\sigma(x) = \prod_{i \in \mathcal{E}} (x - \alpha^{-i}) \quad (34.67)$$

If somehow we can determine the polynomial  $\sigma(x)$ , by finding its roots, we can obtain the set  $\mathcal{E}$  of locations in error. Once we have the set of locations in error, we need to find the errors themselves. We define a second polynomial, called the *error evaluator polynomial* and denoted by  $\omega(x)$ , as follows:

$$\omega(x) = \prod_{i \in \mathcal{E}} E_i \prod_{\substack{l \in \mathcal{E} \\ l \neq i}} (x - \alpha^{-l}) \quad (34.68)$$

An  $[n, k]$  RS code corrects at most  $(n-k)/2$  errors, so we assume that  $|\mathcal{E}| = \deg(\sigma) \leq (n-k)/2$ . Notice also that  $\deg(\omega) \leq |\mathcal{E}| - 1$ , since  $\omega$  is a sum of polynomials of degree  $|\mathcal{E}| - 1$ . Given a polynomial  $f(x) = a_0 + a_1 x + \dots + a_m x^m$  with coefficients over a field  $F$ , we define the (formal) derivative of  $F$ , denoted  $f'$ , as the polynomial

$$f'(x) = a_1 + 2a_2 x + \dots + m a_m x^{m-1}$$

For instance, over  $GF(8)$ , if  $f(x) = \alpha + \alpha^3 x + \alpha^4 x^2$ , then  $f'(x) = \alpha^3$  (since  $2 = 0$  over  $GF(2)$ ). The formal derivative has several properties similar to the traditional derivative, like the derivative of a product,  $(fg)' = f'g + fg'$ . Back to the error locator and error evaluator polynomials, we have the following relationship between the two:

$$E_i = \frac{\omega(\alpha^{-i})}{\sigma'(\alpha^{-i})} \quad (34.69)$$

Let us prove some of these facts in the following lemma:

**Lemma 7** The polynomials  $\sigma(x)$  and  $\omega(x)$  are relatively prime, and the error values  $E_i$  are given by (34.69).

*Proof:* In order to show that  $\sigma(x)$  and  $\omega(x)$  are relatively prime, it is enough to observe that they have no roots in common. In effect, if  $\alpha^{-j}$  is a root of  $\sigma(x)$ , then  $j \in \mathcal{E}$ . By Eq. (34.68),

$$\omega(\alpha^{-j}) = \sum_{i \in \mathcal{E}} E_i \prod_{\substack{l \in \mathcal{E} \\ l \neq i}} (\alpha^{-j} - \alpha^{-l}), = E_j \prod_{\substack{l \in \mathcal{E} \\ l \neq j}} (\alpha^{-j} - \alpha^{-l}) \neq 0 \quad (34.70)$$

Hence,  $\sigma(x)$  and  $\omega(x)$  are relatively prime.

In order to prove (34.69), notice that

$$\sigma'(x) = \sum_{i \in \mathcal{E}} \prod_{\substack{i \in \mathcal{E} \\ l \neq i}} (x - \alpha^{-l})$$

hence,

$$\sigma'(\alpha^{-j}) = \prod_{\substack{i \in \mathcal{E} \\ l \neq i}} (\alpha^{-j} - \alpha^{-l}) \quad (34.71)$$

By Eqs. (34.70) and (34.71), Eq. (34.69) follows.  $\square$

The decoding methods of RS codes are based on finding the error locator and the error evaluator polynomials. By finding the roots of the error locator polynomial, we determine the locations in error, while the errors themselves can be found using Eq. (34.69). We will establish a relationship between  $\sigma(x)$  and  $\omega(x)$ , but first we need to define a third polynomial, the syndrome polynomial. We define the syndrome polynomial as the polynomial of degree  $\leq n - k - 1$  where coefficients are the  $n - k$  syndromes. Explicitly,

$$S(x) = S_1 + S_2x + S_3x^2 + \cdots + S_{n-k}x^{n-k-1} = \sum_{j=0}^{n-k-1} S_{j+1}x^j \quad (34.72)$$

Notice that  $R(x)$  is in  $\mathcal{C}$  if and only if  $S(x) = 0$ .

The next theorem gives the so-called *key equation* for decoding RS codes, and it establishes a fundamental relationship between  $\sigma(x)$ ,  $\omega(x)$ , and  $S(x)$ .

**Theorem 3** There is a polynomial  $\mu(x)$  such that the error locator, the error evaluator and the syndrome polynomials verify the following equation:

$$\sigma(x)S(x) = -\omega(x) + \mu(x)x^{n-k} \quad (34.73)$$

Alternatively, Eq. (34.73) can be written as a congruence as follows:

$$\sigma(x)S(x) = -\omega(x) \pmod{x^{n-k}} \quad (34.74)$$

*Proof:* By Eqs. (34.72) and (34.66), we have

$$\begin{aligned} S(x) &= \sum_{\substack{j=0 \\ n-k-1}}^{n-k-1} S_{j+1}x^j \\ &= \sum_{j=0}^{n-k-1} \left( \sum_{i \in \mathcal{E}} E_i \alpha^{i(j+1)} \right) x^j \\ &= \sum_{i \in \mathcal{E}} E_i \alpha^i \sum_{j=0}^{n-k-1} (\alpha^i x)^j \\ &= \sum_{i \in \mathcal{E}} E_i \alpha^i \frac{(\alpha^i x)^{n-k} - 1}{\alpha^i x - 1} \\ &= \sum_{i \in \mathcal{E}} E_i \frac{(\alpha^i x)^{n-k} - 1}{x - \alpha^{-i}} \end{aligned} \quad (34.75)$$

because  $\sum_{l=0}^m a^l = (a^{m+1} - 1)/(a - 1)$  for  $a \neq 1$ . Multiplying both sides of (34.75) by  $\sigma(x)$ , where  $\sigma(x)$  is given by Eq. (34.67), we obtain

$$\begin{aligned}\sigma(x)S(x) &= \sum_{i \in \mathcal{E}} E_i ((\alpha^i x)^{n-k} - 1) \prod_{\substack{l \in \mathcal{E} \\ l \neq i}} (x - \alpha^{-l}) \\ &= - \sum_{i \in \mathcal{E}} E_i \prod_{\substack{l \in \mathcal{E} \\ l \neq i}} (x - \alpha^{-l}) + \left( \sum_{i \in \mathcal{E}} E_i \alpha^{i(n-k)} \prod_{\substack{l \in \mathcal{E} \\ l \neq i}} (x - \alpha^{-l}) \right) x^{n-k} \\ &= -\omega(x) + \mu(x)x^{n-k}\end{aligned}$$

because  $\omega(x)$  is given by (34.68). This completes the proof.  $\square$

The decoding methods for RS codes concentrate on solving the key equation. In the next section we describe an efficient decoder based on Euclid's algorithm for polynomials. Another efficient decoding algorithm is the so-called Berlekamp–Massey decoding algorithm [1].

## Decoding RS Codes with Euclid's Algorithm

Given two polynomials or integers  $A$  and  $B$ , Euclid's algorithm provides a recursive procedure to find the greatest common divisor  $C$  between  $A$  and  $B$ , denoted  $C = \gcd(A, B)$ . Moreover, the algorithm also finds two polynomials or integers  $S$  and  $T$  such that  $C = SA + TB$ .

Recall that we want to solve the key equation

$$\mu(x)x^{n-k} + \sigma(x)S(x) = -\omega(x)$$

In the recursion,  $x^{n-k}$  will play the role of  $A$  and  $S(x)$  the role of  $B$ ;  $\sigma(x)$  and  $\omega(x)$  will be obtained at a certain step of the recursion.

Let us describe Euclid's algorithm for integers or polynomials. Consider  $A$  and  $B$  such that  $A \geq B$  if they are integers, and  $\deg(A) \geq \deg(B)$  if they are polynomials. We start from the initial conditions  $r_{-1} = A$  and  $r_0 = B$ .

We perform a recursion in steps  $1, 2, \dots, i, \dots$ . At step  $i$  of the recursion, we obtain  $r_i$  as the residue of dividing  $r_{i-2}$  by  $r_{i-1}$ , i.e.,  $r_{i-2} = q_i r_{i-1} + r_i$  where  $r_i < r_{i-1}$  for integers and  $\deg(r_i) < \deg(r_{i-1})$  for polynomials. The recursion is then given by

$$r_i = r_{i-2} - q_i r_{i-1} \quad (34.76)$$

We also obtain values  $s_i$  and  $t_i$  such that  $r_i = s_i A + t_i B$ . Hence, the same recursion is valid for  $s_i$  and  $t_i$  as well:

$$s_i = s_{i-2} - q_i s_{i-1} \quad (34.77)$$

$$t_i = t_{i-2} - q_i t_{i-1} \quad (34.78)$$

Because  $r_{-1} = A = (1)A + (0)B$  and  $r_0 = B = (0)A + (1)B$ , we set the initial conditions  $s_{-1} = 1, t_{-1} = 0, s_0 = 0$  and  $t_0 = 1$ .

**TABLE 34.4** Euclid's Algorithm for gcd(124,46)

$i$	$r_i$	$q_i$	$s_i = s_{i-2} - q_i s_{i-1}$	$t_i = t_{i-2} - q_i t_{i-1}$
-1	124		1	0
0	46		0	1
1	32	2	1	-2
2	14	1	-1	3
3	4	2	3	-8
4	2	3	-10	27
5	0	2	23	-62

Let us illustrate the process with  $A = 124$  and  $B = 46$ . We will find  $\text{gcd}(124,46)$ . The idea is to divide recursively by the residues of the division until obtaining a last residue 0. Then, the last divisor is the gcd. The procedure works as follows:

$$46 = (0)124 + (1)46$$

$$32 = (1)124 + (-2)46$$

$$14 = (-1)124 + (3)46$$

$$4 = (3)124 + (-8)46$$

$$2 = (-10)124 + (27)46$$

Because 2 divides 4, 2 is the greatest common divisor between 124 and 46.

The best way to develop the process above is to construct a table for  $r_i$ ,  $q_i$ ,  $s_i$ , and  $t_i$ , using the initial conditions and recursions in Eqs. (34.76)–(34.78). Table 34.4 provides such a table for 124 and 46.

From now on, let us concentrate on Euclid's algorithm for polynomials. If we want to solve the key equation

$$\mu(x)x^{n-k} + \sigma(x)S(x) = -\omega(x)$$

and the error correcting capability of the code has not been exceeded, then applying Euclid's algorithm to  $x^{n-k}$  and to  $S(x)$ , at a certain point of the recursion we obtain

$$r_i(x) = s_i(x)x^{n-k} + t_i(x)S(x)$$

where  $\deg(r_i) \leq \lfloor (n-k)/2 \rfloor - 1$ , and  $i$  is the first with this property. Then,  $\omega(x) = -\lambda r_i(x)$  and  $\sigma(x) = \lambda t_i(x)$ , where  $\lambda$  is a constant that makes  $\sigma(x)$  monic. For a proof that Euclid's algorithm gives the right solution, see [1] or [5].

We illustrate the decoding of RS codes using Euclid's algorithm with an example. Notice that we are interested in  $r_i(x)$  and  $t_i(x)$  only.

**Example 10** Consider the [3,7,5] RS code over  $GF(8)$  and assume that we want to decode the received vector

$$r = (011 \ 101 \ 111 \ 111 \ 111 \ 101 \ 010)$$

which, in polynomial form, is

$$R(x) = \alpha^4 + \alpha^6 x + \alpha^5 x^2 + \alpha^5 x^3 + \alpha^5 x^4 + \alpha^6 x^5 + \alpha x^6$$

**TABLE 34.5** Decoding of RS Codes Using Euclid's Algorithm

$i$	$r_i = r_{i-2} - q_i r_{i-1}$	$q_i$	$t_i = t_{i-2} - q_i t_{i-1}$
-1	$x^4$		0
0	$\alpha^5 + \alpha x + \alpha^3 x^3$		1
1	$\alpha^2 x + \alpha^5 x^2$	$\alpha^4 x$	$\alpha^4 x$
2	$\alpha^5 + \alpha^2 x$	$\alpha^2 + \alpha^5 x$	$1 + \alpha^6 x + \alpha^2 x^2$

Evaluating the syndromes, we obtain

$$S_1 = R(\alpha) = \alpha^7$$

$$S_2 = R(\alpha^2) = \alpha$$

$$S_3 = R(\alpha^3) = 0$$

$$S_4 = R(\alpha^4) = \alpha^3$$

Therefore, the syndrome polynomial is  $S(x) = \alpha^5 + \alpha x + \alpha^3 x^3$ .

Next, we apply Euclid's algorithm with respect to  $x^4$  and to  $S(x)$ . When we find the first  $i$  for which  $r_i(x)$  has degree  $\leq 1$ , we stop the algorithm and obtain  $w(x)$  and  $\sigma(x)$ . The process is illustrated in Table 34.5.

So, for  $i = 2$ , we obtain a polynomial  $r_2(x) = \alpha^5 + \alpha^2 x$  of degree 1. Now, multiplying both  $r_2(x)$  and  $t_2(x)$  by  $\lambda = \alpha^5$ , we obtain  $\omega(x) = \alpha^3 + x$  and  $\sigma(x) = \alpha^5 + \alpha^4 x + x^2$ .

Searching the roots of  $\sigma(x)$ , we verify that these roots are  $\alpha^0 = 1$  and  $\alpha^5$ ; hence, the errors are in locations 0 and 2. The derivative of  $\sigma(x)$  is  $\sigma'(x) = \alpha^4$ . By (34.69), we obtain  $E_0 = \omega(1)/\sigma'(1) = \alpha^4$  and  $E_2 = \omega(\alpha^5)/\sigma'(\alpha^5) = \alpha^5$ . Adding  $E_0$  and  $E_2$  to the received locations 0 and 2, the decoder concludes that the transmitted polynomial was

$$F(x) = \alpha^6 x + \alpha^5 x^3 + \alpha^5 x^4 + \alpha^6 x^5 + \alpha x^6$$

which, in vector form, is

$$\underline{c} = (000 \ 101 \ 000 \ 111 \ 111 \ 101 \ 010)$$

If the information is carried in the first three bytes, the output of the decoder is

$$\underline{u} = (000 \ 101 \ 000) \quad \square$$

## Applications: Burst and Random Error Correction

In the previous sections we have studied how to encode and decode RS codes. This subsection will briefly examine how they are used in applications, mainly for correction of bursts of errors. The two main methods for burst and combined burst and random error correction are interleaving and product codes.

In practice, errors often come in bursts. A burst of length  $l$  is a vector whose nonzero entries are among  $l$  consecutive (cyclically) entries, the first and last of them being nonzero. We consider binary bursts, and we use the elements of larger fields (bytes) to correct them. Below are some examples of bursts of length 4 in vectors of length 15:

$$\begin{array}{ccccccccccccccc} 0 & 0 & 0 & 1 & 0 & 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 & 0 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 \end{array}$$

Errors tend to come in bursts not only because the channel is bursty. Normally, both in optical and magnetic recording, data are encoded using a so-called modulation code, which attempts to match the data to the characteristics of the channel. In general, the ECC is applied first to the random data and then the encoded data are modulated using modulation codes (see the chapter on modulation codes in this book). At the decoding, the order is reversed; when data exits the channel, it is first demodulated and then corrected using the ECC. Now, the demodulator tends to propagate errors, even single-bit errors. Although most modulation codes used in practice tend to control error propagation, nevertheless errors have a bursty character. For that reason, we need to implement a burst-correcting scheme, as we will see next.

A well-known relationship between the burst-correcting capability of a code and its redundancy is given by the Reiger bound, to be presented next, and whose proof is left as an exercise.

**Theorem 4 (Reiger Bound)** Let  $\mathcal{C}$  be an  $[n, k]$  linear code over a field  $GF(2^v)$  that can correct all bursts of length up to  $l$ . Then  $2l \leq n - k$ .

Cyclic binary codes that can correct bursts were obtained by computer search. A well known family of burst-correcting codes are the so-called Fire codes. Here, we concentrate on the use of RS codes for burst correction. There are good reasons for this. One of them is that, although good burst-correcting codes have been found by computer search, there are no known general constructions giving cyclic codes that approach the Reiger bound. Interleaving of RS codes on the other hand, to be described below, provides a burst-correcting code whose redundancy, asymptotically, approaches the Reiger bound. The longer the burst we want to correct, the more efficient the interleaving of RS codes is. The second reason for choosing interleaving of RS codes, and probably the most important one, is that, by increasing the error-correcting capability of the individual RS codes, we can correct multiple bursts, as we will see. The known binary cyclic codes are designed, in general, to correct only one burst.

Let us start with the use of regular RS codes for correction of bursts. Let  $\mathcal{C}$  be an  $[n, k]$  RS code over  $GF(2^b)$  (i.e.,  $b$ -bit bytes). If this code can correct  $s$  bytes, in particular, it can correct a burst of length up to  $(s - 1)b + 1$  bits. In effect, a burst of length  $(s - 1)b + 2$  bits may affect  $s + 1$  consecutive bytes, exceeding the byte-correcting capability of the code. This happens when the burst of length  $(s - 1)b + 2$  bits starts in the last bit of a byte. How good are then RS codes as burst-correcting codes? Given a binary  $[n, k]$  code that can correct bursts of length up to  $l$ , we define a parameter, called the *burst-correcting efficiency* of the code, as follows:

$$e_l = \frac{2l}{n - k} \tag{34.79}$$

Notice that, by the Reiger bound,  $e_l \leq 1$ . The closer  $e_l$  is to 1, the more efficient the code is for correction of bursts. Going back to our  $[n, k]$  RS code over  $GF(2^b)$ , it can be regarded as an  $[nb, kb]$  binary code. Assuming that the code can correct  $s$  bytes and its redundancy is  $n - k = 2s$ , its burst-correcting efficiency is

$$e_{(s-1)b+1} = \frac{(s - 1)b + 1}{2s}$$

Notice that, for  $s \rightarrow \infty$ ,  $e_{(s-1)b+1} \rightarrow 1/2$ , justifying our assertion that for long bursts, RS codes are efficient as burst-correcting codes (as a comparison, the efficiency of Fire codes asymptotically tends to  $2/3$ ); however, when  $s$  is large, there is a problem regarding complexity. It may not be practical to implement a RS code with too much redundancy. Moreover, the length of a RS code is limited, in the case of 8-bit bytes, it cannot be more than 256 (when extended). An alternative would be to implement a 1-byte correcting RS code interleaved  $s$  times.

An  $[n, k]$  code interleaved  $m$  times is illustrated in Fig. 34.63. Each column  $c_{0,j}, c_{1,j}, \dots, c_{m-1,j}$  is a codeword in an  $[n, k]$  code. In general, each symbol  $c_{i,j}$  is a byte and the code is a RS code. The first  $k$  bytes carry information bytes and the last  $n - k$  bytes are redundant bytes. The bytes are read in row order, and the

FIGURE 34.64 Product code  $C_1 \times C_2$ .

parameter  $m$  is called the depth of interleaving. If each of the individual codes can correct up to  $s$  errors, the interleaved scheme can correct up to  $s$  bursts of length up to  $m$  bytes each, or  $(m-1)b+1$  bits each. This occurs because a burst of length up to  $m$  bytes is distributed among  $m$  different codewords. Intuitively, interleaving “randomizes” a burst.

The drawback of interleaving is delay. Notice that we need to read most of the information bytes before we are able to calculate and write the redundant bytes. Thus, we need enough buffer space to accomplish this.

Interleaving of RS codes has been widely used in magnetic recording. For instance, in a disk, the data are written in concentric tracks, and each track contains a number of information sectors. Typically, a sector consists of 512 information 8-bit bytes (although the latest trends tend to larger sectors). A typical embodiment would consist in dividing the 512 bytes into four codewords, each one containing 128 information bytes and six redundant bytes (i.e., each interleaved shortened RS codeword can correct up to three bytes). Therefore, this scheme can correct up to three bursts of length up to 25 bits each.

A natural generalization of the interleaved scheme described above is product codes. In effect, we may consider that both rows and columns are encoded into error-correcting codes. The product of an  $[n_1, k_1]$  code  $C_1$  with an  $[n_2, k_2]$  code  $C_2$ , denoted  $C_1 \times C_2$ , is illustrated in Fig. 34.64. If  $C_1$  has minimum distance  $d_1$  and  $C_2$  has minimum distance  $d_2$ , it is easy to see that  $C_1 \times C_2$  has minimum distance  $d_1 d_2$ .

In general, the symbols are read out in row order (although other readouts, like diagonal readouts, are also possible). For encoding, first the column redundant symbols are obtained, and then the row redundant symbols. For obtaining the checks on checks  $c_{i,j}$ ,  $k_1 \leq i \leq n_1 - 1$ ,  $k_2 \leq j \leq n_2 - 1$ , it is easy to see that it is irrelevant if we encode on columns or on rows first. If the symbols are read in row order, normally  $C_1$  is called the outer code and  $C_2$  the inner code. For decoding, many possible procedures are used. The idea is to correct long bursts together with random errors. The inner code  $C_2$  corrects first. In that case, two events may happen when its error-correcting capability is exceeded: either the code will detect the error event or it will miscorrect. If the code detects an error event (that may well have been

caused by a long burst), one alternative is to declare an erasure in the whole row, which will be communicated to the outer code  $C_1$ . The other event is a miscorrection, that cannot be detected. In this case, we expect that the errors will be corrected by the error-erasure decoder of the outer code.

Product codes are important in practical applications. For instance, the code used in the DVD (digital video disk) is a product code where  $C_1$  is a  $[208, 192, 17]$  RS code and  $C_2$  is a  $[182, 172, 11]$  RS code. Both RS codes are defined over  $GF(256)$ , where  $GF(256)$  is generated by the primitive polynomial  $1 + x^2 + x^3 + x^4 + x^8$ .

### 35.1 Definitions and Importance

---

A distributed operating system is software that runs on several machines whose purpose is to provide a useful set of services, typically to make the collection of machines behave more like a single machine. The distributed operating system plays the same role in making the collective resources of the machines usable that a typical single-machine operating system plays in making that machine's resources more usable.

Distributed operating systems are usually viewed as running cooperatively on all machines whose resources they control. These machines might be capable of independent operation, or they might be usable merely as resources in the distributed system. Unlike parallel operating systems, a distributed operating system typically runs on loosely coupled hardware. Parallel operating systems tend to focus on making all available resources usable by a single large task, while distributed operating systems focus on making the collection of resources usable by a set of loosely cooperating users. Network operating systems are sometimes regarded as systems that attempt merely to make the network connecting machines more usable, without regard for some of the larger problems of building effective distributed systems. The distinctions between parallel, distributed, and network operating systems are somewhat arbitrary, because all must handle similar problems.

Distributed operating systems are not in common use today. Although many interesting research systems have been built since the 1970s, and some systems have been in use for many years, they have not displaced more traditional operating systems designed primarily to support single machines; however, some of the components originally built for distributed operating systems have become commonplace in today's

systems, the most notable example being services to access files stored on remote machines. Many researchers feel that the failure of distributed operating systems to capture a large share of the marketplace is primarily due to our lack of understanding on how to build them. An alternate point of view is that their lack of popularity stems from users not really needing many distributed services not already provided.

Distributed operating systems are also an important field for study because they have helped drive general research in distributed systems. Replicated data systems, authentication services such as Kerberos, agreement protocols, methods of providing causal ordering in communications, voting and consensus protocols, and many other distributed services have been developed to support distributed operating systems, and have found varying degrees of success outside of that field. Popular distributed component services like CORBA owe some of their success to leveraging hard lessons learned by researchers in distributed operating systems. The popularity of the World Wide Web suggests that users would desire a more global view of the resources available to them than is provided by today's operating systems.

Distributed operating systems are hard to design properly. They must solve inherently hard problems in system design. Further, they must properly trade-off issues of performance, user interfaces, reliability, and simplicity. The relative scarcity of such systems, and the fact that most commercial operating systems' design still focuses on single-machine systems, suggests that no distributed operating system yet developed has found the proper trade-off among these issues.

Research continues in distributed operating systems. Current directions are primarily towards the use of distributed operating systems in important specialized cases, such as providing high-performance clustered servers. The increasing popularity of portable and handheld computers is likely to lead to more distributed operating system research to support mobile computing. The emerging field of ubiquitous computing offers different hardware, networking, and application characteristics likely to spur further research on distributed operating systems. Future uses of the Internet are also likely to increase desire for more easily distributed systems.

## **35.2 Why Are Distributed Operating Systems Hard to Build?**

---

This question touches directly on why distributed operating systems are not ubiquitous and also helps explain why research continues rapidly in certain areas, while it moves more slowly in others.

One core problem for distributed operating system designers is concurrency and synchronization. These issues arise in single-machine operating systems, but they are easier to solve there. Typical single-machine systems actually run only a single thread of control simultaneously, simplifying many synchronization problems. Further, they typically have access to memory, registers, or other useful physical resources that are directly accessible by all processes that they must synchronize. These shared resources allow use of simple and fast synchronization primitives, such as semaphores. Even modern machines that have multiple processors typically include hardware that makes it easier to synchronize their operations.

Distributed operating systems lack these advantages. Typically, they must control a collection of processors connected by some form of network, most often a local area network (LAN), but occasionally a network with even more difficult characteristics. The access time across this network is orders of magnitude larger than the access time required to reach local main memory and even more orders of magnitude larger than that required to reach information in a local processor cache or register. Further, such networks are not as reliable as a typical bus, so messages are more likely to be lost or corrupted. At best, this unreliability increases the average access time.

This imbalance means that running blocking primitives across the network is often infeasible. The performance implications for the individual component systems and the system as a whole do not permit widespread use of such primitives. Designers must choose between looser synchronization (leading to odd user-visible behaviors and possibly fatal system inconsistencies) and sluggish performance. The increasing gap between processor and network speeds suggests that this effect will only get worse.

Theoretical results in distributed systems are discouraging. Research on various forms of the Byzantine General problem and other formulations of the problems of reaching decisions in distributed systems has

provided surprising results with bad implications for the possibility of providing perfect synchronization of such systems. Briefly, these results suggest that reaching a distributed decision is not always possible in common circumstances. Even when it is possible, doing so in unfavorable conditions is very expensive and tricky. Although most distributed systems can be designed to operate in more favorable circumstances than these gloomy theoretical results describe (typically by assuming less drastic failure modes or less absolute need for complete consistency), experience has shown that even pragmatic algorithm design for this environment is difficult.

A further core problem is providing transparency. Transparency has various definitions and aspects, but at a high level it simply refers to the degree to which the operating system disguises the distributed nature of the system. Providing a high degree of transparency is good because it shields the user from the complexities of distribution. On the other hand, it sometimes hides more than it should, it can be expensive and tricky to provide, and ultimately it is not always possible. A key decision in designing a distributed operating system is how much transparency to provide and where and when to provide it.

A related problem is that the hardware, which the distributed operating system must virtualize, is more varied. A distributed operating system must not only make a file on disk appear to be in the main memory, as a typical operating system does, but must make a file on a different machine appear to be on the local machine, even if it is simultaneously being accessed on yet a third machine. The system should not just make a multi-machine computation appear to run on a single machine, but should provide observers on all machines with the illusion that it is running only on their machine.

Distributed operating systems also face challenging problems because they are typically intended to continue correct operation despite failure of some of their components. Most single-machine operating systems provide very limited abilities to continue operation if key components fail. They are certainly not expected to provide useful service if their processor crashes. A processor crash in a distributed operating system should ideally allow the remainder of the system to continue operations largely unharmed. Actually achieving this ideal can be extremely challenging. If the topology of the network connecting the system's component nodes allows the network to split into disjoint pieces, the system might also need to continue operation in a partitioned mode and would be expected to rapidly reintegrate when the partitions merge.

The security problems of a distributed operating system are also harder. First, data typically moves over a network, sometimes over a network that the distributed operating system itself does not directly control. Second, access control and resource management mechanisms on single machines typically take advantage of hardware that helps keep processes separate, such as page registers. Distributed operating systems are not able to rely on this advantage. Further, distributed operating systems are typically expected to provide some degree of local control to users on their individual machines, while still enforcing general access control mechanisms. When an individual user is legitimately able to access any bytes stored anywhere on his own machine, preventing him from accessing data that belongs to others is a much harder problem, particularly if the system strives to provide controlled high-performance access to that data.

In many cases, distributed operating systems are expected to run on heterogeneous hardware. Although commercial convergence on popular processors has reduced this problem to some extent, the wide variety of peripheral devices and customizations of system settings provided by today's operating systems often makes supposedly identical hardware behave radically differently. If a distributed operating system cannot determine whether running the same operation on two different component nodes produces the same result, it will face difficulties in providing transparency and consistency.

All the previously mentioned problems are exacerbated if the system scale becomes sufficiently large. Many useful distributed algorithms scale poorly, because the number of messages they require faces combinatorial explosion, or because the delays required to include large numbers of nodes in computations become unreasonable, or because data structures grow in proportion to the number of participants. High scale ensures that partial failures will become more common, and that low probability events will begin to pop up every so often. High scale also often implies that the distributed operating system must operate away from the relatively friendly world of the LAN, leading to greater heterogeneity and uncertainty in communications.

## 35.3 Components of Distributed Operating Systems

---

Distributed operating systems consist of components that generally mirror those in their single-machine counterparts. Some of these components are typically little altered from single-machine operating systems. For example, many distributed operating systems schedule their tasks per machine, using standard scheduling mechanisms. Unless distributed shared memory is supported, components of the operating system that support virtual memory, paging, and swapping are typically similar to other operating systems. Support for devices and the use of device drivers is also common. Note that these similarities are merely the rule in distributed operating systems, and that some such systems handle even these components differently than in single-machine operating systems.

The components that tend to be most different are those related to file systems, interprocess communications, synchronization, reliability and recovery, and security. Also, some distributed operating systems include support for process migration, a facility that makes no sense in an operating system that limits its view to the boundaries of a single machine.

### File Systems

File systems were quickly recognized as one of the areas of a distributed operating system that required the most attention. Before the development of distributed operating systems, remote file access was limited to explicit copying, perhaps abetted by a program such as FTP. Distributed operating system designers instantly recognized the great value added to a computer on a network by giving it better access to files stored on other machines. The approach was generally to provide some integrated view of the collection of files stored on the various machines of the distributed system.

A key question in distributed file system design is the degree of transparency provided. At one extreme, services like FTP offer very little transparency. File locations must be explicitly named; the names effectively change if the file is moved to another machine, and files are accessed very differently if they are stored locally or remotely. Such services do not even allow all normal file operations to be performed on a remote file. At the other extreme, distributed operating systems like Locus tried to conceal the actual location of the file whenever possible. The most successful distributed file systems (NFS and the Windows file-sharing services) provide various intermediate points of transparency. NFS does not make file locations explicit in its naming conventions, but a single file may need to be accessed by different names on different machines. The Windows file-sharing service makes file locations explicit, requiring that users access remote files by looking under icons representing remote machines. But both services support their file access interface for both remote and local files, permitting these files to be read, written, and executed. This degree of transparency has proven to be the minimal acceptable amount that users demand. The World Wide Web provides this same amount of transparency, for example.

Other file system issues must be handled by the distributed operating system. Typically, remote access is slower than local access (though in modern systems, accessing data stored in the main memory of a remote machine may be faster than accessing data stored on a local hard disk drive). Many distributed file systems seek to conceal this speed difference, typically by providing a local copy of the data, thereby avoiding expensive remote access. Caching of data blocks from remote files is common, often using the same facilities that cache data blocks fetched from local disks. The Andrew File System [1] uses a different approach, caching whole files for extended periods (including over reboots) at client sites.

Cache consistency problems are caused by updates. When a local file is written, invalidating locally cached copies of the written block is straightforward and quick. Invalidating remotely cached copies is slower and more difficult, since the local operating system must signal the remote machine's system to perform the actual invalidation. Even being able to do so requires that the local machine keep track of remotely cached copies. If the local machine does keep track of these copies, the remote machine might need to signal the local machine if the cached copy is discarded. Handling all cases of partial and transient failures complicates the problem. The Andrew file system is one example of a system that has successfully handled these problems, aided in part by its use of reliable server machines that store the true permanent copy of all files. If writes are rare, ignoring the problem and accepting occasional reads of stale cached

blocks may be a better solution than trying to maintain perfect consistency of the cached copies. The Sun Microsystems implementation of NFS improves on this approach at a reasonable cost by having caching clients periodically check to see if their cached copy is still fresh. This solution still allows use of stale data, but can be tuned to trade-off freshness versus cost. Not caching at all is another solution, but one with serious performance implications.

When file copies are to be permanently stored at a location, they switch from being cached to being replicated. Replicating files has several advantages, including superior fault tolerance, high performance for all file operations, and good support for disconnected operations, which is especially valuable for mobile computing. Replicating files has a significant cost, however. Beyond the mere storage costs of keeping multiple permanent copies of the same bits, maintaining consistency among replicated files is a difficult problem. Generally, replicated file systems must trade the consistency of the replicas against file system performance. Higher consistency is possible using conservative replication methods, which ensure that no inconsistent updates to files are possible. Conservative methods often have high costs and limit file availability, however. Optimistic replication reverses these advantages and disadvantages, offering lower cost and higher availability at the risk of permitting inconsistencies, which must then be handled by some method—typically a reconciliation process that tries to merge the results of conflicting updates. Sample replicated file systems include Coda (which uses optimistic client/server replication) [2] and Ficus (which uses optimistic peer replication) [3]. The systems in wide commercial use tend not to provide full functionality replicated file systems because of their cost and complexity.

File replication is widely used in an informal fashion. For example, programs that automatically distribute new versions of executables to all machines in an office are performing a limited form of file replication. Mechanisms like the Microsoft Briefcase offer limited forms of file replication for special cases, such as sharing files between a desktop and a portable computer, where typically only one machine is active at any given moment. By leveraging the special circumstances of such uses, many of the harder problems of file replication can be avoided. Such adoption of simple limited expedients for common circumstances is characteristic of much real-world use of distributed operating systems technology.

File migration is another alternative available to distributed file systems to avoid performance problems. Files move to the sites that use them. This paradigm requires a high degree of transparency, since all processes in the system must be able to access all files, local or remote, under the same names. Otherwise, applications might stop working when the file migrates from the remote to the local site. Further, such alternatives face difficulties in preventing popular files from moving constantly. This paradigm of remote data access has been more widely used and studied in the field of distributed shared memory.

## **Interprocess Communications Services**

Many distributed operating systems are designed to support distributed computations, where cooperating processes run on different nodes. Allowing the processes to cooperate implies that they can exchange information, which in turn implies a need for interprocess communications (IPC) services.

Single-machine systems have the same requirement, so a variety of IPC services exist for such environments, including remote procedure calls, messages, and shared memory. Generally, the implementation of these services in single-machine environments leverages shared hardware. For example, all three of these services are provided in most single-machine operating systems by writing information into main memory that can be read by all communicating processes, or by copying information from the memory of one process into the memory of another, or into buffers provided by the operating system. The shared hardware and the synchronization provided by the shared processor simplify many issues in making these IPC services work.

In a normal distributed system, the participating machines can only communicate by passing messages across a network. Such networks typically do not offer the guarantees available from the shared hardware of a single machine. Further, the participating machines are typically under the control of their local processor. No single processor controls the complete collection. These characteristics require different implementations of familiar IPC services.

Message-passing IPC shares many characteristics from the single-machine case. Bytes are gathered into an explicit message. Instead of merely being transferred from one buffer to another on the same machine, the message goes over the network. Failure of the network or the receiver introduces new problems. The issue of how long to block the sender is also different, since the time required to confirm delivery of the message in the remote case can be much longer than in the local case. Issues of message addressing must also be considered. In a single-machine system, all addressable processes are locally known. In a distributed system, some facility must be provided to allow the local process to discover the addressable names of remote processes and to send messages to those names.

Remote procedure call (RPC) faces similar challenges. In a single machine, remote procedures aren't that remote. Although they may have a different address space, the local operating system has access to all necessary facilities of both the calling and called processes. In distributed systems, the caller is on one machine and the called process on another. Further, the actual transfer of data must take place via messages crossing the network. One implication is that call-by-reference must be translated to call-by-return-value. Other complexities exist, including some similar to those for message passing. Another issue is handling partial failures. Either the caller or the called process can fail independently of the other, requiring the operating system on the surviving machine to recover.

Shared memory is the hardest common IPC mechanism to provide in distributed operating systems, because it relies most heavily on hardware characteristics not present in the distributed environment. Early distributed operating systems made no attempt to provide shared memory across the network; however, as LANs became more capable, researchers tackled the difficult problems of providing the semantics of shared memory across the network. This problem spawned vast amounts of research, which will not be covered in detail here. A slightly closer look at the concept of distributed shared memory will reveal why this research was necessary.

As before, the distributed system can only communicate via messages. Yet the distributed operating system must provide the illusion that two processes on different machines are sharing a single piece of physical memory. The basic approach is to give each process access to a local copy of the memory, then have the operating systems work behind the scenes to provide a consistent view between the processes. Another approach is to migrate the memory segments between machines, as needed. This approach can run into difficulties if processes frequently access the same memory locations. Also, because the overheads of handling shared memory at the word level are too extreme, distributed shared memory systems must aggregate words into shared blocks. If the aggregation is too large, *false sharing* occurs, where one process accesses the first part of a block while another process accesses the second part. Because the two parts are aggregated into a single block, the block must migrate back and forth, despite no actual commonly accessed memory locations.

Alternately, memory segments can be replicated. Doing so leads to problems when writes occur. Either the other copies of the segment must be updated (before they are accessed again), or they must be invalidated. Either approach requires much bookkeeping and incurs overheads when writes occur. False sharing effects can also play a role here, since writing to the first word of a block tends to invalidate or cause updates to the entire block.

Much inventive research has been performed on distributed shared memory, using various techniques to overcome its challenges. Although distributed shared memory has been demonstrated to be feasible, its performance, complexity, and limitations have prevented it from becoming popular. Few systems today provide this facility. Research continues on distributed shared memory, but not as widely as in the past.

## Naming Services

Names play an important role in operating systems. Many operating systems support several distinct name spaces for different purposes. For example, one name space might describe the file system, while another describes the processes running on a machine, and a third describes the users permitted to work on the machine. One legacy of Unix systems is that the file name space is used aggressively to provide name spaces for things that are not classically files, such as devices and interprocess communication services. (One distributed operating system, Plan 9, relies on this abstraction for all its naming needs [4].)

Distributed operating systems have similar naming needs, but now some of the entities that must be named are not located on the local machine. As before, these entities are of various types. The distributed nature of the system leads to different problems, however. For example, in a single machine, one directory can contain the names of all the entities in the system. Scaling and organizational concerns usually lead to breaking the single directory into hierarchical components, but there are relatively few difficulties with maintaining a single name space that describes the name-to-resource mappings of anything currently available in the system.

In a distributed system, independently operating nodes can create, destroy, and change names rapidly. These operations are local, so they are likely to appear instantly in the local name space. But how do the other machines in the system become aware of namespace changes?

One approach is to build a single global namespace for the entire distributed system. The Locus Operating System took this approach, for example. It extended the standard Unix file system naming convention across multiple machines. By providing a single hierarchical name space, the naming changes made by one machine were available to all machines. An advantage of this approach is high transparency. Files (and other nameable resources) had the same names on all machines, which provided an easier model for users. The difficulties with the Locus approach are that it scales poorly and only works well when all machines tend to be connected most of the time. Maintaining a global name space on multiple machines is very hard. Further, if replication is being used, name space changes in one replica can sometimes conflict with name space changes in other replicas.

The Andrew file system overcame some of these problems by storing all files on reliable servers. Whole file caching was used to provide fast access on machines that interacted directly with users. The Andrew file system has been operated at high scale, but usually in circumstances where one collocated set of servers can access all clients via a high-speed reliable network.

Windows file sharing and NFS provide a more limited form of global name space. In the Windows file sharing service, each machine has complete autonomy over its own name space, and exports that name space to remote machines explicitly, under its own machine name. NFS allows portions of one machine's name space to be spliced into the name spaces of other machines at fairly arbitrary points. Neither service is as transparent as a true global name space, but many control problems are avoided. As the World Wide Web has demonstrated, such a name space can scale well; however, the World Wide Web's name space also demonstrates some problems with the approach, such as poor results when a resource changes its location, since such a change implies a name change.

## **Recovery, Reliability, and Fault Tolerance Services**

Because distributed operating systems are more prone to partial failure, some such systems provide special facilities for recovery. The system itself must have internal mechanisms (typically hidden from normal users) that handle failure problems. These facilities ensure that system services like the file system and name spaces continue to exhibit reasonable behavior even in the face of failures. One common requirement was to provide transactional behavior in the face of failures and arbitrarily slow system components. The two-phase commit protocol is typically used for this purpose. The system might also provide checkpointing facilities for processes, services that allow cooperative processes on different machines to deal with failure of some of their components, or the ability to request replication or backup versions of important processes or data.

Arguably, such services are best provided transparently. Typical users and programmers are not experts in the complexities of distributed computations and failure handling, so few of them can make effective use of any such tools that the system provides. On the other hand, transparent recovery and reliability services are hard to provide.

## **Process Migration**

Some distributed operating system designers have foreseen value in permitting running processes to be migrated to other nodes, for load balancing, to achieve better performance for high-priority processes, to move processes closer to critical resources (typically files), or to provide improved reliability. Migrating a

process at any arbitrary stage in its operations is difficult. The Locus Operating System provided such a facility, but handling all complex cases is tricky. A more common approach is to provide facilities that allow processes to enter migratable states where the more complex situations cannot arise. Typically, this means they are temporarily quiescent until the migration completes. Not providing process migration at all is even more common. Process migration has not been a popular capability in the systems that do provide it.

## Security Services

Single-machine operating systems provide some degree of security by relying on the characteristics of the hardware they run, and by leveraging the fact that the operating system trusts itself. Access control mechanisms for files, separation of data belonging to different processes, and authentication of users to the system work on these assumptions. In a distributed operating system, communications often go over insecure shared networks, and the remote operating systems might not be as fully trusted as the local system. The security problems are thus harder to solve, and distributed operating systems sometimes provide facilities to handle the problems.

The use of an insecure network is typically handled by either authenticating or encrypting network traffic. A properly designed cryptographic system can usually make it difficult for outsiders to improperly inject or alter traffic, or to read secret information in transit. Such a cryptographic approach does not solve all problems, since one system must still rely on a remote system to enforce security restrictions just as the local system would. For example, if a sensitive file is stored at node A, when node B requests access to the file, node A can check that the request was made by a user with the right to view the file; however, if in response node A provides blocks of the file to the proper user on node B, node A must trust that node B will not maliciously or accidentally also provide the blocks to improper users. Node B has concerns, as well, because it cannot determine if node A has properly applied access control to the file. If node A has not done so, node B might provide its user with data that should be inaccessible. These concerns make it relatively difficult to set up a distributed operating system in environments where all participant systems do not completely trust one another.

Assuming that the nodes are all trustworthy to the extent that they will properly handle data that they can properly access, the distributed system must still authenticate the requests from participants. Otherwise, one of the nodes in the distributed system might tag requests to remote nodes from user X with the identity of user Y, allowing X to access data improperly. The remote node must independently verify that the request really came from user Y. Many cryptographically based mechanisms can provide such authentication. One option is the Kerberos system, which allows machines in a distributed environment to authenticate identities and provide controlled access to services [5]. Security designers are generally happiest with heavily tested and used mechanisms, because they are less likely to have undiscovered security bugs, so Kerberos' long history and the amount of scrutiny applied to it make it popular.

## 35.4 Sample Distributed Operating Systems

---

### Locus

The Locus Operating System was an early ambitious attempt to build a distributed operating system that provided all users with a single system image [6]. It was developed at UCLA and the Locus Computing Corporation throughout the 1980s and into the 1990s. Locus was intended to be Unix-compatible, both in terms of the operating system interface provided and the experience of users. Ideally, a Locus user would be given the illusion of a single large Unix system vastly more powerful than any single machine could provide. In actuality, the distributed operating system would run on each component node of the system. The nodes worked together to maintain the single image.

The Locus system achieved some success, but ran into several problems that prevented it from becoming popular. The system demonstrated the value and feasibility of providing high transparency in a distributed operating system, and pioneered concepts such as file replication. But the challenges of providing

a true single image were immense. Particularly, handling all of the difficult uncommon cases properly required much complexity. Further, one fundamental mechanism in achieving the single system image was to reach agreement on the set of participating nodes, a task that proved difficult and expensive. The final lesson from the Locus project was that, although transparency was valuable and attractive, too much obsession with providing complete transparency in all circumstances could be counterproductive.

## **Amoeba**

Amoeba provides service to a large community of users working at low-powered workstation systems. It does this by maintaining a pool of servers capable of working interchangeably with any of the workstations, as well as some specialized servers [7]. When a user logs in to an Amoeba workstation, he is implicitly logging in to the entire distributed system. The Amoeba system software assigns user tasks to one or more machines in the server pool, handling all issues of communications and synchronization. Because any task can potentially run on any server in the pool, Amoeba must provide a high degree of transparency. Persistent data is typically stored remotely from both the workstation currently occupied by the user and the machines in the server pool working on the request, which also implies a need for high transparency.

Amoeba provides RPC and reliable multicast for interprocess communications. It handles issues of network security by using randomly assigned ports to obscure communications and by requiring cryptographic capabilities to access resources.

Amoeba provides a distributed file system with replication capabilities. An interesting aspect of the Amoeba file system is that it only permits creation of files, not their alteration. Instead of altering an existing file, a new file is created with the altered contents. This choice simplifies many replication issues, but requires users to adopt a different model of file behavior than is typical.

Amoeba was used for production purposes in several environments, and is available from Vrije Universiteit, where it was developed.

The design philosophy behind Amoeba and many other distributed operating systems is to support operations at one large, well-connected organization. Designers also assume that it is more economical to provide low-powered machines as a front end and perform the system's serious work on pools of servers. When a cheap workstation can provide all the computational and storage resources required by a particular user, there is less advantage in this approach; however, it still has some advantages because of system simplifications inherent in localizing important operations in well-connected, well-maintained servers. Also, this model is not well suited for integrating portable computers, because those machines can be disconnected from the network and are expected to continue providing service.

## **Plan 9**

Plan 9 is one of the more recent attempts to build a new distributed operating system [4]. Plan 9's approach to building a distributed operating system shares some similarities to Amoeba's. The system is designed primarily to support a single large organization, using a pool of CPU servers, file servers, and many terminal servers. All machines are connected by a high-speed LAN. All resources in Plan 9 are represented in a name space that resembles a Unix file system. A user at a terminal requests resources by mounting name space components representing those resources into his own name space. One standard protocol handles access to all resources, be they files, devices, or interprocess communications facilities. Plan 9 is still in use and being studied, but has not achieved widespread popularity.

## **35.5 Recent Research in Distributed Operating Systems**

---

Although distributed operating systems have not become ubiquitous, their goals continue to be tempting, and the success and importance of some distributed operating system components suggest that further research and development is worthwhile. Further, changes in the use of computers, such as mobile computing and ubiquitous computing, demand new research to handle the problems of distribution encountered in these new environments.

Few attempts were made in the past decade to produce revolutionary new general-purpose distributed operating systems akin to Locus, Amoeba, and Plan 9. The focus has been on producing better distributed services and designing distributed operating systems for important special uses.

## Distributed File Systems

LAN speed and bandwidth now permit some remote file accesses to be cheaper than local accesses. Further, designating particular machines as file servers (as is commonly done with NFS and other similar systems) causes scaling problems when those machines become overloaded. The xFS project addressed these issues by striping files across the storage of all machines on a LAN [8]. By ensuring that commonly used files were in main memory at all participating machines, xFS allows most file accesses to proceed at network speeds, rather than disk speeds. The management responsibilities are spread across all participating nodes. By using RAID techniques, the failure of any individual machine does not cause unavailability of any files, unlike failure of an NFS server. Since RAID redundancy does not require full duplication of all bits of a file, this solution is less wasteful of storage than file replication. Other file systems, such as Zebra [9] and Frangipani [10] use similar methods to spread file data across multiple machines. This approach assumes that all machines are trustworthy, and is most suitable for use on a LAN, where partitioning of sets of the machines are rare. These limitations, the complexity of the implementations, and the lack of practical experience with their use have prevented this class of solution from being widely used, so far.

Striping files across multiple machines has particular advantages for video servers. Such services must move large quantities of data from persistent storage to a remote network location, quickly and predictably. Leveraging the capabilities of several cooperating servers simultaneously has proven advantageous for systems like the Tiger File System [11]. Such special purpose systems can often afford high-speed interconnection networks that avoid some performance problems.

Peer file-sharing services such as Gnutella have become popular recently. Such peer services seek to leverage the vast amount of storage available on machines connected to the Internet to make various kinds of files widely available to many users. These services spread requests out to other nearby machines running the service, with relatively little information distributed about what files are stored at which machines. Finding a particular file involves searching some of the participating machines to find the site (or sites) storing it. Such services can face scaling problems for a variety of reasons, especially if only a small number of participants actually store the files, since they can become overloaded. Also, machines connected via slow links can be quickly flooded by traffic generated by the system, rendering it ineffective for users at those machines and making the files they store hard to reach for other users.

## Networks of Workstations

The commercialization of the Internet has led to some high requirements for servers. Handling millions of Web page hits per day is vital to some companies, and other types of service can be equally stressful. One alternative to buying extremely expensive mainframes capable of handling such loads is to build a network of workstations, using commodity hardware connected by a dedicated high-speed network. This kind of hardware can be much less expensive than mainframes, and offers the promise of cheap expandability by merely adding more workstations to the network. The fundamental architecture is to farm out incoming requests to the workstations, balancing the load and leveraging their combined capabilities. This approach often requires special distributed systems support to handle problems of shared data access, reliability, and scalability.

The problem is relatively easy for loads like most web service, where almost all incoming requests are read-only. In such cases, the entire set of data required to respond to requests can be replicated at each machine in the system. The situation is trickier when writes are more common. One approach is to assign users or categories of requests to particular machines, but such approaches may face problems with load balancing and scaling when the pattern of work changes or large numbers of users are added. More sophisticated approaches have been investigated recently.

The DDS service provides tools for building distributed data structures to run on workstation clusters [12]. The DDS service must handle many of the problems of distributed systems in general, including performance and reliability; but by limiting its requirements to supporting particular types of carefully chosen data structures, the system can solve these hard problems and provide the necessary services. Porcupine uses a network of workstations to handle mail service, which requires significant amounts of writing and thus demands more sophisticated mechanisms to leverage the power of the distributed system [13]. Porcupine uses a set of nodes that can provide interchangeable services and replication techniques to build a high-performance mail server out of a network of workstation machines.

## Distributed Systems for Ubiquitous Computing

Many researchers predict that homes, offices, and other buildings of the future will contain large numbers of objects that have embedded processors and communications devices. For example, all appliances in a house might contain processing and communications capabilities. Also, humans may carry several computing and communications devices on their bodies, in much the same way that most people today wear a watch. The purposes and uses of machines in these environments are not yet clear, but they seem likely to differ from the way office workstations in a LAN or machines browsing the Web behave. Plausibly, they will require different sets of system services than today's distributed system services. Various researchers have started examining the requirements of these systems and designed distributed services for them.

One area of interest is naming in such systems. The publish/subscribe model of naming has been proposed and implemented in systems like the Jini service discovery system. In this model, devices on the network publish their capabilities, and other devices that hear the publications subscribe to the services they are interested in. Another proposed model of naming for this environment is intentional naming, where the system provides name resolution and request routing via a self-configured overlay network [14]. In such systems, users name objects by what they want to do with them, and the naming service takes responsibility for forwarding the request to some entity capable of fulfilling their need.

Ubiquitous computing systems also require access to persistent storage, both to access standard persistent data (e.g., files) and to allow the system to keep track of the state required to give users a consistent view of the world. Mobility, limited communications links, security concerns, and varying capabilities of participant machines make providing persistent data harder. One approach to solving the problem is provided by OceanStore, which postulates a utility-like model for providing persistent data handling in a ubiquitous environment [15]. OceanStore uses replication aggressively and relies on a combination of fast (but not always successful) search techniques and slow (but reliable) lookup algorithms.

## Security in Distributed Operating Systems

Some recent research has tried to tackle the problems of running a secure distributed operating system when not all participants are fully trusted. For example, recent enhancements to SFS have produced a secure read-only file system that allows remote clients to independently verify that the data provided to them by a server is indeed the true version of the data [16]. Another difficult security problem for distributed systems that span multiple administrative domains is proper authentication across those boundaries, particularly when the different domains use different authentication mechanisms. One recent approach to solving this problem is to build a logic of authentication and mechanisms for applying that logic to authentication information attached to remote requests [17]. The system can then determine if it should regard incoming requests as being legitimately made by the putative requestor.

## 35.6 Resources for Studying Distributed Operating Systems

---

Research appears frequently in the field of distributed operating systems. Some of the work is commercial, but much of it is described in the research literature. The principal conferences where distributed operating system research appears most often are the bi-annual Symposium on Operating Systems (SOSP), the bi-annual Conference on Operating Systems Design and Implementation (OSDI, held in

alternate years with SOSOP), and the annual Usenix Technical Conference. Interesting research on more specialized areas often appears in other venues. For example, mobile computing distributed system research often appears in the MOBICOM conference, and distributed systems security research will often appear in security conferences. A workshop called HotOS publishes early results on new areas of research in operating systems, including distributed operating systems.

The primary journals where distributed operating systems research appears are the ACM Transactions on *Computing Systems* journal and the *IEEE Transactions on Computers* journal. Again, research on specialized topics often appears in other journals, such as mobile computing research in Mobile Networks and Applications (MONET).

### 36.1 Introduction

---

Programmability and reconfigurability are considered to be a key ingredient for future silicon platforms [1]. An increase in the complexity of integrated circuits and a shorter time-to-market requirement result in a need to develop hardware platforms shared across multiple applications. In the next generation of electronic systems, it is expected that the conventional embedded systems are unlikely to be sufficient to meet the timing, power, and cost of such systems. Diversity and increasing number of applications do not allow fully customized system design methodology for each application such as ASIC designs. One of the fundamental keys is integrating programmability and reconfiguration in the systems [1,2]. On the other hand, the current *general-purpose* fully programmable solutions cannot satisfy the future aggressive timing and power constraints. Therefore, a new design methodology has to be developed to combine reconfiguration into system design for future applications. One of the techniques to handle the increased complexity in integrated circuits is programmable system-on-a-chip (SoC) design methodology [1]. In this style, there is a combination of IP cores, programmable logic core, and memory blocks on a chip.

System design can be viewed in a variety of levels of granularity from architecture level to logic/interconnection level. Configuration can be applied in different hierarchy levels of a design [1]. For instance, programmability in logic/interconnect level of system is realized via a programmable module such as FPGA chip. Reconfigurable devices provide the necessary flexibility in such systems. FPGAs are mostly the reconfiguration cores. An FPGA is an array of logic blocks placed in an infrastructure of interconnections, which can be configured in logic functionality of logic blocks, interconnection between logic blocks, and input/output (I/O) interface (see [Fig. 36.1](#)). SRAM-based FPGAs allows reconfiguration of the device via string of bits loaded from external source once or several times. An FPGA is programmable at hardware level. Many high-performance operations, such as computationally intensive signal processing functions can be implemented very efficiently using FPGAs.

Xilinx™ first introduced FPGAs in mid-1980s. In the past, considerable research effort was made for developing programmable architectures in the past. Also, numerous commercial programmable devices

FIGURE 36.1

were introduced; however, not many works have been published on how those architectures were designed. The latest FPGA devices are provided by companies such as Xilinx™, Altera™, Actel™, and Lucent™. Industrial designers are increasingly capturing their designs using hardware description languages such as VHDL and Verilog. There are tools developed for FPGAs, which synthesize designs in VHDL format or other description format. Current synthesis tools for FPGAs are provided by companies Synopsys™, Synplicity™, and Leonardo Spectrum™. Physical design tools perform placement and routing for FPGAs. Xilinx™ and Altera™ provide place/route tools for their own FPGA devices.

Today's high-volume applications require a fabric with higher complexity and better performance than FPGAs. Also, shorter development cost and more flexible reconfiguration are required. Several contributions have been made in FPGA devices toward this direction. Capacity of FPGAs has been increased. High-density FPGAs are available in the market offering competitive solutions to ASICs and programmable systems such as DSPs. Hierarchical features have been added into logic and routing architecture of FPGAs. The new generation of FPGAs have a trend towards embedding coarser grain units. Most applications require a large amount of storage. Architectural support for implementation of memory is crucial. Some FPGA devices have embedded memory (RAM, ROM). In addition, implementing general logic in these embedded arrays of memory blocks is viable. In order to support high repetitive and data intensive computation on FPGAs more efficiently, arithmetic resources have been developed. Examples of such enhancement are cascade chain, multipliers, and dedicated adders, etc. Fine-grain FPGA architectures are shifting towards new architectures where memory blocks, hard IPs, and even CPUs are being integrated into FPGAs. In these designs the traditional FPGA is not a co-processor, instead a reconfigurable fabric is embracing all the mentioned components and enabling a much tighter integration among them. Today, FPGA CAD tools provide integration of macro blocks into designs. Macro blocks are optimized for area, delay, or power consumption. In addition, placement of such macro blocks can be predefined in CAD tools such as CoreGEN® integrated with Xilinx™ design implementation tool. MemGen® and LogiBlox® in Xilinx™ tool enable the implementation of embedded memory blocks. Hence, tool vendors are moving to higher-level optimization. There is better integration between synthesis and physical design tool.

Flexibility in reconfigurable systems comes at the expense of the reconfiguration time. The amount of time required to set the function to be implemented on the reconfigurable logic is the configuration time, which can become a serious bottleneck especially in systems where run-time reconfiguration is performed [3,4].

We have introduced a new architecture for a system that uses reconfigurable logic, which is referred to as a strategically programmable system (SPS) [5]. The basic building blocks of our architecture are parameterized functional blocks that are pre-placed within a fully reconfigurable fabric. They are called versatile parameterizable blocks (VPBs). When implementing an application, operations that can be mapped onto these fixed blocks will be performed by the VPBs; computational blocks that will be instantiated on the fully reconfigurable portion of the chip will perform the remaining operations. Properties of VPBs will be discussed in more detail in later sections. The motivation is to generate reconfigurable architectures that target a set of applications. Such architectures would contain VPBs to specially suit the needs of the particular family of applications. Yet the adaptable nature of our programmable device should not be severely restricted. The SPS will remain flexible enough to implement a very broad range of applications, thanks to the reconfigurable resources. These powerful features help our architecture maintain its tight relation to its predecessors, traditional FPGAs. At the same time the SPS is forming one of the first efforts in the direction of context-specific programmable devices.

Because the VPBs are custom made and fixed on the chip, they do not require configuration, hence there are considerably less switches to program as compared to the implementation of the same design on a traditional FPGA. More important, an instance of our SPS architecture is generated such that for a given set of applications the suitably selected fixed blocks provide the best performance.

In the proceeding sections, we introduce the basic concepts of our architecture and the notion of generating an instance of the SPS architecture for a given set of applications. We present a framework that provides tools for generating SPS instances and implementing applications once a fixed SPS architecture is given. In the following section, we present related work in the field of reconfigurable architecture. Examples of versatile programmable blocks are presented in Sections 36.3, 36.4 and 36.5 as well as details of our architecture. We complement our architecture with tools that perform the mapping of applications onto the architecture and the actual implementation and tuning for an application on our platform. These two major tasks will be discussed in Section 36.4. In Section 36.6 we present our preliminary results.

## 36.2 Related Work

---

With the current trend towards hybrid programmable architectures, new systems with embedded reconfigurable cores are also being developed. Among these architectures the basic distinction is due to the level of granularity of the reconfigurable logic.

Commercial FPGAs from several vendors such as Xilinx™, Altera™, and Actel™ are available in the market. Traditional FPGA chips like Xilinx™ 4000 series, or Altera™ Flex family all contain some form of an array of programmable logic blocks. Those blocks usually are not very complex and contain a few LUTs and a small amount of storage elements. They are designed for general-purpose use. Since they only contain fine-grain reconfigurable logic, for a new application to be implemented the whole chip goes through a configuration phase. Although newer devices such as Xilinx™ Virtex FPGA allow partial reconfiguration of selected rows or columns, this is still a critical issue.

Hybrid systems also contain reconfigurable cores as coprocessors. The Garp architecture developed at Berkeley combines a MIPS-II processor with a fine-grained FPGA coprocessor on the same die [6]. Unlike the Garp architecture the main load of hardware implementation lies on the coarse grain parameterized blocks in SPS architecture.

Chimaera [7] is a single chip integration of reconfigurable logic with a host processor. The reconfigurable coprocessor is responsible for performing the reconfigurable functional unit (RFU) instructions. An RFU instruction is any instruction from the program running on the host processor that is performed by the reconfigurable coprocessor. The Chimaera architecture is for a very specific class of data path applications and still requires a large amount of reconfiguration time.

Another reconfigurable architecture with fine granularity is the dynamically programmable gate array (DPGA) [8]. Although the logic structure is just like existing FPGAs, DPGAs differ from traditional

FPGAs by providing on-chip memory for multiple array configurations. The on-chip cache exploits high, local on-chip bandwidth to perform quick reconfiguration.

In addition, several systems with coarse-grain granularity exist, such as RaPiD [9], Raw [10], and Pleiades [11]. RaPiD is a configurable architecture that allows the user to construct custom application-specific architectures in a run-time configurable way. The system is a linear array of uncommitted functional units, which contain datapath registers, three ALUs, an integer multiplier, and some local memory. The RaPiD architecture targets applications that can be mapped to deep pipelines formed from the repeated functional units.

The Reconfigurable Architecture Workstation (Raw) is a set of replicated tiles, where each tile contains a simple RISC-like processor, small amount of bit-level configurable logic, and some memory for instructions and data.

The CS2112 reconfigurable communications processor (RCP) from Chameleon Systems, Inc.<sup>TM</sup> contains reconfigurable fabric organized in slices, each of which can be independently reconfigured. The CS2112 includes four slices consisting of three tiles. Each tile comprises seven 32-bit datapath units, two  $16 \times 24$ -bit single-cycle multipliers, four local store memories, and a control logic unit. The RCP uses a background configuration plane to perform quick reconfiguration. This reconfigurable fabric is combined with a 32-bit embedded processor subsystem.

The Pleiades architecture is a processor approach that combines an on-chip microprocessor with an array of heterogeneous programmable computational units of different granularities, connected by a reconfigurable interconnect network. The programmable units are MACs, ALUs, and an embedded FPGA.

Xilinx<sup>TM</sup> has recently introduced the Virtex-II<sup>®</sup> devices from the new Xilinx Platform FPGAs. The Virtex-II architecture includes new features such as up to 192 dedicated high-speed multipliers. Designers can use Virtex-II<sup>®</sup> devices to implement critical DSP elements of emerging broadband systems. This is somewhat a similar effort in the same direction that we are heading. The Virtex-II device is providing the dedicated high-performance multipliers for DSP applications like the VPBs on the SPS, which are intended to improve performance for a set of applications. SPS differs from a Virtex-II device in the following:

- The architecture can contain blocks of various complexities. Depending on the requirements of the applications fixed blocks can be as complex as an FFT block or as simple as an adder or multiplier. Examples of VPBs will be provided in the next section.
- The generation of an SPS instance is automated. Given a set of target applications an architecture generation tool determines the number and types of VPBs to be placed on the chip. Although the Virtex-II device is still general purpose, an instance of an SPS will be more context-defined according to a given set of applications.

## 36.3 Strategically Programmable System

---

Recently, reconfigurable fabric was integrated into SoCs forming hybrid (re)configurable systems. *Hybrid (re)configurable systems* contain some kind of computational unit, e.g., ALUs, intellectual property units (IPs) or even traditional general-purpose processors, embedded into a reconfigurable fabric (see Fig. 36.2).

One type of hybrid reconfigurable architecture embeds reconfigurable cores as a coprocessor to a general-purpose microprocessor, e.g., Garp [6] and Chimaera [7]. Another direction of new architectures considers integration of highly optimized hard cores and hardwired blocks with reconfigurable fabric. The main goal here is to utilize the optimized blocks to improve the system performance. Such programmable devices are targeted for a specific *context*—a class of similar applications, such as DSP, data communications (Xilinx Platform Series), or networking (Lucent's ORCA<sup>®</sup>). The embedded fixed blocks are tailored for the critical operations common to the application class. In essence, the programmable logic is supported with the high-density high-performance cores. The cores can be applied at various levels, such as the functional block level, e.g., fast Fourier transform (FFT) units, or at the level of basic arithmetic operations (multipliers).

FIGURE 36.2

Presently, a context-specific architecture is painstakingly developed by hand. The SPS explores an automated framework, where a systematic method generates context-specific programmable architectures.

The basic building blocks of the SPS architecture are parameterized functional blocks called VPBs. They are preplaced within a fully reconfigurable fabric. When implementing an application, operations can be performed on the VPBs or mapped onto the fully reconfigurable portion of the chip. An instance of our SPS architecture is generated for a given set of applications (specified by C or Fortran code). The functionality of the VPBs is tailored towards implementing those applications efficiently. The VPBs are customized and fixed on the chip; they do not require configuration, hence there are considerably less configuration bits to program as compared to the implementation of the same design on a traditional FPGA.

The motivation is to automate the process of developing hybrid reconfigurable architectures that target a set of applications. These architectures would contain VPBs that specially suit the needs of the particular family of applications. Yet, the adaptable nature of our architecture should not be severely restricted. The SPS remains flexible enough to implement a very broad range of applications due to the reconfigurable resources. These powerful features help the architecture maintain its tight relation to its predecessors, traditional FPGAs. At the same time the SPS is forming one of the first efforts in the direction of context-specific programmable devices.

In general, two aspects are part of the SPS system. The first area involves generating a context-specific architecture given a set of target applications. Once there is a context-specific architecture, one must also be able to map any application to the architecture.

## 36.4 Overview of SPS

### Versatile Parameterizable Blocks (VPBs)

The main components of SPS are the VPBs. The VPBs are embedded in a sea of fine-grain programmable logic blocks. Consider a lookup table (LUT) based logic blocks commonly referred to as combinatorial logic blocks (CLBs), though it is possible to envision other types of fine-grain logic blocks, e.g., PLA-based blocks.

Essentially, VPBs are hard-wired ASIC blocks that perform a complex function. Because the VPB is fixed resource, it requires little reconfiguration time when switching the functionality of the chip.\* Therefore, SPS is not limited by large reconfiguration times like current FPGAs. But, the system must strike a balance between flexibility and reconfiguration time. The system should not consist mainly of VPBs, as it will not be able to handle a wide range of functionality.

\* By functionally, we mean the application of the chip can change entirely, e.g., from image detection to image restoration, or part of the application can change, e.g., a different image detection algorithm.

FIGURE 36.3

There is a considerable range of functionality for the VPs. It ranges from high-level intensive tasks such as FFT to a “simple” arithmetic task like addition or multiplication. Obviously, there is a large range of complexity between these two extremes. Because we are automating the architecture generation process, we wish to extract common functionality for the given context (set of applications). The functionality should be as complex as possible while still serving a purpose to the applications in the context. An extremely complex function that is used frequently in only one application of the context would be wasted space when another application is performed on that architecture.

The past decade has brought about extensive research as to the architecture of FPGAs. As we previously discussed, many researchers have spent copious amounts of time analyzing the size and components of the LUT and the routing architecture. Instead of developing a new FPGA architecture, the SPS leverages the abundant body of FPGA architecture knowledge for our system. Embedding the VPs into the programmable logic is the most important task for the SPS architecture generation.

## SPS Framework

In this section, the tools and algorithms that actually generate strategically programmable systems and perform the mapping of applications on the architecture are discussed. The architecture formation phase and the architecture configuration phase are the two major parts of the framework. The SPS framework is summarized in Fig. 36.3.

### Architecture Formation

This task can be described as making the decision on the versatile programmable blocks to place on the SPS chip along with the placement of fine-grain reconfigurable portion and memory elements, given an application or class of applications. In this phase, SPS architecture is customized from scratch given certain directives. This process requires a detailed description of the target application as an input to the formation process. A tool will analyze these directives and generate the resulting architecture. Again, the relative placement of these blocks on the SPS chip along with the memory blocks and the fully reconfigurable portions need to be done by the architecture formation tool.

Unlike a conventional fine-grain reconfigurable architecture, a uniform distribution of configurable logic blocks does not exist on the SPS. Hence, for an efficient use of the chip area as well as high performance, the placement of VPs on the chip and the distribution of configurable logic block arrays and memory arrays among those are critical. The fact that the routing architecture supports such hybrid architecture is equally important and requires special consideration. If the routing architecture cannot provide sufficient

routing resources between the VPBs and the configurable blocks, the hardware resources will be wasted. The type and number of routing tracks and switches need to be decided such that the resulting routing architecture can support this novel architecture most efficiently. The most important issues here is the routability of the architecture and the delay in the connections.

**Fixed Architecture Configuration**

Another case to be considered is mapping an application onto a given architecture. At this point we need a compiler tailored for our SPS architecture. This SPS compiler is responsible for three major tasks.

The compiler has to identify the operations, groups of operations, or even functions in the given description of the input algorithm that are going to be performed by the fixed blocks. These portions will be mapped onto the VPBs and the information regarding the setting of the parameters of the VPBs will be sent to the SPS chip.

Second, the SPS compiler has to decide how to use the fully reconfigurable portion of the SPS. Based on the information on the available resources on the chip and the architecture, mapping of suitable functions on the fine-grain reconfigurable logic will be performed. Combining these two tasks the compiler will generate the scheduling of selected operations on either type of logic.

Finally, memory and register allocation need to be done. An efficient utilization of the available RAM blocks on the SPS has to be realized.

**36.5 Target Applications**

The first set of applications is DSP applications. Repetitive arithmetic operations on a large amount of data can be very efficiently implemented using hardware. The primary examples focus on several image-processing applications. This soon will be extended to cover other types of applications. First, algorithms that have common properties and operations are grouped together. Such algorithms can use a common set of VPBs for their implementation. The algorithms and the classes to which they belong are summarized in [Table 36.1](#).

Image-processing operations can be classified into three categories. Those that generate an output using the value of a single pixel (point processing), those that take a group of neighboring pixels as input (local processing), and those that generate their output based upon the pixel values of the whole image (global operations) [12]. Point and local processing operations are the most suitable for hardware implementation, because they are highly parallelizable. We have designed three blocks, each representing one algorithm class. The blocks that we are currently considering are described in the following. Later, a reference will be made to the implementation of these blocks on fully reconfigurable logic versus the parameterized block realization and present the potential reduction in the number of configuration bits.

**Filter Operations Block**

Many signal-processing algorithms are in essence filtering operations. Basically weighted sum of a collection of pixels indicated by the current position of the mask over the image is computed for each pixel.

The filter block is currently the most complex block we have designed. It is developed to cover an iterative image restoration algorithm, and several other filtering operations such as, mean computation, noise reduction, high pass sharpening, Laplace operator, and edge detection operators (e.g., Prewitt, Sobel). The block diagram is shown in [Fig. 36.4](#).

**TABLE 36.1** Classification of Algorithms

Algorithms	Operations	Class
Image restoration, mean computation, noise reduction, sharpening/smoothing filter	Weighted sum, addition, subtraction, multiplication	Filter operations
Image half-toning, edge detection	Comparison	Thresholding
Image darkening, image lightening	Addition, subtraction	Pixel modification

FIGURE 36.4

The general form of the computation that this block performs is given by the following equations:

$$\text{weighted\_sum} = \text{Sum}\{w_i \times \text{input\_pixel}_i\}$$

$$\text{output\_pixel\_value} = B \times \text{input\_pixel\_value} + A \times \text{pixel\_value\_from\_prev\_iteration} - b$$

$$\quad \quad \quad \times \text{weighted\_sum} + c \times \text{weighted\_sum}$$

This block takes five parameters that define its operation. The mask coefficients array holds the values of the coefficients. The parameters  $B$ ,  $A$ , and  $c$  all take the value zero for all the functions except the iterative image restoration algorithm.

### Thresholding Block

The operators in this class produce results based on a single pixel's value. The computation is rather simple; it compares the value of the input pixel to a predetermined threshold value. The output pixel value is determined accordingly. The parameters of this block are the threshold value  $T$  and the algorithm selection input. For the image halftoning application, the threshold value  $T$  is set to be 127, where the pixel values range between 0 (black) and 255 (white). If the pixel value is above threshold, output is given as 255, otherwise it is 0. For the edge detection operation, the output is set equal to the input value if the pixel value is above threshold, and to 0 otherwise.

### Pixel Modification Block

Pixel modification operations are point-processing operations. This block performs darkening, lightening, and negation of images. It takes two parameters,  $J$  and algorithm selection input ALG. For the darkening operation a positive value  $J$  is added to the input pixel value. Lightening is achieved by subtracting  $J$  from each input pixel. The negative of an image is achieved by subtracting the input pixel value from  $J$ , which takes the value 255 for this case.

## 36.6 Experiments

In this section, the author presents the experiments to estimate the potential gain in reconfiguration time that our SPS architecture will yield. This is an exploration of the reduction in reconfiguration bits that would follow as a result of providing preplaced computation blocks with our coarse grain architecture.

### Application Profiling

First, a profiling has been done on the image processing benchmarks in order to gain insight into what type of components are used more frequently. Such a profile can give directives to the architecture formation tool and guide it to employ certain blocks. Looking at the numbers and types of components that were selected by our scheduling tool, we have obtained the component usage profile as shown in Fig. 36.5.

FIGURE 36.5

The first version of the experimental SPS architecture will be created, given the directives from the profiling information. According to Fig. 36.5 the most popular component is the adder with an average of approximately 14 adders per benchmark. Some components such as the 8-bit multiply and bit-wise could not average over 1. These components can be eliminated and we will focus on the rest and decide how many of each of the remaining ones to use on the SPS. If the numbers are normalized according to the constant multiplier, for each constant multiplier there would be one comparator, one subtractor, two right shifters, two left shifters, and seven adders. In the next section, this information will be used to estimate the gain of fixing different numbers of components on the chip. The start point will be the relative usage values given by our analysis.

## Reconfiguration Time

In the ideal case, the preplaced blocks should cover all the operations in our target applications such that we can fully exploit the benefits of the custom designed high-performance blocks and improved reconfiguration time. In reality it is not possible to create such an architecture that would support every operation that might be encountered in a wide variety of applications. Hence, in cases where provided blocks are not adequate, extra components are instantiated on the reconfigurable fabric. Here, we evaluate the gain that the VPBs would bring to the configuration process. Our scheduler uses the blocks that are made available and as many additional components as necessary for the best latency. As a result it produces an assignment of the operations to the hardware resources.

Compare the implementation of the same design on two architectures: a traditional fine-grain FPGA and a SPS. We are fixing certain blocks on the SPS assuming they are pre-placed blocks on the chip. These blocks will be the gain in reconfiguration time if they are used by the given application. The potential gain is modeled in configuration time by assuming that the number of configuration bits is proportional to the amount of logic to be implemented on the reconfigurable fabric. The higher the contribution of the pre-placed blocks is to the total design, the more reduction in reconfiguration time is achieved.

Initially, an architecture is evaluated, which contains low-level blocks such as adders and subtractors. A set of functional blocks fixed on the chip is provided to the scheduler for operation assignment. The scheduler decides on the types and numbers of additional components, if they are needed. The first experiment fixes seven 8-bit adders, one 8-bit subtractor, two right shifters, two left shifters, and one constant multiplier. Then we have doubled the amount of hardware fixed in proportion at each step except the last one, where we have increased the fixed hardware 50% from the previous setup. Figure 36.6 presents the relative gains in configuration times for different setups. Observe how the gain in reconfiguration time improves with more logic provided, and how this trend saturates at a certain point. For the initial architecture setup the average reduction in reconfiguration time is 35%. Observe that, as resources available on the chip are duplicated, this reduction goes as high as 75%.

**TABLE 36.2** Programming Bits Required Implementing the VPBs with Reconfigurable Logic

Parameterizable Block	Size (CLBs)	Programming Bits
Pixel modification	30	29,910
Thresholding	11	10,967
Filtering	99	98,703

**FIGURE 36.6**

If a VPB can cover all operations of an application, then the largest gain can be obtained. Our image processing blocks presented in Section 36.5 will serve this purpose. They are capable of supporting several different image-processing applications. For the three blocks that we are initially considering, the potential savings in the number of programming bits is shown in Table 36.2. We have synthesized three parameterized designs for these blocks and obtained area information. Using the CLB count for these blocks we can estimate the number of programming bits required, proportional to the size of the designs just as we did for the first set of experiments. We assume that the reconfigurable fabric is similar to a Virtex chip. By using the numbers reported in [13] we derive the number of programming bits required per CLB and hence per parameterizable block.

## 36.7 Conclusion

A novel reconfigurable architecture was presented. The SPS can provide the degree of flexibility required in today's systems. Although offering high-performance for its application set and still a high degree of flexibility for other applications, the architecture promises a good performance and smaller reconfiguration time as well. Experiments indicate that a proper selection of common blocks among a fairly wide range of applications can yield an average reduction of 35% up to 100% in the number of programming bits that need to be transferred to the chip for configuration/reconfiguration. Because the VPBs eliminate a considerable amount of programming switches on the chip, the improvement in delay will be accompanied by improved power consumption as well. The individual VPBs will be designed targeting the best trade-off between delay and power consumption. Implementation of applications that are within the covering region of this system will highly benefit from these abilities.

## 37.1 Reconfigurable Computing

---

*John Morris*

### Preamble

Architects of general-purpose processors face a herculean task: to design a processor that will run *every* application fast. However, applications vary widely in instruction mix, frequency, and patterns of data access, input and output bandwidth requirements, etc. A designer may incorporate elaborate and space-consuming circuitry that simulation shows will dramatically improve performance for one application but has no effect on another—or worse, slows it down. For example, designers will normally incorporate as large a cache as space allows on a die, since cache speeds up most applications; however, the data cache adds nothing to the performance of an application that copies data from one place to another.

Programmable hardware can be used to build systems in which the circuitry matches the structure of the problem. In particular, inherent parallelism in problems, which a general-purpose processor—despite multiple “go-fast” enhancements—cannot exploit, can be exploited in a system in which multiple circuits are used to speed up the computation.

### Programmable Hardware

Programmable hardware has evolved in capability and performance—tracking processor capabilities for many years now. Designers have a wide spectrum of devices that they can draw upon—from ones that

provide a handful of gates and flip-flops to ones that provide well over a million gates.<sup>1</sup> In addition, modern devices provide:

- Considerable on-chip memory: this partially overcomes an inability of early devices to effectively solve problems that required more than a few memory bits
- Large numbers of I/O pins—permitting high data bandwidths between a custom processor and its environment
- Multiple I/O protocols, such as LVDS, GTL, and LVPECL—enabling high speed serial channels between the device and other components of a system

Programmability may be provided by a number of technologies:

- Fuses or anti-fuses, in which links are programmed open or closed
- EEPROM, in which a configuration bit is stored in nonvolatile read-only memory, and
- Static RAM cells, which store configuration bits, but, which need to be reloaded every time the device is powered up

Thus, a designer has a broad palette of devices on which to base a system design. All the usual trade-offs apply: in particular, the ability to change the circuit by reprogramming it invariably introduces a speed penalty. A configurable circuit is more complex and has longer propagation delays than a fixed one: this translates to a slower maximum clock frequency. This trade-off is discussed further when we consider whether an application is a good candidate for a reconfigurable processor compared to a general-purpose commodity processor.

A number of terms have been used to describe programmable devices. Simple early devices (ones with a simple programmable and-or array, coupled with ~10 flip-flops and ~20 I/O pins) were commonly called “programmable array logic” chips or PALs, but a host of other similar terms have been used for marketing purposes. The most important group of devices for building processors are now almost universally termed “field programmable gate arrays” (FPGAs)<sup>2</sup> and this chapter section will focus on them as the key building blocks of a reconfigurable system. As with general-purpose processors, designing a “universal” FPGA is essentially an impossible task and a number of different architectural styles have been proposed and manufactured. The following subsections will describe the key elements of some representative devices.

## FPGA Architectures

An FPGA’s capability can usually be described in terms of three elements:

- *Logic blocks*: These are small blocks of logic, commonly consisting of a small number of simple and-or arrays, some multiplexers for steering signals, one or two flip-flops. Other features such as memory bits, lookup tables, special logic for handling the carry chains in adders, etc., may be present also. Marketing pressures have produced a bewildering array of names for these blocks: fortunately, most of them are readily understood. Examples are logic array blocks (Altera APEX 20k family), logic elements (Altera FLEX 10KE), macrocells (Altera MAX7000/MAX3000), configurable logic blocks (Xilinx), and programmable function units (Lucent ORCA).
- *Routing resources*: A typical FPGA will provide lines of various lengths to interconnect the logic blocks. Short lines provide low propagation delay paths between neighbouring blocks; longer lines connect more distant blocks with low delay. A small number of buffered low delay lines, which can interconnect large groups of logic blocks are usually provided for clocks.

---

<sup>1</sup>2001 value: apply Moore’s Law for 2002 and forward.

<sup>2</sup>Market habits die hard, though: Altera persists in referring to its devices as programmable logic devices (PLDs).

FIGURE 37.1 Simplified block diagram of the Xilinx XC4000 device control logic block. (The XC4000 CLBs have additional capabilities [1].)

- *I/O buffers*: Special purpose logic blocks provide interfaces to external circuitry. In modern devices, the I/O buffers provide a variety of electrical protocols eliminating the need to use special interface buffers. Reducing chip-to-chip connections provides greater data transfer bandwidth between the reconfigurable processor and its environment.

Recent devices include memory blocks, which may be configured in several ways.

### ***Xilinx 4000 and on***

Xilinx' 4000 series devices [1] were not the first of their family, there were several antecedents; however, in order to avoid turning this chapter section into a history lesson, I will describe it first the author. It is a good representative of a number of commercially available devices.

### ***Control Logic Blocks***

Figure 37.1 shows the essential features of the 4000 series control logic blocks (CLBs). It contains three logic function blocks—each capable of implementing any arbitrarily defined boolean function of its inputs—and two flip-flops controlled by a common clock. “Programming” the device sets the logic functions in the logic function blocks, the signal steering multiplexers and the set/reset control. There are nine basic inputs: F<sub>1-4</sub>, G<sub>1-4</sub> and C<sub>4</sub> (a direct data input to the flip-flops) and four outputs—two registered and two combinatorial. Paths can be chosen which bypass either or both flip-flops. Xilinx's designers have chosen to implement a moderately complex logic block. In contrast, Altera devices have simpler logic blocks with a single flip-flop[2] and Quicklogic's super cells are more complex [3]. Lucent refers to the ORCA logic block as a programmable functional unit (PFU) reflecting its complexity: 19 inputs and 4 flip-flops [4]. Additionally, the logic in the function blocks can be configured to act as a block of RAM, which can be configured as 16 × 1, 16 × 2, or 32 × 1 bit blocks. Without this capability, applications requiring memory are forced to use the CLB flip-flops, using a whole CLB for each 2 bits. This was a significant limitation of early devices, but newer ones, in addition to the 32 bits per CLB provided in the 4000 series, provide dedicated RAM blocks with significant capacities [2,5].

### ***Routing Resources***

A great challenge to FPGA designers is achieving a good balance in the allocation of die area to programmable logic (the CLBs) versus routing resources. The XC4000 designers provide a combination of short lines which connect each CLB to a programmable switch matrix adjacent to it, double and quad length lines which connect every second (or fourth) switch matrix, and long lines which run the entire length of a device (see Fig. 37.2). Connections through the switch matrices provide ultimate flexibility—any

**FIGURE 37.2** Conceptual view of the routing on an XC4000 device showing the pattern of logic blocks (CLBs) embedded in “channels” of routing resources. Direct connections to the programmable switch matrix (PSM) are shown as well as the patterns for double lines connecting every second PSM. Similarly, quad lines (omitted) connect every fourth PSM. Long lines run the length of horizontal and vertical channels. This is a concept diagram only: actual devices may differ in details [1].

**FIGURE 37.3** Simplified block diagram showing essential features of the Xilinx XC4000 input/output block (IOB). (The XC4000 IOBs have additional capabilities [1].)

CLB may be connected to any other; however, there is a penalty: the switch points are implemented with pass transistors which add to the propagation delay of any signal passing through them. Thus, the short lines through the switch matrices should not be used for critical signals connecting widely separated CLBs. The double, quad, or long lines need to be used to reduce delays. Predicting the optimal allocation for any application is obviously a hard task and many strategies may be seen in the commercially available devices. For example, Altera’s Apex 20K devices employ a hierarchical structure, grouping basic logic elements (LEs) into logic array blocks (LABs), which are in turn grouped into MegaLABs [2]. Each block has appropriate internal routing resources. Copper is also used to reduce resistance and thus propagation delay.

### *I/O Buffers*

I/O buffers provide circuitry to interface with external devices. Apart from input buffers and output drivers, the main additional feature is the ability to latch both inputs and outputs. The simplified diagram of an XC4000 I/O buffer (IOB) in Fig. 37.3 shows the output driver, input buffer, registers, several

inverters, and the programmable multiplexors. The inverters provide almost all combinations of normal and inverted direct output or latched signals synchronized with direct or inverted clocks: this avoids the need to use resources in the CLBs simply to invert signals. Limited slew rate control was also added to the output buffers—a precursor to the support for multiple electrical protocols now found in more modern designs.

#### *Additional Features*

Adders, including counters, occur on the critical paths in many calculations, so the 4000 series, like most of its modern counterparts, provides “fast-carry” logic. Ripple carry adders are simple, regular, and use minimal logic, but they must wait until a carry bit has “rippled” through all the summing (full adder) blocks. By providing a fast, direct path for carry bits between blocks, the critical delay in a ripple carry adder is significantly reduced. The fast carry logic is so effective that there is no advantage to be gained from more complex adders, such as carry-lookahead ones. A carry-lookahead adder requires a much larger number of CLBs and the signal propagation times between these additional CLBs outweigh any benefit to be gained from a complex adder: trials with carry-lookahead adders show them to be slower than ripple carry adders that use the fast-carry logic [6].

The special needs of global clocks are addressed by providing “semi-dedicated” I/O pads connected to four primary global buffers designed for minimum delay and skew. The clocks of each CLB can be connected to these global buffers, a set of secondary buffers or any other internal signal. Thus multiple global and local clock domains can be established.

Problem diagnosis and boundary scan testing is facilitated through support for IEEE 1149.1 (JTAG) boundary scan logic attached to each I/O buffer.

The CLB structure lends itself to efficient implementation of functions of up to 9 inputs, but address decoders commonly require many more bits. Special decoders accepting up to 132 bits for large XC4000 devices are provided to ensure fast, resource-efficient decoding.

A simple internal oscillator and divider provides clock signals when precise frequencies are not required.

#### ***Virtex***

The Virtex family [5] are enhanced versions of the Xilinx 4000 series. Improved process technology has allowed the gate capacity to exceed one million ( $4 \times 10^6$  are claimed for the largest member of the family, requiring 2 MB of configuration data). Supply voltages as low as 1.8 V allow internal clocks up to 400 MHz to be used.

#### *Memory*

Blocks of dedicated memory are now provided, which can be programmed to a number of single- and dual-port configurations. This will allow considerable performance enhancements for designs which were previously forced to use external memory.

#### *I/O Buffers*

One of the most dramatic additions to the newest devices from all manufacturers is the support of numerous electrical protocols at the I/O pins. For example, Virtex supports single-ended standards: LVTTTL, LVCMOS, PCI-X, GTL, GTLP, HSTL, SSTL, AGP-2X and differential standards: LVDS, BLVDS, ULVDS, LDT, and LVPECL. Support for PCI-X means that a Virtex device can implement the industry-standard PCI interface, considerably reducing the complexity of PCI cards which can now combine interface logic, control logic, some memory, and external bus interfaces (e.g., LVDS) in a single chip.

Virtex devices are also partially reconfigurable: individual columns may be reprogrammed.

#### ***Algotronix***

Algotronix’s approach to FPGA design was radically different from the Xilinx<sup>3</sup> approach. Cells were much simpler *and used for routing as well as logic*. The basic cell is shown in Fig. 37.4. By using a much simpler cell, it becomes possible to fit more logic per silicon die and the XC6264 device [7] was rated as containing

---

<sup>3</sup>However, Algotronix was taken over by Xilinx and its devices appeared as the Xilinx XC6200 series [7].

FIGURE 37.4 Block diagram of the cell in an XC6200 device. This cell is used for routing also.

$10^5$  gate equivalents early in 1997—about twice as many as devices with distinct logic blocks and routing resources at the same time. Routing—other than between neighboring cells—uses the logic cells programmed simply to route a signal from input to output. Signals routed in this way pass through transmission gates and suffer significant delays, so the XC6200 devices provided a hierarchy of “FastLANE” connections, which linked lines of 4 and 16 cells.

These devices also permitted fast reconfiguration: the SRAM cells that hold the configuration data can be directly addressed so that part of an operating circuit may be quickly reconfigured. (By contrast, the XC4000 devices are programmed either with a serial bit stream or byte-by-byte from an EEROM—requiring milliseconds for a complete chip to be reconfigured.)

The “sea-of-gates” approach provided by the XC6200 devices may be viewed as one end of a spectrum stretching from simple cell/no dedicated routing devices to complex cell/dedicated routing devices such as the XC4000 and most other commercially available devices. Regular applications requiring large numbers of operations or very wide uniform data paths are likely to match a sea-of-gates device better. Less regular problems with complex control requirements—requiring functions of many signals—are likely to match the complex logic device devices better. The industry, however, appears to have voted strongly for complex logic block devices and the XC6200 series is no longer commercially available.

## Reconfigurable Systems

Reconfigurable systems are easy to build: a designer has only to decide what interconnection patterns will best serve the needs of target applications and some systems, e.g., UWA’s Achilles, even allow that to be deferred. The major proportion of the circuitry may be changed once the basic hardware system has been constructed. As a consequence, an enormous number of experimental and several commercial systems have been built: Guccione has compiled a list, it contains summaries of over 80 systems [8]. An attempt to cover all of these is clearly futile: a small representative sample has been chosen.

### SPLASH 2

One of the best known systems is SRC’s SPLASH 2 [9]. It consists of an array of FPGAs and interface allowing the array to be attached to a SPARC host. The FPGA array itself was composed of a number of array boards, each containing 17 Xilinx XC4010 FPGAs—16 “computing” devices and one interface device. Typical of devices of its time (~1990), the XC4010 can provide limited amounts of memory itself, so 512 KB of conventional memory were attached to each FPGA. Apart from nearest neighbour connections, a crossbar switch permitted dynamic (“almost” tick-by-tick [9]) connection changes to be made.

## Programmable Active Memories (PAM)

A dozen copies of the variant named DECPeRLe-1 found their way into research centers around the world and were applied to a diverse set of problems [10]. The computing surface was a  $4 \times 4$  array of XC3090 devices with seven additional FPGAs acting as memory and interface controllers. FPGAs in the array were connected directly to each of their four neighbours. Devices in each row and column shared common 16-bit buses, so that there were four 64-bit buses running the length of the array—one for each geographic direction N, S, E, and W. Static RAM was added to provide the storage lacking in the early devices used and FIFOs provided elasticity in a high-speed interface to a host processor. Vuillemin et al. discuss an extensive list of problems to which PAMs were applied [10]: long integer arithmetic, RSA cryptography, molecular biology, finite differences, neural networks, video compression, image classification, image analysis, cluster detection, image acquisition, stereo vision, sound synthesis, and Viterbi decoding.

They consistently applied the following rule in deciding what part of any problem should be allocated to the hardware:

“Cast the inner loop in PAM hardware; let software handle the rest [10]!”

PAM spawned a successor, PAMETTE, a PCI card with 5 Xilinx 4000 series devices on it [11]. One device served as the PCI interface with the remaining four arranged in a  $2 \times 2$  matrix. SRAM and DRAM may be added and provision is made for external connections via a daughter board. A large number of similar boards—all with the same basic idea: place a number of FPGAs on a card, which may be inserted into the bus of a suitable host—have been designed by research groups. Several commercial products are also available.

## SPACE

The Scalable Parallel Architecture for Concurrency Experiments (SPACE) machine was developed at the University of Strathclyde [12]; it was followed by the SPACE-II, built at the University of South Australia [13]. Both variants used fine-grain FPGAs (Algotronix CAL1024s in SPACE and Xilinx XC6216s in SPACE 2) as the primary target was the simulation of highly concurrent systems such as digital circuits, traffic systems, particle flow, and electrical stimuli models of the heart. SPACE 2 processor boards contained 8 XC6216 processor FPGAs and an XC4025 providing a PCI interface to an Alpha host. On each board, the fine-grained processors are connected in a mesh in order to provide a seamless array of gates on the board. Additional memory (32 Mb of static RAM) was present on each board. A secondary backplane allowed high-bandwidth connections between SPACE 2 boards.

## Achilles

The Achilles architecture aims to provide much more flexible interconnection patterns: [Figure 37.5](#) shows the 3-D arrangement in which small PCBs containing a single FPGA are arranged in a vertical “stack” [14,15]. A limited number of fixed bussed interconnections are provided at the base of the stack, committing only about one-third of the available I/O pins to fixed interconnect. A second side of the stack is used for programming and diagnostic connections: this enables the stack to be “gang” programmed—each FPGA is loaded with an identical program—or individually. The remaining two sides have uncommitted connections: connectors are provided for groups of eight signals and ribbon cables are used to connect FPGAs as the target application requires. This system offers wide variations in communication patterns at the expense of manual reconfiguration.

## Applications

The list of applications, which have been successfully implemented in reconfigurable hardware systems, is long; it includes applications from such diverse areas as:

- Image processing
- Cryptography

**FIGURE 37.5** Achilles 3-D stack. Each small PCB contains one FPGA: connections are made by cabling between the connectors visible on each small PCB.

- Database and text searching
- Compression
- Signal processing

It is generally straightforward to transfer an algorithm from a general-purpose processor to reconfigurable hardware; synthesizers which convert VHDL or Verilog models into the bit streams necessary to program an FPGA-based system are available and efficient; however, a *successful* transfer must provide a solution which is more efficient, by some criterion, than the same algorithm running on fast commodity general-purpose processors. Reconfigurable hardware generally runs slower,<sup>4</sup> consumes more power, and costs more than commodity processors. This remains true at most points in the performance spectrum. At the low performance end, small processors, e.g., Motorola's HC11 series, are available at very low cost and very low power consumption and will thus perform simple control and data processing tasks effectively. Although a modern FPGA may outperform the relatively slow processors available at the low end of the performance spectrum, there are a host of general-purpose embedded processors, e.g., the PowerPC-based devices, which will provide the additional processing power while still consuming less power and costing less than an FPGA. At the high performance end of the spectrum, the internal clock speeds of FPGAs lag behind those of commodity processors and thus their sequential processing capability does not match that of, for example, a state-of-the-art Pentium or SPARC processor; however, although it is clear that reconfigurable hardware will not provide efficient solutions for all problems, there are areas in which it is extremely efficient.

The general characteristics of successful applications are

- (a) *Sufficient parallelism*: The processing algorithm must have sufficient inherent parallelism to allow multiple processing pipelines to be created. This parallelism can be either *direct* or *pipelined*.
- (b) *Low storage requirements*: Early FPGAs provided very few bits of memory—the flip-flops in logic blocks were an expensive way to provide memory. Later FPGAs have addressed this problem by allowing the configuration bits to be used as lookup tables and thus provides tens of bits per logic block. The newest generation of FPGAs provide blocks of dedicated memory but capacities are

<sup>4</sup>However, Tsu et al., argue that there is no inherent reason why an FPGA should be slower [16].

measured in megabits, not megabytes. Although external memory can always be added and wide buses employed to provide high bandwidth, this uses valuable I/O pins, the path to external memory is likely to become a bottleneck and limit performance.

- (c) “*Decision-free*” *processing patterns*: Multiplexors in the data paths will readily handle simple decisions, which switch the dataflow between down-line functional blocks, but complex decision trees will generally not map efficiently to hardware. When large numbers of branches exist, inevitably many paths are little used and thus expensive to implement in fixed hardware relative to their benefit. In particular, error handling logic will generally be complex relative to its frequency of use. Complex decision logic is efficiently handled in high-performance modern processors, which move common logic to cache at the expense of little used code. When branches have similar probabilities, speculative execution ensures good average rates of instruction completion. However, this criterion for successful hardware implementation should be applied with caution: if high throughput for all possible processing paths is required, then the resources devoted to implementing all paths (including little used ones) may be justified. In the near future, dynamically reconfigurable logic may also provide effective solutions when there are complex decision trees.
- (d) Ability to use local (i.e., between neighbouring devices) data paths in problems that are large enough to require multiple devices. Most systems provide high-bandwidth paths between nearest neighbors with lower-bandwidth multiple device buses and global interconnects. The 3-D Achilles design provides more device–device data path flexibility but at a cost—wiring patterns must be set up manually for each application [14].
- (e) *Integer arithmetic*: Although it is possible to implement arbitrary precision floating-point processors in FPGAs, the number of logic blocks required and hence the delays introduced by data paths between logic blocks make them expensive in area and low in performance compared to those found in superscalar processors.<sup>5</sup> On the other hand, the ability to easily implement arbitrary precision integer arithmetic allows a reconfigurable system designer to pack more functional units of higher performance into a given area by choosing the minimum required word length.

## Image Processing

Real-time image processing presents a classic application for custom processors. A stream of pixels emanating from a camera can be passed through a wide deep pipeline—performing as many unrelated and complex operations on each pixel as needed. Unrelated operations (e.g., thresholding and masking) are performed in parallel and complex operations (e.g., masking) are performed in deep pipelines. For basic operations, little storage is required and the relatively inefficient memory on an FPGA suffices. A masking operation, such as applying a  $3 \times 3$  mask to a group of neighboring pixels, requires the storage of two scanlines in a shift register and thus is feasible in large FPGAs. The reverse process, visualisation, or the processing of machine generated images for display is already the domain of special purpose processors, but market volumes have justified use of ASICs.<sup>6</sup>

## Stereo Vision

The matching problem dominates research into fully automated stereo vision systems; it requires the comparison of pixels (or regions of pixels) to determine matches between corresponding segments of two images. The distance between matching regions on the left and right images (the disparity) is combined with camera system geometry to determine the distance to objects in the field of view. Without the apparent ability of a human brain to “jump” to the obvious match, a machine must try all possible disparities in order to find candidate matches between pixels or to correlate regions. Objects close to the camera system

---

<sup>5</sup>Superscalar processor manufacturers are also prepared to invest large amounts in order to win benchmark competitions, which allows man-years of effort to be used to optimize individual circuits and layouts.

<sup>6</sup>However, prototyping designs which are destined for ASICs are a major application for reconfigurable processors. They can be used to ensure that a design is correct and that the silicon will function correctly first time. Some foundries will take FPGA-based designs and convert them directly to ASICs.

have disparities approaching infinity, but one of the major applications of stereo vision is collision avoidance in which it is possible to put a lower bound on the distances of objects from the camera.<sup>7</sup> In practical camera systems, this results in a need to consider objects with disparities from 0 pixels (i.e., at infinity) to of the order of 10–100 pixels at closest permissible approach. Thus this problem has all of the required attributes for an efficient pipeline parallel implementation:

- Parallelism of 10–100 or more
- Simple calculations (comparing pixel intensities)
- Regular computation (the same correlation operators are applied to each pixel)

Woodfill et al., using the census transform to reduce problems caused by intensity variations and depth discontinuities, programmed a PARTS engine [17] to calculate object depths from pairs of  $320 \times 240$  pixel images. With a maximum disparity of 32, their system was able to compute depth at 42 frames per second [18]. They estimated that it was performing about  $2.3 \times 10^9$  RISC equivalent operations per second. Piacentino et al. have built a video processing system (Sarnoff Vision Front End 200) in which reconfigurable processing elements are used not only for stereo computations, but for motion estimation and warping also [19]. They estimate that the VFE-200 can provide ~500 GOPS of processing power.

### Encryption/Decryption

Shand and Vuillemin have used RSA cryptography as a benchmark for their PAM machines; they were able to demonstrate an order of magnitude improvement in performance relative to the best software implementations of the time. In 1992, PAM achieved over 1 Mb/s for 512 bit keys compared to 56 kb/s on a 150 MHz Alpha processor [20]. This relative performance will not change; state-of-the-art FPGAs can now fit the entire PAM system in a single device, giving the reconfigurable hardware system additional speed as it no longer needs to use slower inter-device links or external memory.

Symmetric encryption algorithms are easily and efficiently implemented in FPGAs; they require a number of “rounds” of application of simple operations. Each round can be implemented as a pipeline stage. Thus, as an example, TwoFish [21] requires 16 rounds of lookup table accesses, which can be implemented as a 16-stage pipeline. This allows a stream of 32-bit input data words to be encrypted at very high input frequencies with a latency of 16 cycles. In a study of four AES candidates, Elbirt et al. report an order of magnitude difference between FPGA-based implementations and the best software ones [22]; however, they also note that for one AES candidate, CAST-256, FPGA implementations were slower than their software counterparts. This result highlights the fact that the performance advantage of commodity processors can only be overcome when the problem matches the capabilities of FPGA-based custom processors. By adding further pipeline stages within each round—24 for TwoFish, for example—Chodowicz et al. were able to achieve throughputs greater than 10 Gb/s for five of the AES candidate algorithms (12 Gb/s using a 95 MHz internal clock for Rijndael, the eventual winner of the AES competition) [23].

Secure communications systems require encryption hardware; placing the encryption subsystem in hardware makes it less susceptible to tampering and enables keys to be hidden in “write-only” registers. Reconfigurable hardware provides an additional capability, algorithm agility [24]. This not only enables an encryption algorithm which has become insecure to be replaced with a secure one, but permits an algorithm independent security protocol to use the hardware effectively, loading the appropriate algorithm on a transaction-by-transaction basis.

### Compression

Using a systolic array style implementation of the LZ algorithm, Huang et al. were able to obtain throughputs 30 times greater than those achievable with commodity processors [25]. This speedup was obtained even though their FPGAs (Xilinx XC4036s) were clocked at 16 MHz versus 450 MHz for the fastest software implementation. Huang et al. believe that even better relative performance would be obtained

---

<sup>7</sup>The vehicle carrying the camera system is expected to move away before this bound is violated.

from modern FPGAs, e.g., Altera's APEX 20K devices have built-in content addressable memories (CAMs), which would speed up the process of matching input strings with the dictionary.

### **Arithmetic**

When designing a reconfigurable system, the widths of arithmetic function units, and hence their propagation delays, can be constrained trivially to the number of bits actually required for the application. This saves space, logic resources, and time. Designers also have considerable flexibility when complex arithmetic expressions must be evaluated; they can choose a single-stage combinatorial circuit or increase throughput by adding registers and forming a pipeline. This can often be done at essentially no cost: the logic blocks contain flip-flops already, so there is no space penalty and negligible time penalty.

An application requiring floating point arithmetic may be a poor candidate for a reconfigurable system—to achieve performance comparable to that offered by a commodity processor will require significant effort; however, reconfigurable systems are excellent at processing streams of data from sensors: this data will be fixed point and readily handled by the same circuits used for integer arithmetic.

### **CORDIC**

Even trigonometric functions of fixed-point data are readily implemented using CORDIC arithmetic. CORDIC algorithms are iterative, but require only shifts and adds. Again, the designer has a large space in which to work [26]. Bit-serial designs are simple and compact, but require many cycles; this may not be a problem if the input data rate is relatively slow. An iterative bit-parallel design will require more space but fewer cycles. Finally, the iterative loop can be unrolled by one or more stages to produce the desired throughput/space balance.

### **String and Text Matching**

Genetic sequencing technology is just one technology that is producing enormous databases of data that must be searched. Thus, there has been considerable interest in hardware to accelerate the process of comparing new sequences with those in existing databases. Biologists use a measure known as the edit distance when comparing sequences. A simple implementation of a dynamic algorithm can compute the edit distance in  $O(mn)$  time ( $m, n$  = length of source and target sequences, respectively), but if the calculation is carried out on a processor array, then it can be seen that all operations on the diagonal may be performed in parallel. A single board Splash 2 machine achieved a factor of 20 speedup over a CM-2—a massively parallel processor [27]!

Similarly, full text searching of documents for relevance has sufficient parallelism to make FPGA-based hardware effective. When document content cannot be adequately described by keywords, a searcher will supply a list of relevant words and require that every word of every document be checked against the list in order to build a relevance score for each document. Gunther et al. demonstrated that the original SPACE machine was effective in this application [28]. They used a technique called “data folding” in which the data are built into the circuitry. Match circuitry is built for each of the words in the list of relevant words and incorporated into a fixed matching structure. This is an excellent example of the power of partial reconfiguration; circuit patterns corresponding to the relevant words are loaded for each new search. They demonstrate that matching in hardware does not need to be limited to direct character-by-character matching. It is possible to implement simple regular expressions allowing, e.g., matching on the root of a word only. Overall the system is able to test for each word in the relevant list in parallel and aggregate a weighted relevance score as the document is read, results become available at a rate which is basically limited by the rate at which documents can be read from disc.

### **Simulations**

Cellular automata map readily to reconfigurable systems. They involve arrays of cells: each cell is a simple finite state machine whose behavior depends only on its current state and the state of cells in its immediate environment. Milne extends the fundamental cellular automata concept by removing the restrictions on identical components, uniform update and synchronization of all updates to create generalized cellular

automata (GCA); an example of traffic system simulation is described—digital circuits and forest fire development are further systems, which have suitable characteristics [13].

Petri net models are also used extensively in simulation studies; as with cellular automata, there is abundant low level parallelism to be exploited—the firability of each transition can be evaluated simultaneously. Petri net models are based on simple units—places and transitions. It is possible to create generic models in VHDL for these units [14], paving the way to automatic generation of VHDL code from natural visual representation of Petri nets, which can be compiled and downloaded to suitable hardware. A single Achilles stack is able to accommodate a model containing of the order of 200 transitions [14].

## Reconfigurable Processors vs. Commodity Processors

Any special purpose hardware has to compete with the rapid increase in performance of commodity processors. Despite the relative inefficiency of a general-purpose processor for many applications, if the special purpose hardware only provides a speedup of, say 2, then Moore’s Law will ensure that the advantage of the special purpose hardware is lost in a year.<sup>8</sup> When assessing whether an application will benefit from use of a reconfigurable processor, one has to keep the following points in mind.

### Raw Performance

The raw performance of FPGA-based solutions will always lag behind that of commodity processors. This is superficially reflected in maximum clock speeds: an FPGA’s maximum clock speed will typically be one-third or less of that of a commodity processor at the same point in time. This is inevitable and will continue: the reconfiguration circuitry loads a circuit and requires space, increasing its propagation delay and reducing the maximum clock speed.

### Parallelism

Thus, to realize a benefit from a reconfigurable system, the application must have a considerable degree of inherent parallelism which can be used effectively.

The parallelism may be exploited simply by deploying multiple processing blocks—each processing a separate data element at the same time—followed by some “aggregation” circuitry, which reduces results from the individual processing blocks in some way.

### Long Pipelines

Alternatively, a long pipeline may be employed in which the same data element transits multiple processing blocks in successive clock cycles. This approach trades latency for throughput: it may take many cycles—the latency—for the first result to appear, but after that new processed data are available on each clock cycle giving high throughput. Many signal processing tasks can effectively use long pipelines.

### Memory

FPGA devices do not provide large amounts of memory efficiently: recent devices (e.g., Altera’s APEX 20K devices [2]) do attempt to address this deficiency and provide significant dedicated memory resources; however, the total number of memory bits remains relatively small and is insufficient to support applications which require large amounts of randomly accessible data. This means that, although preprocessing an image which is available as a pixel stream from a camera for edge detection is feasible, subsequent processing of the image in order to segment it is considerably more difficult. In the first case, to apply a  $3 \times 3$  mask to the pixel stream, only two preceding rows of the image need be stored. The application of the  $3 \times 3$  mask requires a maximum of nine basic multiply-accumulate operations. Thus, it can be effectively handled in a 9-stage pipeline—easily allowing an edge-detected image to be produced at the same rate as the original image is streamed into the FPGA (allowing for an 8-pixel clock latency before the first result is available). In the second, the whole image needs to be stored and be available for random access. Although an FPGA with auxiliary memory might handle this task, it is less likely to offer a significant advantage over a general-purpose processor.

---

<sup>8</sup>The author has (somewhat arbitrarily) shortened the “break-even” point from the 18 months of Moore’s Law, because the extra cost of additional hardware needs to be factored in versus using cheap commodity hardware.

## Regularity

A processing pipeline with large numbers of decisions (if .. then .. else blocks in a high-level language program) is also not likely to be efficiently implemented in reconfigurable hardware. In such a pipeline, there will generally be a large number of branches which are rarely taken, but all need to be implemented in hardware, taking up considerable space (or numbers of logic blocks). Paths with large numbers of blocks of variable size also present a problem for the fixed routing resources in a device.

## Power and Cost

FPGAs consume more power and cost more per gate than either commercial processors or custom ASICs. Although FPGA technology tracks processor technology and power consumption is being reduced through lower power supply voltages and reduced transistor size, it is unlikely that one will see reconfigurable technology in micro power applications such as wearable computers; however, experiments are underway to test their viability in spacecraft, where power is limited [29]. The cost factor is generally offset in low volume production by the significantly lower design cost, faster design cycles, and ease with which modifications can be incorporated.

## Dynamic Reconfiguration

There is considerable interest in the ability to reconfigure a running circuit. This would allow applications (or groups of applications) to load circuits on demand to meet the requirements of a current task. This would make a reconfigurable system a truly general purpose one: able to load processing tasks as demanded by the input data.

Although most commercial devices require a complete new configuration program to be loaded every time, usually by paths with limited bandwidths requiring thousands of cycles to completely reprogram a device, some commercially available devices have had limited dynamic reprogramming capabilities for some time, e.g., the original Algotronix CAL1024, its successor the Xilinx XC6200 (both now out of production), Atmel's AT6000 (now superceded), AT40K, and Xilinx's Virtex family.

These devices extend the standard device programming model by allowing a part of the configuration to be reloaded from an external source: an alternative has been proposed—the DPGA model [30]. A DPGA device would hold several configurations in the configuration memory for each logic block and allow the context to select one dynamically. The flexibility gained from this arrangement allows much more effective gate utilization—at the expense of the additional space for the configuration memory and context selection logic.

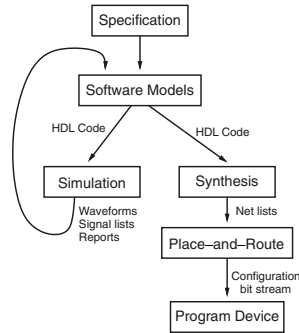

Noting some of the limitations introduced by conventional approaches to dynamic reloading of configuration data, Vasilko and Ait-Boudaoud have proposed an optical system for transferring new configuration data to a device [31]. Optical buses not only allow massively parallel data transfer but provide an additional dimension for information transfer and thus reduce the conflict for routing space between data paths and configuration nets. The advent of devices similar to their proposals would remove some of the practical limitations constraining effective dynamically reconfigurable systems.

One requirement for effective run-time reconfiguration is a model which allows a computation to be split into swappable computational blocks. Caspi et al. summarise several proposed models in introducing their SCORE (Stream Computations for Reconfigurable Extension) model [32]. SCORE divides a computation into fixed size pages, which can be swapped between the running hardware and backup store. A dataflow computation model is used, allowing the run-time system to manage resources: a dataflow model is “memory-less” as far as the programmer is concerned. Data flowing between pages is buffered transparently by the run-time system when necessary.

## Hybrid Systems

Hybrid systems couple a conventional processor and an area of uncommitted logic that may be configured to suit the demands of algorithms in which the conventional processor cannot exploit data or pipeline parallelism. Berkeley's Garp processor is an example of this approach [33]. Garp contains a RISC processor core (MIPS-II) and  $32 \times 23$  array of logic blocks. A 24th column of logic blocks is responsible for

**FIGURE 37.6** Design flow using an HDL (e.g., VHDL). Note the absence of a feedback loop in the synthesis branch: for a design verified in simulation, the synthesis process is a black box.

communication outside the array. Logic blocks take up to four 2-bit inputs and produce 2-bit outputs: a row of the array can thus process up to four 46-bit words. Garp’s designers hypothesize that the reconfigurable section may be used effectively to implement the critical kernels found in most code: the ability to hard-wire the control logic will reduce instruction fetch bottlenecks and better exploit parallelism. Memory queues, which handle streaming of data to and from memory, were added because many applications which use reconfigurable systems effectively process streams of data.

Results from the Garp simulator on a wavelet image compression program showed an overall speedup of 2.9 compared to the MIPS processor. Individual kernels within this program showed speedups up to 12, observed when a kernel had high exploitable instruction level parallelism and the configuration loading time could be amortized over many compute cycles. Comparisons of Garp’s performance with a 4-issue superscalar processor also showed significant speedups, indicating that Garp was able to exploit more instruction level parallelism, sustaining 10 instructions per cycle in many cases.

## Programming Reconfigurable Systems

### High-Level Hardware Design Languages

The design flow for a reconfigurable system is shown in Fig. 37.6; a high-level hardware design language (HDL) is usually used for the software modeling stage: VHDL and Verilog are widely used as excellent support tools are available. The design process is basically identical to that used for any software system: specifications are drawn up and validated, software models created and verified and the compiled “program” is loaded onto the target devices or burnt into ROMs. The only significant difference is that two compilers are generally used. A simulator compiles VHDL or Verilog source and produces diagnostic output not only as text to consoles or logged to files, but as waveforms or lists of changes in signal values. When the designer has verified that the models perform in accordance with their specifications under simulation, a synthesizer compiles the source again to a netlist—an intermediate representation of the final circuit. Device-specific place-and-route tools take netlists as input and place logic into logic blocks and configure the FPGA’s routing resources to make the necessary connections between logic blocks and I/O pins. The output of this stage is a configuration file—a stream of bits which are loaded onto the device to program its internal registers, multiplexors, etc. For many designs, the whole process (synthesis → place-and-route → configuration bit stream) can be viewed as a single step black-box, which turns verified HDL models into configuration files. Whilst it may take several hours for a complex system, it does not require any input from the user. The designer will usually simply advise the tools whether speed or area is the primary constraint. Significant interaction with the place-and-route tools is needed only if there are performance constraints which cannot be met with default parameters: in this case, manual placement of logic blocks can assist in satisfying the constraints.

## Other Languages

Other routes from high-level languages are possible: Callahan et al. describe a tool which starts with C [34]: it is aimed at “dusty-deck” systems. Of more potential for effective use of reconfigurable systems are special purpose high-level languages such as Milne’s process algebra, CIRCAL [35].

## Conclusions

In this chapter section, instead of providing a litany of praise for reconfigurable computing in all its forms, the author has tried to set out the general characteristics of problems, which a reconfigurable processor might be expected to solve efficiently. A key requirement is clearly sufficient exploitable parallelism, but that may appear either as raw or pipeline parallelism. Raw parallelism is a requirement to perform many simultaneous operations on a single item of data or the same operation on many data items, which may be presented to the reconfigurable hardware at the same instant. Pipeline parallelism, on the other hand, requires many operations to be performed on individual elements of a data stream, allowing a deep pipeline to process data at its arrival rate and produce results in real time, even if some latency penalty must be paid.

Reconfigurable systems are always competing against the inexorable rise in the power of general-purpose processors. Although reconfigurable devices track the performance gains due to better device technology, they inevitably lack the commercial drive that propels commodity processors forward in performance and thus lag behind their better funded cousins in raw performance. Thus, when considering a special purpose processor for any task, one must keep in mind the performance point at which commodity processors will be when the design is complete. With “multimedia extensions” such as MMX and AltiVec, commodity processors even have limited parallel processing capabilities; however, these are limited to very regular computations and a reconfigurable system—with its ability to implement multiple parallel data paths—will generally be better at matching the “shape” of a multiple processing step algorithm. The use of high-level design languages, such as VHDL and Verilog, also shortens design cycles making time-to-completion for projects based on reconfigurable hardware considerably shorter than custom hardware designs.

Thus, although problems that fail to meet the criteria are set out here, and thus will be more effectively solved using commodity processors, the author has shown that many problem domains also exist in which large numbers of individual problems are well suited to reconfigurable processors.

In this chapter section, discussion of successes has, for the most part, focussed on systems in which reconfiguration times are long—requiring hours if the time for synthesis software to compile, analyze, and place and route a model expressed in a high-level design language is included; however, there is much active research into dynamically reconfigurable systems, which has the goal of producing hardware whose function may be altered as quickly and conveniently as the general-purpose processors. The significant problems with which researchers in this area are now grappling will be solved eventually. Thus, we can anticipate systems in which parallelism present at some level in virtually all problems, which cannot be exploited now, will be exploited by systems that have been configured on-the-fly. As with statically programmed systems, when data paths can be provided that match problem structures, we will obtain orders of magnitude larger processing powers efficiently. We will not need to use large processor arrays in which many processors are needed for a few vital steps but are idle for much of the time.

## 37.2 Using Configurable Computing Systems

---

*Danny Newport and Don Bouldin*

### Definitions

**Configurable computing systems:** Systems that use reprogrammable logic components, typically field programmable gate arrays (FPGAs), to implement a specialized instruction set and/or arithmetic units to improve the performance of a particular application. These systems can be reconfigured, enabling the same hardware resource to be reused depending on its interaction with external components, data dependencies, or algorithm requirements.

**Configuration time:** Time required to program an FPGA or configurable computing system with a given configuration. This time varies from hundreds of nanoseconds to seconds depending on the system and the FPGAs that are used in the system.

**Field programmable gate array:** Integrated circuit containing arrays of logic blocks and programmable interconnect between these blocks. The logic blocks can be configured to implement simple or complex logical functions and can be changed as required. Example functions are registers, adders, and multipliers. The programmable interconnect permits the construction of even more complex functions and/or systems.

**FPGA:** Acronym for field programmable gate array.

**Reconfigurable computing systems:** Alternate term for “configurable computing systems.” This term is usually used to indicate that the system can be “reconfigured” at any time for some desired function.

### Introduction

Configurable computing systems use reprogrammable logic components, which are now capable of providing more than a million logic gates on a single chip. These systems can be reconfigured at runtime, enabling the same hardware resource to be reused depending on its interaction with external components, data dependencies, or algorithm requirements.

**FIGURE 37.7** Basic internal structure of an FPGA.

In essence, a specialized instruction set and arithmetic units can be configured as desired by an application designer on an as-needed basis to achieve optimal performance. The location of configurable components within a computing system is one of the keys to achieving maximum efficiency and performance. A variety of architectures driven by the location of configurable components are described in a later section.

## Configurable Components

Before describing various architectures of configurable computing systems, an understanding of the internal structure of FPGAs, the major component of a configurable computing system is necessary. In 2001, the top two FPGA vendors were Altera Corporation and Xilinx, Inc. The FPGA products from these, and other vendors, differ in their internal structure and programming. However, the basic internal structure for FPGAs can be illustrated as shown in Fig. 37.7. Note that the “PLB” blocks are “programmable logic blocks” and the “PI” blocks are programmable interconnect. A current trend among the FPGA vendors is to also include RAM and/or a fixed microprocessor core on the same integrated circuit as the FPGA. This enables even greater system flexibility in a design.

The means by which the logic blocks and interconnect are configured for specific functions are of a proprietary nature and specific to each vendor’s FPGA families. In general terms, the logic blocks and interconnect have internal structures that “hold” the current configuration and when presented with inputs will produce the programmed logic outputs. This “configuration” is FPGA-specific and contained in a vendor-specific file. A specific FPGA is programmed by downloading the information in this file through a serial or parallel logic connection.

The time required to configure an FPGA is known as the configuration time. Configuration times vary based on the FPGA family and the size of the FPGA. For a configurable computing system composed of several FPGAs, the configuration time is based not only on the configuration time of the individual FPGAs, but on how *all* the FPGAs are configured. Specifically, the FPGAs could be configured serially, in parallel, or a mixture of serial and parallel depending upon the design of the system. Thus, this time can vary from hundreds of nanoseconds to seconds. This directly impacts the types of applications that have improved performance on a particular configurable computing system. A configurable computing system that has a configuration time on the order of seconds is best suited for applications that do not

(a)

(b)

**FIGURE 37.8** Basic architectures for multiple FPGAs.

require reconfigurations “on-the-fly,” i.e., applications with a single configuration associated with them or ones that are pipelined with slow pipeline stages. On the other hand, a configurable computing system that has a very short configuration time can be used for the same applications as one with a slower configuration time and applications that require “on-the-fly” reconfiguration.

As implied previously, the configurable component of a configurable computing system can be composed of a single FPGA or multiple FPGAs. Many architectures are used for a configurable component composed of multiple FPGAs. Figure 37.8 illustrates the basic architectures from which most of these architectures would be derived. Note that these architectures are very similar, or identical, to those used for parallel processing systems. As a matter of fact, many of the paradigms used in configurable computing systems are derived from parallel processing systems. In many cases, a configurable computing system is the hardware equivalent of a software parallel processing system. Figure 37.8(a) is a pipelined architecture with the FPGAs hardwired from one to the other. This type of architecture is well suited for functions that have streaming data at specific intervals. Note that variations of this architecture include pipelines with feedback, programmable interconnect between the FPGAs, and RAM associated with each FPGA. Figure 37.8(b) is an array of FPGAs hardwired to their nearest neighbors. This type of architecture is well suited for functions that require a systolic array. Note, as with the pipelined architecture, that variations of this architecture include arrays with feedback, programmable interconnect between the FPGAs, and RAM associated with each FPGA. Also note that an array of FPGAs is very similar to the internal structure of a single FPGA. Thus, one has a hierarchy of configurability.

### Configurable Computing System Architectures

The placement of one or more configurable components within a computing system is largely determined by the requirements of the application. Several architectures are shown in Fig. 37.9. In some cases as shown in Fig. 37.9(a), no additional computing power is required and the component can be utilized in a stand-alone mode. This situation occurs in Internet routing nodes and in some data acquisition systems as well as controllers for actuators. Note that the use of FPGAs to replace logic or to be used as state machines is this type of architecture. This type of application was the first widespread use of FPGAs.

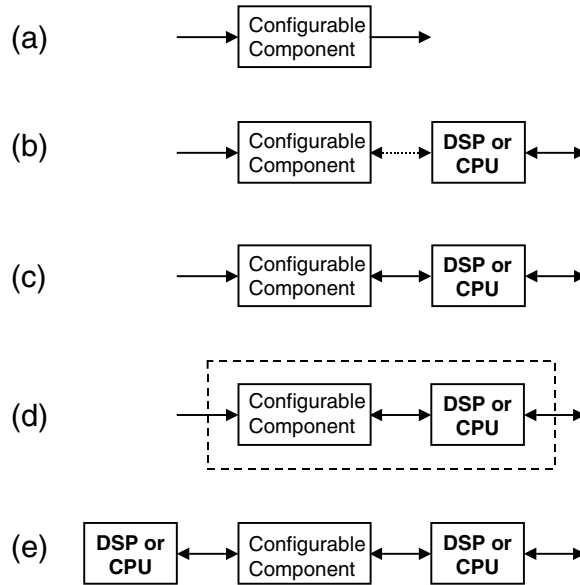

FIGURE 37.9 CPU/configurable computing architectures.

For configurable computing systems, configurable components are more commonly coupled with conventional DSPs or CPUs such that the processor can accomplish general purpose computing while acceleration of specialized functions can be performed by the configurable components. The type of general purpose computing required by the application determines the choice of a DSP or CPU. An application involving signal processing would naturally lead to the use of a DSP. Whereas, an application involving user interaction and/or user services (disks, etc.) would more likely lead to the use of a general purpose CPU. For this discussion on general configurable computing system architectures, the type of “general purpose” processor used is irrelevant; however, it is very relevant when an actual application and system are being developed.

Figures 37.9(b–e) depict architectures that have configurable components coupled with DSPs or CPUs. The communication requirements between the different types of processors determine the amount of bandwidth and latency provided. If infrequent communication is needed, a serial line or some other slow-speed connection may be sufficient as shown in Fig. 37.9(b). For higher bandwidth applications, placing the two types of components on a bus or some other high-speed connection as shown in Fig. 37.9(c) may be appropriate. In both of these cases, tasks best suited for a particular component can be delegated to that component and sharing of data and results are facilitated. Figure 37.9(d) depicts the tightest coupling with the lowest latency and highest bandwidth since both types of components are placed inside the same package. Often, the DSP or CPU manages the data, especially when disk storage is involved. When the data is being acquired at a high rate from a sensor, the configurable component is often used to perform initial operations to reduce the size of the data. Thus, the DSP or CPU has only a fraction of the data to be processed or stored. Note that the current trend to include RAM and a fixed microprocessor core on the same integrated circuit as the FPGA is an implementation of this architecture. Another variation of this theme of placing the configurable component within the system just where it is needed can be seen in a network of workstations as shown in Fig. 37.9(e). In this case, the configurable component can be inserted into the router itself to perform dedicated operations as the data is passed from processor node to processor node. The processing performed in this manner appears to be “free” because it occurs during message passing.

## Selected Applications

Several classes of applications have improved performance when implemented on configurable computing systems including image analysis, video compression, and molecular biology. In general, these applications exploit the parallel processing power of configurable computers.

### Image Analysis

Image analysis requires manipulating massive amounts of data in parallel and performing a variety of data interaction (e.g., point operations, neighborhood operations, and global operations). Many of these operations are ideally suited for implementation on a configurable computing system due to the parallel nature of the operations. Example implementations are image segmentation, convolution, automated target recognition (ATR), and stereo vision. Image segmentation is often the first step in image analysis and consists of extracting important image features. For intensity images (i.e., those represented by point-wise intensity levels) four popular approaches are: threshold techniques, edge-based methods, region-based techniques, and connectivity-preserving relaxation methods. A systolic array of configurable components, similar to that depicted in Fig. 37.8(b), can be used to perform an edge-based image segmentation. Implementation results for various applications have shown that this approach is superior to the conventional digital signal processor approach.

Two-dimensional convolution is commonly used for filtering, edge detection, and feature extraction. The basic idea is that a window of some finite size and shape is scanned across the image. The output pixel value is the weighted sum of the input pixels within the window where the weights are the values of the filter assigned to every pixel of the window itself. Using a systolic array of configurable components, the convolution window can be applied in parallel with an output pixel value being produced as new pixel values are provided. The storage of intermediate pixel values within the window are inherent in the systolic array structure. Implementation results have shown impressive performance gains.

Automated target recognition (ATR) is a computationally demanding application in real-time image analysis problems. The objective of an ATR system is to analyze a digitally represented input scene to locate/identify all objects of interest automatically. Typically, algorithms begin with a preprocessing step to identify regions of interest in the input image. Next, template matching is performed to correlate these regions of interest with a very large number of target templates. The final identification step identifies the template and the relative offset at which peak correlation occurs. The template matching process is the most computationally intensive among these three steps and has the potential of being implemented in a parallel form. Therefore, the template matching is a good candidate to be mapped into a configurable computing system. Implementation results have shown significant performance improvements.

Stereo vision involves locating the same features in each of two images and then measuring the distances to objects containing these features by triangularization. Finding corresponding points or other kinds of features in two images, such that the matched points are the same projections of a point in the scene, is the fundamental computational task. Matching objects at each pixel in the image leads to a distance map. This is very similar to the template matching process in an ATR system and implementation results are similar.

### Image and Video Compression

Image and video compression are used in many current and emerging products. Image compression is widely used in desktop publishing, graphic arts, color facsimile, and medical imaging. Video compression is at the heart of digital television set-top boxes, DSS, HDTV decoders, DVD players, video conferencing, Internet video, and other applications. Compression reduces the requirements for storage of large archived pictures, less bandwidth for the transmission of the picture from one point to another, or a combination of both. Image and video processing typically require high data throughput and computational complexity. JPEG is widely used for compressing still pictures, and MPEG or wavelets are more appropriate for compressing videos or general moving pictures.

A configurable component using a pipelined approach, as depicted in Fig. 37.8(a), provides a much cheaper and more flexible hardware platform than special image compression ASICs, and it can efficiently accelerate desktop computers. A speed improvement over a modern workstation of a factor of ten or more can be obtained for JPEG image compression.

## Molecular Biology

Scanning a DNA database is a fundamental task in molecular biology. This operation consists of identifying those sequences in the DNA database that contain at least one segment sufficiently similar to some segment of a query sequence. The computational complexity of this operation is proportional to the product of the length of the query sequence and the total number of nucleic acids in the database. In general, segment pairs (one from a database sequence and one from query sequence) may be considered similar if many nucleotides within the segment match identically. This similarity search may take several hours on standard workstations when using common software that is parameterized for high sensitivity.

One method of performing DNA database searches is to use a dynamic programming algorithm for computing the edit distance between two genetic sequences. This algorithm can be implemented on a configurable computing system configured as two systolic arrays. Execution has been found to be several orders of magnitude faster than implementations of the same algorithm on a conventional computer. Another method is to use a systolic filter for speeding up the scan of DNA databases. The filter can be implemented on a configurable computing system, which acts as a coprocessor that performs the more intensive computations occurring during the process. An implementation of this system boosted the performances of the conventional workstation by a factor ranging from 50 to 400.

## Virtual Computing Power

Quantifying computing power is a challenging task due to differing computing architectures and applications. Vullemin et al. [13] define virtual computing power based on the number of programmable active bits (PABs) and the operating frequency. He defines a “reference” PAB as a 4-input Boolean function. These functions are essentially the core configurable elements of a configurable computing component; however, each vendor defines them differently. For example, Xilinx calls them “logic cells (LCs)” and organizes them into groups of four called “configurable logic blocks (CLBs).” Whereas, Altera calls them “logic elements (LEs)” and organizes them into groups of ten called “logic array blocks (LABs).” As newer and larger FPGAs with new architectures are constructed, the vendors will likely rename these logic blocks. But the configurable blocks can always be defined as Boolean functions.

Vullemin et al. define the virtual computing power of a configurable computing system with  $n$  PABs operating at a frequency of  $f$  Hz as the product  $P = n \times f$  and is expressed in Boolean operations per second (BOPS). The frequency of operation for the PABs is taken to be the internal operating frequency of the component. Xilinx’s largest component to date is the Virtex XCV2000E that has 43,200 LCs and a quoted “typical” internal operating frequency in excess of 100 MHz [3]. Based on this, the Virtex XCV2000E has a virtual computing power of 4.3+ TBOPS. Altera’s largest available component is the APEX EP20K1500E, which has 54,720 LEs and a quoted “typical” internal operating frequency in excess of 100 MHz [1]. Based on this, the EP20K1500E has a virtual computing power of 5.4+ TBOPS. Note that both Xilinx and Altera quote a maximum internal operating frequency in excess of 200 MHz and have announced plans for even larger and faster components.

By comparison, an Intel Pentium III 32-bit microprocessor can execute two unrelated integer operations every clock cycle. When operating at 600 MHz, it has a virtual computing power of 38.4 GBOPS. Based on this analysis, a single, state-of-the-art configurable computing component has over 100 times the raw virtual computing power of a state-of-the-art microprocessor; however, taking full advantage of the virtual computing power of configurable computing systems is not trivial. The previous subsection listed a variety of application areas in which success has been achieved but the widespread use of these systems is presently hampered by the difficulty of programming them.

## Development Systems

Developing applications for microprocessor-based systems is currently far easier than developing applications for a configurable computing system. Microprocessor development systems have been optimized over years, even decades, while those for configurable computing systems are in their infancy. A design for a single FPGA is typically created using tools similar to those used for other digital systems, tools such as schematic capture, VHDL, etc. Due to the proprietary nature of FPGAs, however, a designer must typically use the design tools available from the FPGA vendor.

A software design environment that facilitates the rapid development of applications on configurable computing systems should permit high-level design entry, simulation, and verification by application designers who need not be familiar with the details of the hardware. Of course, on occasions, it may be necessary to expose to the application designer those hardware details deemed essential to ensure feasible and efficient implementations. Metrics and visualization are desirable to assist the application designer in achieving near-optimal system implementation rapidly. The tools available from the FPGA vendors are currently intended for digital systems designers not the application designer. Research efforts underway at various universities and startup companies are producing the first development systems for configurable computing systems similar to those for microprocessor systems.

## To Probe Further

More in-depth information on configurable computing systems is readily available. The first sources of information are the FPGA vendors. A few of these are

1. Altera Corporation, San Jose, CA. <http://www.altera.com>
2. Atmel Corporation, San Jose, CA. <http://www.atmel.com>
3. Xilinx, Inc., San Jose, CA. <http://www.xilinx.com>

Several sites on the World Wide Web are dedicated to configurable computing systems. A search using the terms “configurable computing systems” or “reconfigurable computing systems” via any of the search engines will yield a great number of hits. One of these sites is <http://www.optimagic.com> that provides not only information on configurable computing systems, but also information on programmable logic in general.

Currently, very few books focus specifically on configurable computing systems; however, many books about programmable logic provide excellent references for someone interested in configurable computing. Some of these are

4. *Digital Designing with Programmable Logic Devices*, John Carter, Prentice-Hall, Englewood Cliffs, NJ, 1996.
5. *Programmable Logic: PLDs and FPGAs*, Richard C. Seals and G.F. Whapshott, Macmillan, New York, 1997.
6. *FPGAs and Programmable LSI: A Designer's Handbook*, Geoff Bostock, Butterworth-Heinemann, 1996.
7. *Digital System Design Using Field Programmable Gate Arrays*, Pak K. Chan and Samiha Mourad, Prentice-Hall, Englewood Cliffs, NJ, 1994.

Many excellent conferences are held annually to provide the latest information on configurable computing systems from the FPGAs to development systems. Some of these conferences are

8. *Symposium on Field-Programmable Custom Computing Machines (FCCM)*. <http://www.fccm.org>
9. *ACM/SIGDA International Symposium on Field-Programmable Gate Arrays (FPGA)*.
10. *International Workshop on Field Programmable Logic and Applications (FPL)*.
11. *Reconfigurable Architectures Workshop (RAW)*.
12. *Design Automation Conference (DAC)*. <http://www.dac.com>

The proceedings from these conferences contain many articles on not only configurable computing systems but applications for which configurable computing systems have been shown to be effective.

Other application areas that one may find configurable computing systems applied to are: cryptography, fingerprint matching, multimedia, and astronomy.

More in-depth information on virtual computing power and a list of applications of configurable computing system is

13. J. Vuillemin, P. Bertin, D. Roncin, M. Shand, H. Touati, and P. Boucard, Programmable active memories: reconfigurable systems come of age, *IEEE Trans. on VLSI Systems*, vol. 4, no. 1, pp. 56–69, March 1996.

More information on research and development into design tools for configurable computing may be obtained by visiting the web sites of the research groups involved. Some of these are

## 37.3 Xtensa: A Configurable and Extensible Processor

---

*Ricardo E. Gonzalez and Albert Wang*

### Introduction

Until a few years ago, processors were only sold as packaged individual ICs. However, the growing density of CMOS circuits created an opportunity for incorporating the processor as part of a larger system on a chip. Initial processor designs for this market were based on the processor existing as a separate entity, and cores were handcrafted for each manufacturing process technology, resulting in costly and fixed solutions. Furthermore, it was not possible to modify these cores for the particular application, in much the same way that it was not possible to modify a stand-alone prepackaged processor.

Xtensa is a processor core designed with ease of integration, customization, and extension in mind. Unlike previous processors, Xtensa lets the system designer select and size only the features required for a given application. The configuration and generation process is straightforward and lets the designer define new system-specific instructions if preexisting features don't provide the required functionality. Furthermore, Xtensa fits easily into the standard ASIC design flow. Xtensa is fully synthesizable, and designers can use the most popular physical-design tools during the place-and-route process.

### Processor Development

Application-specific processor development is an active area of research in the CAD, computer architecture, and VLSI design communities. Early attempts to add application-specific instructions to general-purpose computer engines relied on writable micro-code [1,2]. These techniques dynamically augmented the base instruction set with application-specific instructions.

More recent research focuses on automatic instruction set design [3,4] or on reconfigurable, also called retargetable, processors [5]. These groups, however, try to solve slightly different problems than those addressed by Xtensa. Automatic instruction set design systematically analyzes a benchmark program to derive an entirely new instruction set for a given microarchitecture. Our group—here referred to as “we”—focuses on how to generate a high-performance and low-power implementation of a given microarchitecture with application-specific extensions. In this respect, automatic instruction set design is a good complement to our work. Once the instruction set additions are derived automatically by analyzing the benchmark program, they can be given to the Xtensa processor generator to obtain a high-performance, low-power

implementation. Reconfigurable or retargetable processors couple a general-purpose computer engine with various amounts of hardware-programmable logic. In the extreme, the entire processor is implemented using hardware-programmable logic. The technique, however, is limited by the large difference in operating frequency between programmable and nonprogrammable logic. Processors implemented entirely using programmable logic operate an order of magnitude slower than nonconfigurable processors implemented in a comparable process technology. Razdan and Smith present an interesting compromise [5]. Their approach couples a custom-designed high-performance processor with small amounts of hardware-programmable logic. Their system uses compiler-generated information to dynamically reconfigure a small amount of hardware-programmable logic to implement new application-specific functional units. This technique also has limitations due to the disparity in operating frequency of programmable and nonprogrammable logic. Thus, the new functional units must be extremely simple or be deeply pipelined.

The authors' approach is similar to that taken by Razdan and Smith except that we don't attempt to dynamically reconfigure the system. The Tensilica processor generator adds the application-specific functionality at the time the hardware is designed. Thus, the extensions are implemented in the same logic family as the rest of the processor. This eliminates the disadvantages of using programmable logic for implementing the extensions, but precludes modification of the extensions for different applications.

Due to a lack of automated tools, designers incorporated application-specific functionality in CPUs by adding specialized coprocessors [6,7]. This approach introduces communication overhead between the CPU and the coprocessor, making system design more arduous. Recently, with the advent of synthesizable processors, some groups have proposed manual modification of the register-transfer level (RTL) description of the processor and the software development tools [8]. This approach is tedious and error prone. Furthermore, the extensions are only applicable to one implementation. If users want to add similar extensions to a future implementation of the same processor, they must modify the RTL again.

The authors' research differs from previous studies because we use a high-level language to express processor extension. This language, called Tensilica Instruction Extension (TIE), expresses the semantics and encoding of instructions. TIE can add new functionality to the RTL description and automatically extend the software tools. This lets the system developer code applications in a high-level language, such as C or C++. TIE imposes restrictions on functions that designers can describe, which greatly simplify verification of the processor and extensions. Because the extensions become an integral part of the processor, there is no communication overhead.

## Overview of Xtensa

We designed the Xtensa instruction set architecture (ISA) to allow ease of extension and configuration. Furthermore, the ISA minimizes code size, reduces power dissipation, and maximizes performance.

The Xtensa ISA consists of a base set of instructions, which exist in all Xtensa implementations, plus a set of configurable options. The designer can choose, for example, to include a 16-bit multiply-accumulate option if it is beneficial to the application. The base ISA defines approximately 80 instructions and is a superset of traditional 32-bit RISC instruction sets [10]. The architecture achieves smaller code size through the use of denser encoding and register windows. The ISA defines 24- and 16-bit instruction formats, as opposed to 32-bit formats found in traditional RISC instruction sets. The Xtensa architecture provides a rich set of operations despite the smaller instruction size. These sophisticated instructions, such as single-cycle compare and branch, enable higher code density and improve performance.

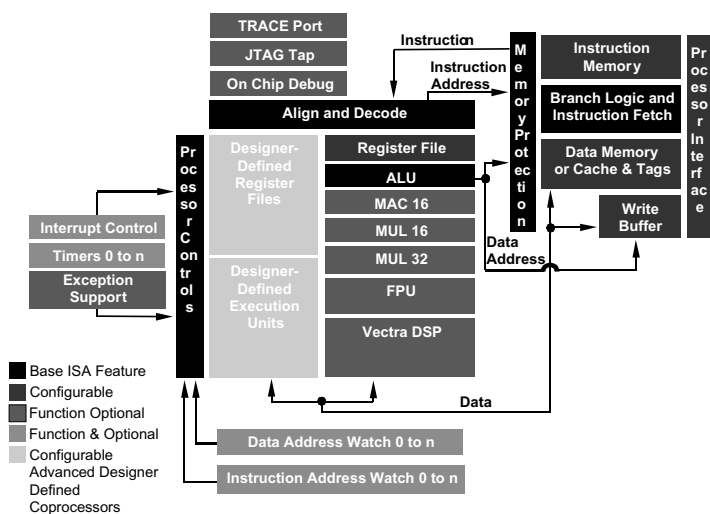

The size of Xtensa instructions is encoded in the instruction, enabling 24- and 16-bit instructions to freely intermix at a fine granularity. The 16-bit instructions are a subset of the 24-bit instructions. Thus, the compiler optimization to reduce code size is trivial: replacing 24-bit instructions with their 16-bit equivalent. The compiler can reduce code size without sacrificing performance.

## Hardware Implementation

We built the first implementation of Xtensa around a traditional RISC five-stage pipeline, with a 32-bit address space. Many other characteristics of the processor implementation, however, are configurable. The configurability and extensibility of the implementation matches those of the architecture. [Figure 37.10](#)

**TABLE 37.1** Xtensa Configuration Parameters

Parameter	Legal Values
Instruction/data cache size	1–256 KB
Instruction/data cache associativity	Direct-mapped, 2-way, 4-way
Instruction/data RAM size	1 KB, 2 KB, 4 KB, 8 KB, 16 KB
Instruction/data ROM size	1 KB, 2 KB, 4 KB, 8 KB, 16 KB
Size of windowed register file	32, 64
Number of interrupts	0–32
Interrupt levels	0–3
Timers	0–3
Memory order	Big-endian, little-endian

**FIGURE 37.10** Block diagram of Xtensa.

shows a high-level block diagram of Xtensa. The base ISA features correspond to roughly 80 instructions. The designer can size or select configurable options, for example, how many physical registers to include in the implementation, or the size of the instruction and data caches. Optional features, shown as green in the figure, are selections the designer can make, such as whether to include a 16-bit multiply-accumulate functional unit. Optional and configurable functions let the designer select whether to include that feature and also to size it. For example, whether to include data watch-point registers and, if so, how many. Xtensa optionally supports several data formats such as fixed-point and floating-point. Vectra adds a configurable fixed-point vector coprocessor.

Table 37.1 shows a few of the configuration parameters and associated legal values available in the current Xtensa implementation. Unlike conventional processors, Xtensa gives designers a choice regarding the functionality of the processor.

## Configuration

The configuration process begins by accessing the Tensilica processor generator Web page at <http://www.tensilica.com>. Here, using a standard browser, the designer can select and size the desired features. The site's configuration page gives the designer instant feedback on whether a particular choice will affect the speed, power, or area of the core. The user interface warns the designer of conflicting options or requirements for a particular option.

The designer starts the generation process at the push of a button. The generation process produces the processor's configured RTL description and its configured software development tools. The software tools consist of an ANSI C/C++ compiler, linker, assembler, debugger, code profiler, and instruction set simulator.

The generation process takes approximately one hour to complete. After the process is complete, the designer can download and install the RTL and software development tools. At this point, the designer can either compile an application and measure the performance using the instruction set simulator, or start the hardware synthesis using the RTL description.

The software tools are built on top of the industry-standard GNU tools and include an optimizing C compiler enabling application development in a high-level language. The instruction set simulator and code profiler help the designer quickly identify bottlenecks in application performance. Optionally, the designer can recode the application to work around these bottlenecks or add new instructions to the processor designed to optimize this particular application.

The designer can map the RTL description to a gate-level netlist using industry-standard synthesis tools. Included with the RTL description are a set of synthesis scripts that help automate this process. These scripts let designers quickly obtain a fully optimized gate-level netlist of Xtensa. Tensilica also provides a set of scripts to automate the place-and-route process. It is common for new users to place and route Xtensa within a day or two of downloading the configured RTL.

## Instruction Set Extension

Hardware designers realized the advantages of extending a general-purpose processor with application specific functional units long time ago [6,7]. Until now, however, the only way to do this was to add the functional units as a coprocessor. This often meant there was some communication overhead between the processor and the application-specific logic. Also, often the coprocessor would require sophisticated control, which had to be implemented with finite state machines or with micro-sequencers.

The Tensilica processor generator provides a more flexible and powerful approach to processor extension. Using TIE the system designer can describe, at a high-level, the functionality of the new functional units. The TIE compiler will then automatically generate an efficient pipelined implementation. The system designer must specify only the functionality of the new hardware and the required (and architecturally visible) storage elements—register files and special-purpose state elements. The pipeline flip-flops and the bypass and interlock detection logic are then automatically generated by the TIE compiler. Furthermore, the TIE compiler (TC) will automatically extend the software tools so that the new hardware is accessible from C/C++.

Using TIE has many advantages over more traditional methods of extension. First, the sophisticated control can now be accomplished using software—making it easier to debug and optimize. Second, the system designer can quickly prototype different design alternatives enabling him (or her) to quickly converge to a good solution to the problem. Third, verification of the new hardware's functionality can be done using the instruction set simulator (ISS), which can simulate hundreds of thousands of instruction per second, rather than on the RTL model, which can only simulate hundreds of cycles per second.

Similar to most previous machine description languages [14], TIE is an instruction set architecture (ISA) description language. It relies on a tool, the TIE compiler, to generate an efficient hardware implementation and required additions to the software tools, including the compiler, ISS, and debugger. TIE is not intended to be a complete processor description language. Instead, the TIE language provides designers simple ways to describe a broad variety of computational instructions, yet allows the TIE compiler to generate efficient hardware. The language is simple enough for a wide range of designers to master, yet general enough to allow description of sophisticated ISAs. The rest of this section describes the capabilities of the TIE language.

TIE lets the designer specify the mnemonic, encoding, and semantics of new instructions. The designer uses a combination of `field`, `opcode`, `operand`, and `iclass` statements to describe the format and encoding of an instruction. The `field` statement gives a name to a group of bits in the instruction word.

The `opcode` statement assigns instruction fields with values. The `operand` statement specifies how an instruction's operand is encoded in an instruction field. The `iclass` statement describes the assembly format for an instruction and lists the input and output operands of the instruction. A large set of predefined instruction fields and operands (used to describe the base Xtensa ISA) can be used directly in the TIE description. The following example describes two instructions: A4 and S4. These instructions take two 32-bit operands from the core register file, perform four 8-bit additions and subtractions and store the result back to the core register file:

```

opcode   A4      op2 = 0 CUST0
opcode   S4      op2 = 1 CUST0
iclass   RR      {A4, S4} {out arr, in ars, in art}

```

The first two lines define the opcodes for A4 and S4 as sub-opcodes of a previously defined opcode CUST0 with the addition of field `op2` equal to 0 and 1, respectively. The third line makes use of the predefined register operands `arr`, `ars`, and `art`, and defines two new assembly instructions,

```

A4 arr, ars, art
S4 arr, ars, art

```

## Customized Datapath

The computational part of an instruction is specified in a TIE `reference` block. The syntax of a `reference` block is very similar to the Verilog hardware description language. The variables used in the `reference` block are predefined (if they appear in the `iclass` statement), or locally declared variables. The reference block for the A4 and S4 instructions defined in the previous section are shown below,

```

reference A4 {
    assign arr = {
        ars[31:24] + art[31:24],
        ars[32:16] + art[23:16],
        ars[15:8] + art[15:8],
        ars[7:0] + art[7:0]};
}
reference S4 {
    assign arr = {
        ars[31:24] - art[31:24],
        ars[32:16] - art[23:16],
        ars[15:8] - art[15:8],
        ars[7:0] - art[7:0]};
}

```

The reference description for the two instructions is simple and direct, yet may not result in the best hardware implementation. For example, the logic for addition and subtraction could be shared between the two instructions. TIE allows the designer to describe this high-level hardware sharing between multiple instructions using the `semantic` block. The `semantic` block is similar to a `reference`

block but allows multiple instructions to be described at the same time. The semantics of A4 and S\$, for example, can be described as follows:

```
{semantic add sub {A4, S4}}
  assign arr = {
    ars[31:24] + (S4 ? ~art[31:24] : art[31:24]) + S4,
    ars[32:16] + (S4 ? ~art[23:16] : art[23:16]) + S4,
    ars[15:8] + (S4 ? ~art[15:8] : art[15:8]) + S4,
    ars[7:0] + (S4 ? ~art[7:0] : art[7:0]) + S4};
}
```

The semantic statements allow more efficient hardware implementation, while the reference statements are easier to write, are better suited for inclusion in documentation and are a better source for simulation code. Thus, TIE allows instructions to have either a reference block, a semantic block, or both. Most often, designers will write the reference description first. Once they have verified the correctness and usefulness of the instruction they write the semantics to optimize the hardware implementation. TIE allows formal equivalence checking between the semantic and reference description to ensure the implementation is identical.

### Multi-Cycle Instructions

To keep up with the speed of Xtensa, which is pipelined and runs at a high clock rate, instructions with complex computation may require multiple cycles to complete. Writing and verifying multi-cycle instructions is a challenging task for designer unfamiliar with the processor's pipeline, especially if the designer must add the appropriate data-forwarding and interlock detection logic. TIE provides a `schedule` statement that alleviates this problem. The schedule statement captures the timing requirements of the instruction. The designer can then rely on the TIE compiler to derive the implementation automatically. For example, a multiply-accumulate (MAC) instruction that performs the following operation: `acc = acc + (a*b)` typically requires at least two cycles in a pipelined processor. In order to achieve one MAC per cycle throughput, the hardware must use (read) the a and b operands at the beginning of the first cycle, use acc at the beginning of the second cycle, and produce a new acc at the end of the second cycle. The timing of the instruction can be described in TIE as

```
schedule MAC_SCHEDULE {MAC} {
  use a = 1;
  use b = 1;
  use acc = 2;
  def acc = 2;
}
```

The rest of the implementation, including the efficient insertion of pipeline registers, interlock detection, result bypassing, and generation of good code schedules are all handled automatically by the TIE compiler.

### Register Files and State Registers

When adding new application-specific datapaths it is often necessary to add new storage elements. Two main reasons exist for adding new storage elements. First, algorithms often require specific bit widths, which may not be efficiently supported by the core register file. And second, some algorithms require higher bandwidth than the core register file provides. In the MAC instruction described in the previous

subsection, for example, the machine would require a new state register to hold the value of the accumulator. Otherwise it would require an additional read port in the core register file (the accumulator value would be held in a register). Furthermore, the algorithm may require an accumulator value with more precision.

TIE states are extensions to the software visible programming model. They allow instructions to have more sources and destinations than provided by the read and write ports of the core register file. They can also be used as dedicated registers holding temporary values during program execution. When an application needs a large number of such sharable TIE states, it becomes more efficient to group the state into a register file and rely on the C compiler to assign the variables to register entries.

Describing instructions that use TIE states is simple. The designer must specify, in the `iclass` of the instruction, how the state is used. The state variable is then available in the instruction's `reference` and `semantic` blocks. The following example is a complete description of the MAC instruction,

```
state          acc 40      /* a 40-bit accumulator */
opcode         MAC op2=0 CUST0
iclass        MAC_CLASS {MAC} {in ars, in art} {inout acc}
reference {
    assign acc = (ars * art) + acc;
}
```

Using a register file involves one more step: describing the register operands. The following TIE code, for example, adds a 24-bit register file:

```
regfile       GR 24 16      /* 26 entries, 24-bits each*/
operand       gr r {GR[r]}
operand       gs s {GR[s]}
operand       gt t {GR[t]}
```

The three register operands use predefined instruction fields (`r`, `s`, `t`) as indices to access the register file contents. An instruction that uses these operands can be describes as,

```
iclass  RF {AVE} {out gr, in gs, in gt}
```

Using TIE it is possible to very quickly develop sophisticated hardware that can significantly enhance the application performance of the processor. Furthermore, the new hardware is easily accessible to the C/C++ programmer.

## Software Support

One key advantage of TIE is that it allows hardware and software to be extended together. This allows the programmer to access the new hardware from C or C++. This allows the programmer to focus on algorithmic optimization, rather than mapping the algorithm to a fixed processor architecture. Programmers often spend more time designing how to map the algorithm's data-types to the processor data-types than they do on optimizing the algorithm for their application. Using TIE it is possible to extend the hardware and software together so the mapping of the algorithm's data-types is more natural.

In order for this extension to be useful to the programmer, however, it must be complete. The compiler, assembler, simulator, debugger, real-time operating system, and application libraries must be extended to use the new hardware datapaths. The TIE compiler generates dynamically loadable libraries (DLLs) that are used to configure the software tools at runtime. Generation of the DLLs takes less than a minute (even for large TIE descriptions). This allows designers to quickly make changes to the TIE description and evaluate the performance of the system. TIE allows designers (or programmers) to define new C

data-types that are mapped to TIE register files. The programmer must also specify, in the TIE description, instruction sequences to load and store these data-types from (to) memory. The programmer can then use these new data-types in C/C++ as if they were built-in data-types. Operations are described via intrinsics (every TIE instruction is available as an intrinsic in C/C++) but register allocation, variable saves and restores, addressing arithmetic, and control flow generation for the new data-types are handled automatically by the C compiler. The C compiler is also aware of any side-effects and pipelining of TIE instructions so it can efficiently schedule the instructions.

The TIE compiler also generates libraries to save and restore processor state on a context switch. The compiler uses the instruction sequences described by the programmer to load and store the new data-types. The libraries are used by commercial operating systems, such as WindRiver's VxWorks™. The operating system is delivered as a pre-built binary with hooks to call the context switch code generated by the TIE compiler.

The TIE compiler must also add knowledge of the new instructions and register files to the instruction set simulator and the debugger. The TIE compiler translates the reference block of each instruction to a C implementation that can be used by the simulator to model the execution of the instruction. The TIE compiler also extends the debugger to allow visualization of new register files and state registers.

## Application Examples

### DES

To demonstrate the potential of TIE, we extended Xtensa to improve the performance of the Data Encryption Standard (DES)—a popular encryption and decryption algorithm often used for secure Internet communication. We chose DES for two reasons: its growing popularity in embedded applications that require secure Internet transactions, and the relatively poor encryption and decryption performance of general-purpose processors.

A simple DES modification, known as Triple-DES, extends the key to 168 bits by iterating the DES algorithm three times with three different keys. Triple-DES has been specified as an encryption algorithm for both the secure shell tools<sup>11</sup> and the Internet protocol for security<sup>12</sup>. Both of these applications require high-speed encryption and decryption and are implemented as part of many of today's interesting embedded systems.

The DES algorithm requires extensive bit permutations, which are difficult to implement efficiently in software. However, designers can efficiently implement these permutations in hardware, since each corresponds to a simple renaming of the wires. The algorithm also specifies rotation on 28-bit boundaries. Even if the processor has a rotate instruction, it often is not usable since it most likely rotates on 32-bit boundaries. Finally, the algorithm requires bit packing, unpacking, and table lookups. These operations are slow in software but easy to implement with hardware. We modified the Xtensa processor to include special instructions to speed up these operations.

Based on run-time profile information, we defined four new instructions and reimplemented the application to use these instructions. We verified the implementation of the TIE instructions by comparing the output of the modified application, which uses the TIE-generated C description of the instructions, with the results of a reference implementation of DES written completely in C. In addition to four new instructions, we also added three new state registers to the processor. The registers hold intermediate values during the encryption and decryption process. Of the four new instructions, one performs the encryption and decryption step using values in the state registers. The other three instructions transfer data to (and from) the processor registers from (and to) the state registers, while concurrently permuting the data values. When compiled for the Xtensa architecture, the new application required only 154 bytes of object code and no static or dynamic data storage. Thus, the original implementation required 36 times more memory than this implementation.

Figure 37.11 shows the speedup of the DES-enhanced Xtensa core compared to an unmodified Xtensa core. The X-axis shows the block size used for encryption and decryption. The original DES implementation gains much of its speed by precomputing large tables of values from a fixed key, making key changes

**FIGURE 37.11** DES speedup using TIE.

very expensive. Thus, small blocks can attain speedup by a greater factor than large blocks (where key changes are less frequent). The modified Xtensa can encrypt and decrypt data at the rate of 377 MB/s. The hardware cost of the TIE instructions is roughly 4,500 equivalent (NAND2) gates (measured in a 0.25- $\mu$ m process technology). The reduced storage requirements of the application offset this hardware cost. In addition, the new TIE instructions did not increase the cycle time of the machine. DES is only one of the applications that can benefit from specialized hardware.

### Consumer Multimedia

The EEMBC consumer benchmarks contain a representative sample of multimedia applications of interest today. A baseline configuration of Xtensa contains many features suitable for these applications. At 200 MHz operation Xtensa delivers more than 11 times the performance of the reference processor (ST Microelectronics ST20C2™ at 50 MHz). Performance is measured as the geometric mean of the relative number of iterations per second for each algorithm compared to the reference processor; however, when we added instructions for image filtering and color-space conversion (RGB to YIQ and RGB to CYMB) the average performance increased by 17X (193 times faster than the reference). An AMD K6-III+ at 550 MHz, for comparison, is 34.2 times faster than the reference processor. The base configuration was optimized for 200 MHz operation in a 0.18- $\mu$ m technology. The processor was configured with 16 KB two-way set associative caches, 256 KB local data RAM, 16-entry store buffer, and 32-bit multiplier. The total area of the processor was 57,600 NAND2-equivalent gates. The optimized TIE code cost an additional 64,100 NAND2-equivalent gates.

### DSP Telecommunications

The EEMBC “Telemark” benchmark suite includes many kernels representative of DSP applications. The performance of a base Xtensa processor in this suite is comparable to that of other 32-bit microprocessors (2.3 times faster than the reference). Performance was also measured as the geometric mean of the relative number of iterations per second for each algorithm compared to the reference processor (IDT 32334™ – MIPS32™ architecture at 100 MHz). Adding a fixed-point vector co-processor and a few more specialized instructions, the performance of Xtensa increases by 37X, or a speedup of 85.7X compared to the reference processor. The AMD K6-III+ at 550 MHz has a speedup of 8.7 compared to the reference, while a TI DSP (TMS320C6203) running hand-optimized code at 300 MHz has a 68.5 speedup compared to the reference processor. The base Xtensa configuration was also optimized for 200 MHz operation in 0.18- $\mu$ m technology with 16 KB two-way set associative caches, and 16-entry write buffer. The vector co-processor and new TIE instructions add 180,000 thousand NAND2-equivalent gates.

## Conclusions

Configurable and extensible processors provide significant advantages compared to traditional hard-wired processors. To take full advantage of extensibility, however, requires a methodology that can extend both the hardware and the software together. We showed that TIE provides a methodology for extension that is complete, fast, and robust.

Using TIE can also help reduce design time by simplifying the hardware verification effort and also by allowing a more natural mapping of the algorithm to the hardware implementation.

Furthermore, since the control flow is described in software it is much easier to verify and to enhance. We also showed the extension can significantly increase application performance. We showed that for two different set of application kernels an Xtensa processor with application-specific extension was 20–40 times faster than a high-performance RISC processor.

## Acknowledgments

The authors thank the entire engineering staff at Tensilica. This article reflects their hard work and dedication. The authors are also grateful to Rick Rudell for the development of the DES TIE code and to Michael Carchia who did the EEMBC benchmarking.

### 38.1 Background of Intelligent Transportation Systems

---

Today, one encounters a lot of traffic congestion and hears of people injured or killed by traffic accidents. Moreover, there has been no remarkable improvement in air pollution due to exhaust gases from vehicles in spite of the stringent regulation for vehicles. It is natural that frequent traffic congestion results in lower mean vehicle speed. [Figure 38.1](#) shows an example of mean averaged vehicle speed in Japan. Vehicle speed in urban area like Tokyo and Osaka is very close to that of a bicycle. On the contrary, vehicle speed in countryside is faster than urban area. Therefore, average vehicle speed of the whole of Japan shows a little bit higher value, as shown in [Fig. 38.1](#).

Traffic accidents are a more serious matter than vehicle speed. [Figure 38.2](#) shows an example of the number of people killed due to traffic accidents in Japan. About ten thousand persons are still killed by traffic accidents. Moreover, the death rate of senior people has become higher in Japan.

A third example of traffic problems—the status of air pollution in Japan—is shown in [Fig. 38.3](#). Both hydrocarbon (HC) and carbon monoxide (CO) have decreased gradually. On the contrary, nitric oxide (NO<sub>x</sub>) has not decreased. It has remained nearly constant in spite of the stringent Japanese exhaust gas regulation. These three examples are related to Japan. But the traffic situation of all countries is very much similar.

FIGURE 38.1 Average vehicle speed.

FIGURE 38.2 Numbers of persons killed by traffic accidents.

In principle, these phenomena are eliminated by constructing new roads because it gives smoother traffic flow. The cost to construct them, however, has become very expensive in every country. So such a conventional way to solve these traffic problems is not available. On the other hand, information technology has progressed remarkably these days. As a result of this, many government officers have embraced an idea to solve these traffic problems by using information technology. Indeed the idea has led to a system image called Intelligent Transportation Systems (ITS), as shown in Fig. 38.4.

## 38.2 An Overview of Japanese ITS and the Nine Developing Fields of Japanese ITS

It was in 1995 that the second ITS World Congress was held at Yokohama. In Japan, several projects on ITS had been carried before 1995. Table 38.1 shows those projects. The first project was called comprehensive automobile traffic control system (CACS) proposed and lead by Ministry of Construction of the Japanese government at that time. Then the Ministry of Transport, Ministry of Post and Telecommunication,

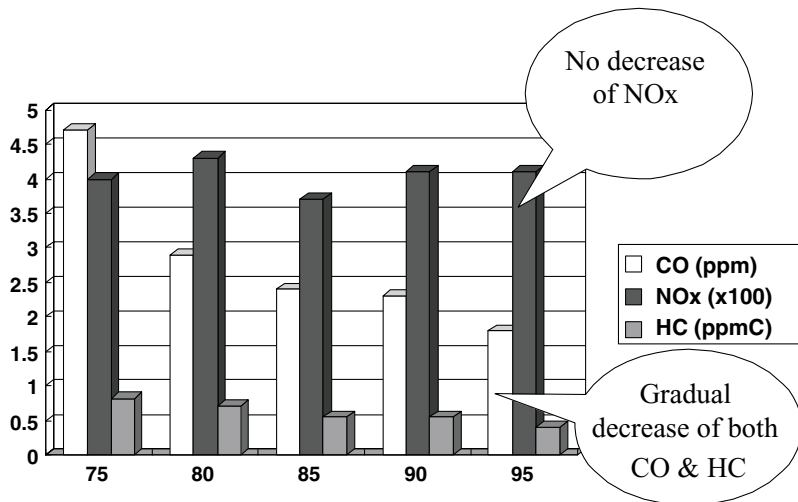

FIGURE 38.3 Air pollution.

FIGURE 38.4 Concept of ITS.

Ministry of International Trade and Industry, National Police Agency, and Ministry of Construction proposed several projects on ITS and they had also promoted these projects. These are the major six projects to develop ITS in Japan, as shown in Table 38.1.

VICS means vehicle information & communication system. This mainly provides traffic information such as congestion, road construction, road restriction, traffic accidents, and parking information. VICS supposes an in-vehicle navigation system is loaded in a vehicle; this is already widespread in Japan as shown later.

ETC means electronic toll collection system. One often sees congestion in front of a tollgate due to “stop” and “go” at the tollgate. The aim of this project is to reduce such congestion using communication technologies between vehicle and road infrastructure.

**TABLE 38.1** ITS Projects in Japan

---

• VICS (MOC, NPA, MPT) Vehicle Information & Communication System
• ETC (MOC, MPT) Electronic Toll collection System
• AHS (MOC) Advanced cruise-assist Highway System
• ASV (MOT) Advanced Safety Vehicle
• SSVS (MITI) Super Smart Vehicle System
• UTMS (NPA) Universal Traffic Management System

---

**TABLE 38.2** Nine Developing Fields of Japanese ITS

---

1. Advances in navigation systems (ANS)
2. Electronic toll collection systems (ETC)
3. Assistance for safe driving (ASD)
4. Optimization of traffic management (OTM)
5. Increasing efficiency of road management (IERM)
6. Support for public transport (SPT)
7. Increasing efficiency in commercial vehicle operation (IECVO)
8. Support for pedestrians (SFP)
9. Support for emergency vehicle operation (SEVO)

---

AHS means advanced cruise-assist highway system originally from automated highway system. This system supposes advanced safety vehicle to enhance traffic safety and reduce accidents. This system is a kind of driving support system with collaborating road infrastructure and vehicle.

ASV is advanced safety vehicle to enhance traffic safety and reduce accidents. It has originally aimed to do so without any aid of road infrastructure. But now both ASV and AHS projects are collaborating because the collaboration is more effective from the point of view of both system performance and its cost.

SSVS means super smart vehicle system. Now, its main activity is related to the development of inter-vehicle communication technologies.

UTMS is an abbreviation of universal traffic management system. This project has an aim to develop ITS using two-way communication between road and vehicle, particularly using infrared light communication.

In 1995, the Japanese government set nine development fields to promote Japanese ITS. Both [Fig. 38.5](#) and [Table 38.2](#) show the nine development fields. In [Fig. 38.5](#), those fields are expressed dividing the two categories of road infrastructure side and vehicle side.

Vehicle side includes only two fields. One is advances in navigation system (ANS) and the other is assistance for safe driving (ASD). For example, VICS is included in the field of ANS. Five of the nine fields belong to infrastructure side. For example, road maintenance by special cars like removal of snow on roads using snow shoveling car is in these five fields.

ETC and SFP, which means support for pedestrians, locate between infrastructure and vehicle because these systems are very effective only when both infrastructure and vehicle are collaborating.

### 38.3 Status of Japanese ITS Development

---

It is apparent that setting these developing fields shown in the above accelerates ITS development. As a result of this VICS has started its service to provide vehicles with real-time traffic information such as congestion, road construction, and accidents since 1996. Though this system assumes that in-vehicle navigation systems are loaded in a vehicle, VICS is the first system to be put into practical use all over the world. In 2001 ETC is also to be started at the several tollgates of highways in Tokyo and Osaka area.

FIGURE 38.5 Nine fields of Japanese ITS.

FIGURE 38.6 Accumulated numbers of units.

As one can easily see, VICS is not likely to reduce traffic congestion and accidents in a direct way. But according to some statistics it is said that VICS also provides people with a kind of comfort when they drive. So VICS is very useful to reduce traffic problems.

At the time the VICS service started, Tokyo, Aichi, and Kansai were the only three available areas to receive the information provided by VICS service. But now the service areas have spread to almost all over Japan. Figure 38.6 shows how rapidly both in-vehicle navigation system and VICS terminals grow in Japan. White bars in Fig. 38.6 show the accumulated number of in-vehicle navigation units in Japan. At the end of the last year, the number reached to about 6 million units. Getting along the growth of in-vehicle

**FIGURE 38.7** Major four functions of car navigation.

navigation systems VICS terminals also have grown very rapidly, as shown by the grey bars in Fig. 38.6 since 1996.

Besides VICS, five private companies shown in Table 38.3, Benz, Toyota, Nissan, Honda, and Sony, are also providing traffic information and other information such as parking area, weather forecast, sightseeing spots, and so on. Using the Internet, as Sony is doing, means no charge or fee to get information, except the media fee, to receive traffic information. In my opinion, it will be interesting to see which of the companies survive—the automakers or Sony.

### In-Vehicle Navigation System and VICS

First of all, the Japanese in-vehicle navigation system will be explained more minutely. Figure 38.7 shows the four main functions an in-vehicle navigation system can provide.

The first function is positioning of present vehicle location. Normally, global positioning system (GPS) and map matching technologies have been used to determine the present location of a car. The second function is route search between a present location of a vehicle and a driver's destination. One can easily get an optimum route between the present location and the destination when only the destination is

**FIGURE 38.8** Real configuration of in-vehicle navigation system.

input into an in-vehicle navigation system. The third function is route guidance to guide you to your destination along with the determined way by the route calculation function. Normally, this guidance is performed by both voice and display for driver's safety. The last important function is to display vehicle position, results of route search, and guidance so that drivers can understand them easily at a glance.

A real configuration of a typical in-vehicle navigation system is shown in Fig. 38.8. It normally consists of the six components shown in this picture. A color monitor for a navigation system is also used to display moving pictures from a TV set and a DVD player, as shown at the lower right of Fig. 38.9. An important issue is that VICS supposes an in-vehicle navigation system to be loaded in a vehicle. So, a TV tuner also includes a receiver for VICS, in general. As shown later, VICS uses three major media such as FM multiplex, electromagnetic beacon, and infrared light beacon.

Figure 38.10 is an example of a map display that often appears on a color display monitor of Japanese in-vehicle navigation system. It shows the three major basic results in the minute map: the display of the present vehicle position, the optimum route for the destination, and vehicle guidance. A simplified map in Fig. 38.10 helps drivers to understand the direction they have to follow at the next intersection. The large red triangle at the lower left of this figure shows the present vehicle position determined by the location identification technology. A row of small yellow triangles shows the optimum route calculated by a navigation system. The right simplified map in this picture enables a driver easily understand which way he or she should take at the next intersection.

Figure 38.11 is another example of map display of in-vehicle navigation system. The left map in this figure shows a real map showing the present vehicle position and the calculated optimum route to the destination. The right picture shows a 3-D, simplified map with several landmarks such as McDonald's, road messages, and a traffic signal. Normally, it is said that a 3-D representation is easily understandable for drivers regarding which way they have to go.

The situation is a bit different between Japan and other countries because of people's preferences for navigation displays are a bit different. For example, Japanese people like a map display as shown in Fig. 38.10, but people of other countries like only displays of the directions drivers have to take.

A block diagram of an in-vehicle navigation system is shown in Fig. 38.12. One can easily understand that essential configuration of an in-vehicle navigation system is the same as that of a personal computer excluding both the VICS unit and the sensors to be used to determine the vehicle location. In the CD-ROM,

FIGURE 38.9 Examples of information display.

FIGURE 38.10 Example of a map display (1).

a map database is stored and accessed when a map is displayed, an optimum route is searched, and route guidance is performed. The software in the ROM in Fig. 38.12 provides the four functions—vehicle location, route search, route guidance, and display. For example, vehicle location is determined with processing signals from GPS, a vehicle speed sensor, and a gyro sensor. After vehicle location is fixed, a map database in the CD-ROM is accessed. Then, both the present vehicle location and a map near to the

FIGURE 38.11 Example of a map display (2).

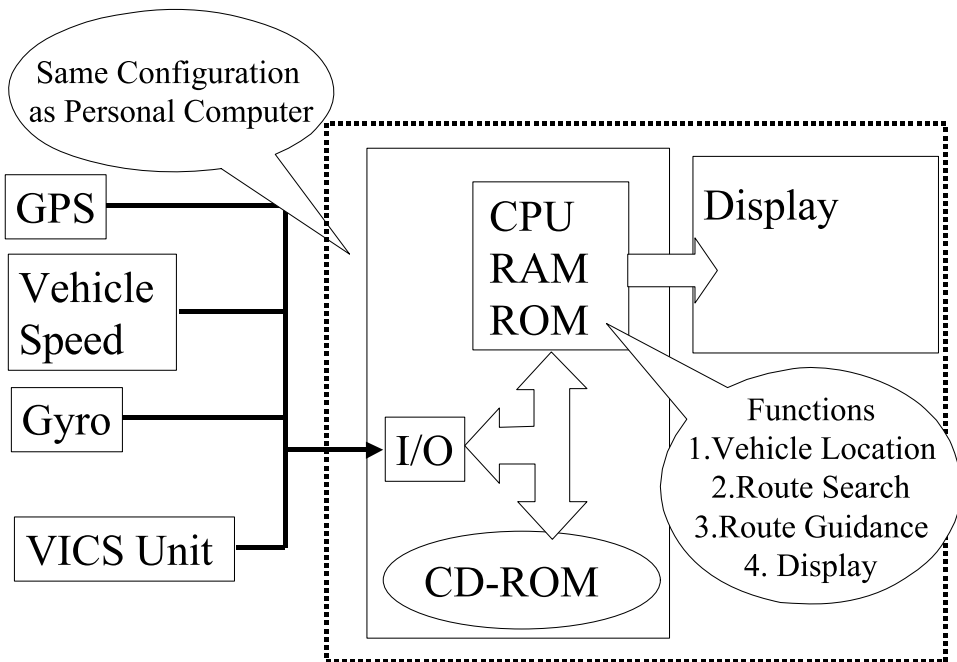

FIGURE 38.12 Vehicle navigation & VICS.

present vehicle location are displayed simultaneously on a color display monitor. If a driver inputs his or her destination to the navigation unit through the color monitor, the optimum route calculation is initiated and then the result is displayed. Along with the optimum route, the navigation unit guides the route to the driver in response to the vehicle movement. In addition to this, information such as the locations of restaurants, convenience stores, and gas stations near the vehicle's present location are also displayed.

FIGURE 38.13 Configuration of VICS.

The four basic functions of an in-vehicle navigation system, including the required function by VICS, are performed by software implemented in a navigation system as previously mentioned. So the scale of the software of an in-vehicle navigation system has become very large, it needs about 10 MB memory. This means it is 100 times as much as that of the software scale of engine control system that can cope with emission regulation of the passenger cars by Japanese government. Therefore, the software development of an in-vehicle navigation system cannot be developed with a conventional way in a short time at low expense.

The whole system of VICS can be explained using Fig. 38.13. Traffic information is collected and edited in VICS center, then it transmitted with the three media—electromagnetic beacon, infrared light beacon, and FM multiplex. One can get information, such as traffic congestion, through display of in-vehicle navigation system with the VICS terminal. VICS is supported by three ministries of Japanese government: the Ministry of Construction, the Ministry of Post & Telecommunication, and the National Police Agency. Figure 38.14 shows an example of a display that shows several pieces of information such as traffic information sent by VICS service. The map display is performed using a map database of an in-vehicle navigation system in Fig. 38.12. A road next to one red line in the left part of Fig. 38.14 shows congestion in only one direction. In this case up direction of this road is congested. Two red lines along a road shown at the right part in Fig. 38.14 means that the road is congested in two directions (up and down). One can easily detour these congested roads if with such real-time traffic information. VICS provides other information about road construction, road restrictions, and even about parking lots. VICS can also provide real-time information regarding traffic information and other useful information, and it gives a kind of comfort to drivers as a result.

## Electronic Toll Collection System

The electronic toll collection system (ETC) is an electronic fare collection system. This system was introduced in foreign countries earlier than in Japan. In Japan, the service of ETC starts this year. One of the aims of this system in Japan is to reduce the congestion at highway tollgates thereby resulting in less emission of exhaust. Figure 38.15 shows the whole system of Japanese ETC. Three major technologies are used: network in the infrastructure, automotive terminals for ETC, and road-to-vehicle communication. The infrastructure is composed of a huge network system into which personal information such as credit card numbers are flowing. Therefore, the information flowing into this network is written in code to ensure the security. Information from the automotive terminals for the ETC system is transmitted to the

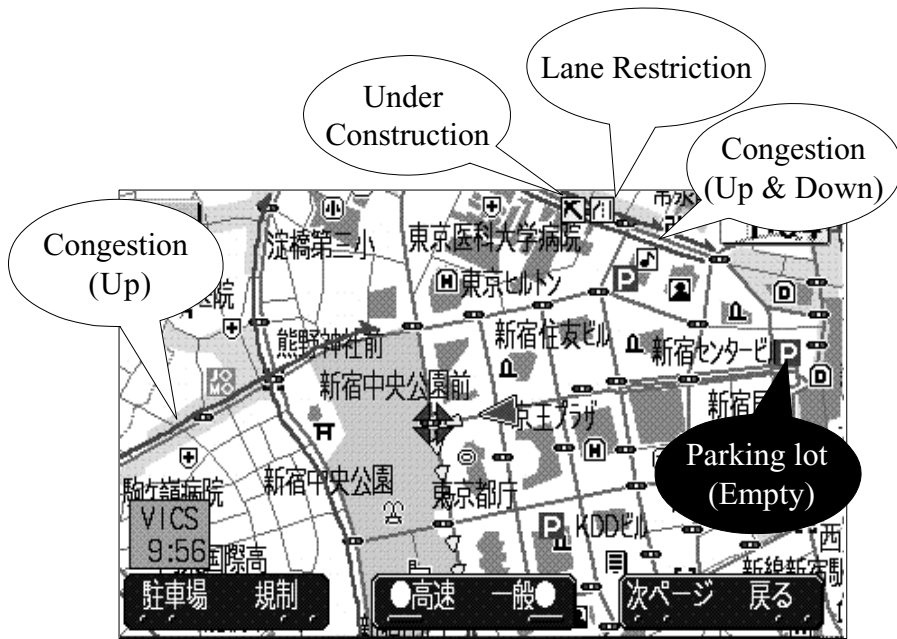

FIGURE 38.14 Examples of displayed information (VICS).

FIGURE 38.15 Network system for ETC.

network through road-to-vehicle communication known as dedicated short range communication (DSRC). Of course, it is also written in code to ensure the security. Specification of DSRC is shown in [Table 38.4](#). In the same manner, information about road infrastructure, such as the location of the tollgate, is also transmitted to a vehicle from the infrastructure and through DSRC.

**TABLE 38.4** Specification of DSRC

Item	Description
Frequencies	Two pairs in the 5.8 GHz band
Bandwidth	8 MHz max.
Transmitter output	10 mW
Communication system	Active type with slotted Aloha
Maximum vehicle speed	80 kph
Data transmission rate	1.024 Mbps
Modulation method	Amplitude shift keying
Bit error rate	Less than 10 ppm
Communication error rate	Less than 1 ppm
Encoding method	Manchester encoding

## Support of Safe Driving System

The support of safe driving system that appears in Fig. 38.5 is defined as the third development field of Japanese ITS has also been developed in Japan. In the early stages of the safe driving system, automatic driving was considered an ultimate support system. But many technical demonstrations on automatic driving from 1996 to 2000 gave people an impression that there were still many issues to be deployed from the point of view of both drivers and legal aspects. The author will demonstrate this more specifically later. So, recently it appears to the author that the idea of automatic driving is disappearing gradually. Instead of this, various warning systems and assistance systems have been considered. Demo2000 held at Japan last year shows effectiveness of those assistance systems such as AHS-I and ASV. “I” in the term of AHS-I means “information provision.” AHS-I is a kind of concept to assure safe driving of vehicle by using information provision of both traffic information and road configuration through road-to-vehicle communication. Not only road-to-vehicle communication but inter-vehicle communication is also useful to ensure traffic safety. A demonstration showing the effectiveness of this technology was also shown in Demo2000 at Tsukuba, Japan. For example, it was shown to form platooning composed of running vehicles using inter-vehicle communication technology.

## 38.4 Issues of ITS Development and Roles of Software Technology

### Issues of ITS Development

The readers can easily think of technological issues to put into practical with the use of ITS, particularly an assist system of safe driving. Actually, the more important issues to deploy ITS are related to social, legal, and human issues, including responsibility, which are recognized with technical demonstration from 1996 to 2000 of the support system for safe driving. Table 38.5 shows the technical issues for deploying ITS. The importance of these technical issues will be easily understood. Figure 38.16 shows social, legal, and driver’s issues summarized by Becker and the author.

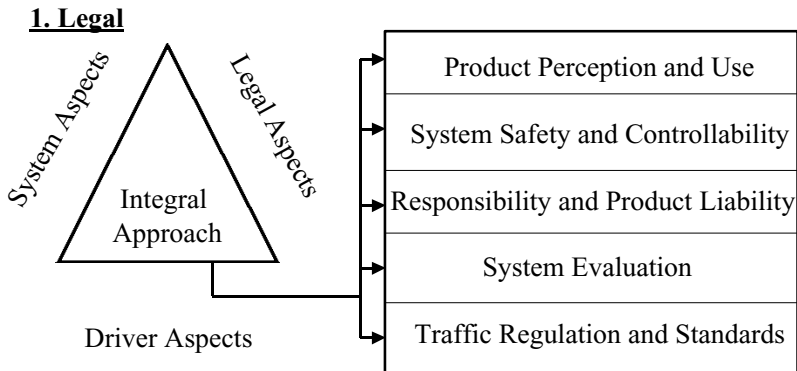

Legal and driver’s issues are composed of five terms, as shown in Fig. 38.16. The first is “product perception and use.” This means how deeply users of the ITS-related system like the assist system for safe driving, can recognize the performance and the use of the system. For example, suppose you buy an air-bag system. You have to understand both its performance and how to use it very well. You have to know how it works depending on magnitude of the crash. If you do not know that, you will be overconfident about the air-bag system, and you may be injured by a traffic accident. In this process, sufficient explanation of a system by a salesman is very important for users to operate the system very well.

The second important issue is about “system safety and controllability” in Fig. 38.16. One can easily understand the importance of this issue if one compares control systems of a car with that of an aircraft. Pilots in an aircraft can operate the control system completely because pilots know how the control

**TABLE 38.5** Technological Issues

- 
1. Robust sensing technology  
(e.g., obstacles, road conditions, traffic flow, and so on)
  2. Robust control technology  
(e.g., vehicle control, traffic control, platoon control, and so on)
  3. Human technology  
(e.g., display, human I/F, drivers intention, and so on)
  4. Information and processing technology
  5. Communication technology
  6. System integration technology
- 

**2. Social**

- 1) Chicken-and-Egg Arguments
- 2) Persuasion of people who suspect effectiveness of ITS

**FIGURE 38.16** Legal and social issues.

**ETC Simulation Result**

**FIGURE 38.17** Simulation results with ITS simulator.

systems work well. Moreover, they know how to override the control systems in an emergency. Pilots are highly disciplined people, but drivers are not necessarily such people. So this issue becomes very important in case of drivers.

The third issue is related to “responsibility and product liability.” Suppose a crash happens. Who has to be responsible for the crash? Which is more responsible, a control system or a driver? Is it the biggest issue to deploy the ITS properly?

System evaluation, the fourth issue, and traffic regulation and standard, the fifth issue, are also very important. So you can easily understand their importance without any explanation on these issues.

Two social issues are shown in Fig. 38.16. One is the chicken-and-egg argument and the other is persuasion of people who suspect effectiveness of ITS deployment. The chicken-and-egg argument holds in the spread of a system that is composed of both infrastructure and automotive equipments, which rely on infrastructure and vice versa. For example, we consider the case of ETC. There will be no incentive of spreading automotive terminal for ETC without preparation of infrastructure for ETC. On the other hand, there is no incentive for infrastructure to be prepared without automotive terminal of ETC. This is a so called a problem that is first infrastructure or automotive terminals.

Now many people say that ITS is necessary to make smoother traffic flow as well as decrease air pollution as a result. But some people are still suspicious as to the effectiveness of ITS. For example, is it true that ITS decreases traffic congestions? Even if it is true, less congestion makes more people use cars. As a result, less congestion cause more traffic demands. This will lead to more traffic flow. Therefore, only more vehicles can run, thanks to ITS. As a final result, they think that more cars can run on roads after ITS is deployed. So gestion will remain almost invariable even if ITS is introduced. It is a conclusion of the people who are suspicious about the effects of ITS and that traffic congestion will not decrease after ITS is introduced. In case of ETC deployment, several people do not believe the effect, and they say ETC will change only location of congestion. For example, suppose there is a junction in front of a tollgate. Before ETC is introduced, the tollgate was congested. After ETC is introduced, there will be congestion at the junction instead of the congestion in front of the tollgate. It seems that the location of the congestion shifts from the tollgate to the junction. This is a conclusion of the people who are suspicious as to the effect of ETC.

## Roles of Software Technology

As discussed earlier, ITS is making full use of both information technology and communication technology. Therefore, the importance of software technology does not need to be explained. For example, in-vehicle navigation system has a size of the software about 10 MB. This size is about one hundred times that of engine control software that meets the stringent exhaust gas regulation. This software can provide important performance, as shown in Fig. 38.7. Besides, this software technology has a great potential to solve these issues mentioned previously.

In advance, to explain the potential of software technology for solving the social and driver's issues, as shown in the preceding section, let us explain the concept to solve these issues. The first issue of "product perception and use" in Fig. 38.16 would be solved by showing both the performance of the product or system to be introduced into the market and how to use it. For this purpose, a simulation program that can simulate the performance is very effective and makes users understand it. For example, a simulation program of the performance of the air-bag system can show both its performance and how it works well. So users can easily understand the performance of an air-bag system or, in some cases, even the limitation of that system. In other words, the issue of product perception and use is realized by software technology.

In a similar way, the second issue of "system safety and controllability" is also solved by software technology. For example, you can very easily learn system safety and controllability if you have a simulation program. For a new aircraft, pilots can learn its control system and can be trained very well with a flight simulator.

As for the third issue of "responsibility and product liability," a simulation program is very helpful in solving this issue. Product liability (PL) is originally set for protecting users of product, but it sometimes makes manufacturers conservative about developing a new product. The solution for this issue, however, is obtained by assuring the safety of a product from the viewpoint of users. This can be done by showing users the safety of the product in every area where the product is supposed to be used. Only a simulation program of the performance of the product can perform this. For the third issue, software technology is also very effective.

The fourth issue of "system evaluation" can also be supported with the use of a simulation program. It would not need to explain. The fifth issue of "traffic regulation and standards" is a little bit different compared with the four issues mentioned previously.

Social issues, including both the “chicken-and-egg argument” and persuasion of people who suspect effectiveness of ITS, are also solved by simulation. For example, people can learn about the effectiveness of ETC by a simulation program of ETC. [Figure 38.17](#) is an example of a simulation of the effect of ETC with the ITS simulator that is under development. You can easily understand that the introduction of ETC decreases the congestion in front of a tollgate, as shown in the upper portion of [Fig. 38.17](#). Even conservative people would agree to build ETC in order to see this result.

## 38.5 Practices of Software Development of Both In-Vehicle Navigation System and ITS Simulator

---

Software scales of both the in-vehicle navigation system and the ITS simulator are relatively large, but there is a difference in both properties between the navigation system and the ITS simulator. In the case of the navigation system it is embedded software that meets the needs of users. On the other hand, the ITS simulator is not embedded. In this section, both the software of the in-vehicle navigation system and the ITS simulator are explained briefly.

### In-Vehicle Navigation Systems

#### Status of the Development of In-Vehicle Navigation System

One of the most severe issues in the development of the software for in-vehicle navigation is the short development time for the software, which meets customer requirements with low expense.

So some people say that only people who can develop in-vehicle navigation system software very quickly, at very low cost, would control the in-vehicle navigation system market.

As discussed earlier, in-vehicle navigation system software size is relatively large compared with other consumer products like a refrigerator, a washing machine, and an air conditioner. The size has reached nearly 10 MB. Cellular phones have almost the same software size. In general, this means that the cost to build the software has become very high and it needs a long time for development.

As you can easily understand, the market of the in-vehicle navigation system has two aspects. One is the aspect of consumer electronic products mainly sold at after-markets. The other aspect is that of the OEM market where the in-vehicle navigation system is sold and delivered directly to automakers from suppliers such as manufacturers of electric equipments. [Table 38.6](#) shows three important issues to be maintained or met by OEM suppliers of in-vehicle navigation system.

The first issue is customer satisfaction. Here, customer means automakers, not drivers themselves. That is, automakers decide which supplier’s navigation system to buy. So, it is necessary for suppliers to meet the various needs of automakers.

The second important issue is keeping the delivery time set by automakers. Automakers have strategies to sell their cars. So the delivery time of navigation systems is set by automakers. The only thing that suppliers can do is to keep the delivery time very strictly. So the lead-time to develop an in-vehicle navigation system is normally very limited for suppliers.

The last important issue to keep in mind is reliability of an in-vehicle navigation system. Of course, reliability is also very important in the case of consumer electronic products; but in the OEM market, reliability is a more important issue because a sold car might have been returned due to the unreliability of the in-vehicle navigation system.

**TABLE 38.6** Features of OEM Market as Customers

---

1. Customer satisfaction	We have to meet the various needs of each automaker.
2. The date of delivery	We have to keep it very strictly.
3. High reliability	It may happen that a sold car is returned to automakers due to unreliability of car navigation system.

---

*Note:* Quick development of navigation software with high reliability.

**FIGURE 38.18** Issues of navigation software development.

Summarizing the three important issues, we can see a quick development of navigation software, with high reliability is a key point. Currently, many difficulties are present in navigation software development based on conventional methodology; however, as large as the software scale becomes, it does not have any problem if we can reuse the software in response to the needs of each automaker. But each auto-maker has many different needs, for example, different functions of a navigation system, man machine interfaces, desired price, and so on. On the other hand, normally the rate of reused software is relatively low, about 40%. Of the software, 60% has to be developed or modified profoundly in response to the needs of each automaker. [Figure 38.18](#) shows the software volume ratio in developing the new navigation systems. About 60% of the software must be renewed for them, and the human-interface related software occupies a large part of all the renewed software. In addition to this, we have often encountered that software specification of each automaker has not been fixed until the end of development of the software.

To reduce both S/W bugs and lead-time to develop the navigation software, adoption of both middleware architecture and auto code generation is desirable. These techniques originate from the so-called object oriented development of software.

To promote determination of software specification of automakers, particularly man machine interface (MMI) portion of in-vehicle navigation system, it is suitable to introduce man machine builder tool that has already developed in another field, such as public infrastructure. The next subsection explains these two technologies realizing the issues stated earlier.

### **New Methodology to Develop In-Vehicle Navigation Software**

The first technology originated from object-oriented software development. [Figure 38.19](#) shows the basic development flow along with the object-oriented software development. In the beginning, that is, the design stage of the object-oriented development model, customer requirements and system functions are decomposed of the object components that represent the basic or initial system. In this stage, various supplemental functions of automakers are decomposed of both each child component and the basic components that will incorporate features as additional components. Because all decomposed components including basic and child components are developed individually, their implementation and tests can be easily performed. For example, both the basic component and child components are implemented

FIGURE 38.19 Object-oriented development model.

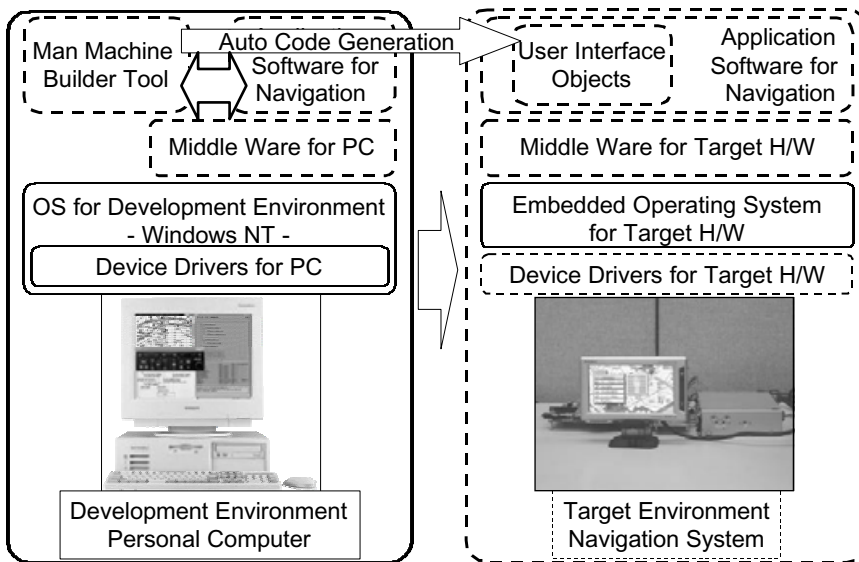

FIGURE 38.20 Hierarchical software architecture model.

and tested separately, and then both implementation and test as a whole system, such as system function, can be performed.

Child components and additional components are also given the same process to assemble the complete system, which meets the customers requirement. In object-oriented development we can easily modify with the addition of additional components. So this modification costs relatively less compared with the conventional waterfall software development. From the point of view of both easy debug and implementation to a target machine, we need another means besides adoption of object oriented development model. Moreover, we need a means to make automakers decide their specifications earlier.

Figure 38.20 shows the hierarchical software architecture models to make us debug easily and implement. The architecture has two distinct points. One is this middleware and the other, man machine

builder tools serving to build MMI of in-vehicle navigation system. The middleware acts as a kind of separator between application software for navigation and hardware like personal computer (PC), and target machine. A detail of man machine builder tools will be shown later.

Generally speaking, it is desirable to use a PC as a software development environment because of its lighter weight, portability, and low price. The operating system (OS) for this environment is Windows NT. This OS includes device drivers for the hardware in the left picture of Fig. 38.20. Now let us explain the flow of navigation software development. In the beginning, application software of navigation system, composed of both child and basic components, is built with man machine builder on PCs as software development tools. Then the software is tested and debugged on the PCs. After that, the software is rewritten in terms of a target machine by using auto code generation and implemented. Then the application software is transferred to the target environment. This software definitely works well on the target machine because all necessary tests are already done by using PC and confirmed that the application software works well without any problem. So the remaining development that has to be done is to develop the device drivers for target hardware, which harmonizes the embedded OS with the hardware, as shown in the right picture of Fig. 38.20.

Also, it is necessary to modify the middleware for target hardware. After the modification of the middleware for target machine, the developed application software, excluding user interface objects, is tested to check how well it works. Thus, the application software for navigation can be easily applied onto the target environment by using this middleware.

The man machine builder tool automatically generates the software code for user interface object, and this software code is included into the application software. When one develops navigation software along with the above processes, one can indeed develop both software and hardware concurrently. This reduces the lead-time of developing new navigation system dramatically and enhances reliability of the software. Because the application software of the navigation system is developed on Windows OS, one can easily confirm its operation, in the early phase of development, even if the target hardware is still under development. CRT display in Fig. 38.21 shows an example of the software test in development phase. In this display, one can confirm how the functions of the navigation software work well, instead of the real

FIGURE 38.21 Confirmation of operation using PC.

FIGURE 38.22 Conventional method for man machine module.

display device; that is, these functions of application software can operate and confirm with virtual operation panel with dummy signal dialog, and voice guide dialog.

The man machine builder tool is also used to make automakers decide the specification of the man machine interface in the early stage of the software development because man machine builder tool can give them virtual MMI and show how it works. For example, using the virtual display, drivers can input their destinations and their requests to search optimum routes or restaurants near their present locations. MMI serves drivers to do these interactively using several icons in Fig. 38.21. Generally speaking, the specification of man machine interface is often not determined until the end of development because the determination needs ergonomic studies. So it is desirable for providers to make a virtual environment to simulate the operation of man machine interface to be developed.

The man machine builder tool consists of both user interface design tool and state chart CASE tool. The missions of the user interface design tool are graphical object design, operation confirmation, and code generation.

On the other hand, the mission of the state chart CASE tool are production of operative transition, graphical confirmation of transition, and code generation of state transition.

Before explaining the function of the man machine builder tool briefly, we will explain about the conventional way to build MMI using Fig. 38.22. In the conventional method, the man machine module including graphical object design for user interface and state transition is designed from requirement analysis in the beginning. After both graphical object design and state transition are proceeded, software code of man machine module are coded separately by manual operation (hand coding).

Then the software code is combined with other application software. Finally, its operational test is performed on a display of target hardware. If some unexpected behavior or shape occurs in the user interface, its correction of design and coding are reprocessed. And, though this is a more important issue, additional requests by customers are often added to the specification to MMI. In order to cope with this, a new environment to build MMI differently from the conventional method is indispensable.

By using the new development environment of building MMI, one can generate the man machine module throughout from design to software code. With this tool, a graphical object is designed with the menu object editor, as shown in Fig. 38.23. This means both the graphic objects for MMI and the animation of their graphic objects are defined simultaneously with production of objects.

State transition is defined in the state chart editor in the right part of Fig. 38.23. In the state chart editor, both the animation parameters of graphic objects and navigation function behavior are defined following the state transition. After the graphical confirmation of both these graphic behaviors and state transition, these tools can generate the software code for man machine module automatically. Thus, you can show

FIGURE 38.23 Development with man machine builder tool.

- Graphical Object production by basic/special components
  - Design Navigation menu objects by polygonal line, polygon, ellipse, character string, bit map, etc.
- “Operation” setting in diagram (Production of animation)
  - Transform each diagram in relation to its variable.

FIGURE 38.24 Function of menu object editor.

automakers how the user interface under development works well, using the virtual display. And you can get necessary suggestions including the additional needs from them. Thus, one can easily understand that this tool can accept various requests from customers interactively. So the specification of MMI is easily determined, unlike the conventional method, by using this tool.

The menu object editor in Fig. 38.23 has two main functions. One is the production of the graphical object of the user interface of the navigation system using the basic and special components. The other is the production of animation in the user interface. In Fig. 38.24 basic components, such as polygonal line, polygon and ellipse are shown in the upper dotted box of the left picture in Fig. 38.24. Special components are only needed for the navigation object, such as character strings, bitmaps representing

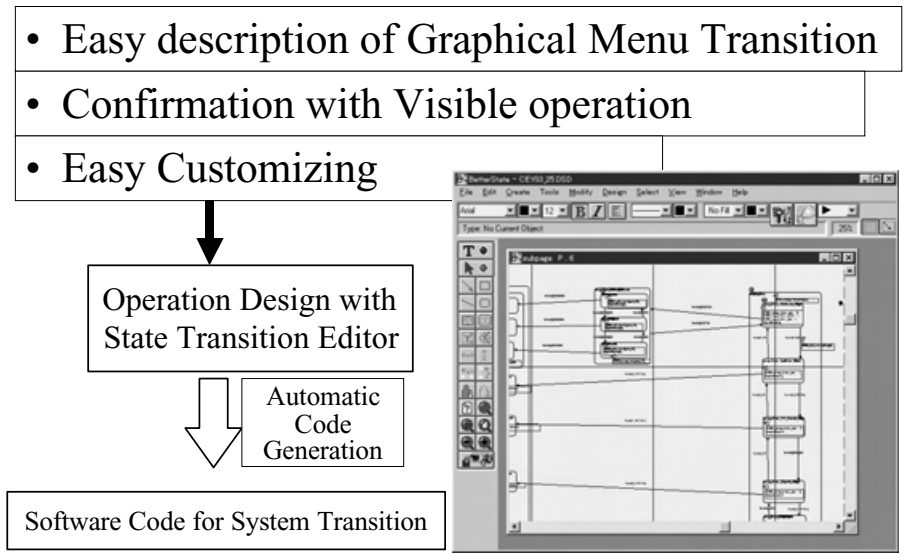

FIGURE 38.25 State transition design.

the specified functions of the system, and the button object for the menu interface are generated. In addition to the object design, animation of the object can also create its transition, and this animation can be simulated on this tool, as shown in Fig. 38.25. This menu object editor also has a function of automation code generation for designed object and animation.

Use of state chart CASE tool to state transition design has these major points. The first major point is the easy description of graphical menu transition. Designed transition can be visually confirmed with the visible state chart, which is the second major point. The third point is easy customizing of the state transition. It can be modified in the visual tool by moving the transition line in the design window in the right picture of Fig. 38.25. So one can introduce it to advanced environment for navigation software development. This CASE tool can also output the software code of the state transition with an automatic code generation function.

Here, we show the operation flow of making the entire software using the MMI builder tool. In Fig. 38.26, the man machine module provides the navigation software code. When the graphical object design is finished, the software code of the menu objects is generated automatically. The software code of the state transition is also generated in the same manner. Both the codes are included in man machine module, then the binary code of the navigation software is built to confirm its function on the PC. This sequence is continued until achievement of all requirements, and it builds for the target hardware to release the actual sample.

**ITS Simulator and Its Functions**

ITS simulator is a kind of driving simulator. So real configuration of the ITS simulator is very similar to that of the driving simulator. Figure 38.27 shows the configuration that is composed of computer, screen, projector, and a half actual vehicle. Although the configuration of the ITS simulator is similar to a driving simulator, the functions are very different from those of a driving simulator. The ITS simulator can simulate both several effects and effectiveness of ITS deployment as a result of simulating the interaction between road infrastructure and vehicles. This is one of the greatest different points between a driving simulator and ITS simulator.

Figure 38.28 shows the architecture of ITS simulator. It consists of four major modules, vehicle dynamics simulator module, micro traffic simulator module, 3D road environmental simulator module, and system control module.

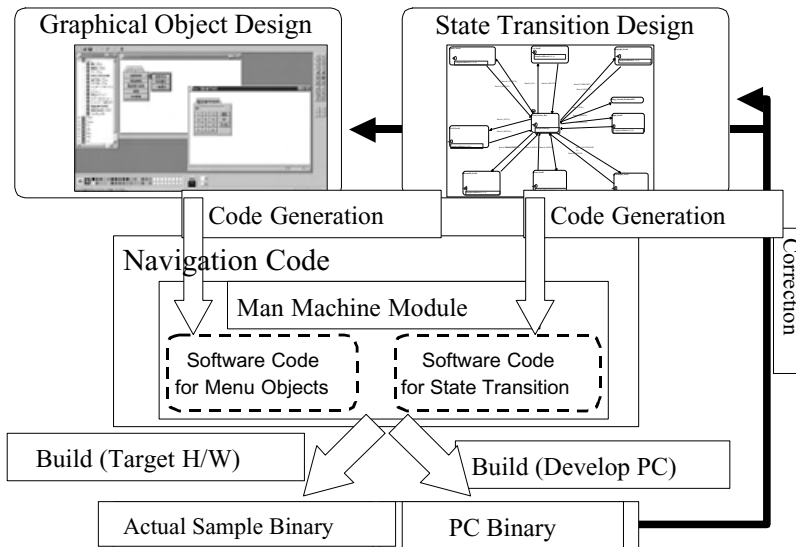

FIGURE 38.26 Operation flow with man machine builder.

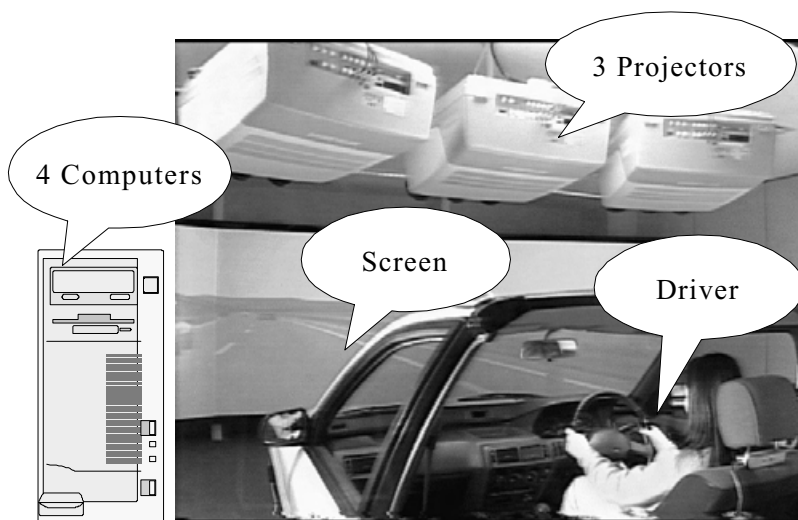

FIGURE 38.27 Physical configuration of ITS simulator.

The first module of vehicle dynamics simulator provides the movement of the half driving vehicle dynamics in real-time. This vehicle dynamics model has nine degrees of freedom of movements. Therefore, you can feel as if you were in a real car in the half vehicle of ITS simulator in the same manner of a driving simulator.

The second module of microscopic road traffic simulator, which is called MELROSE, generates a virtual road traffic environment based on an autonomous driving model. Every vehicle provided by this module acts as surrounded vehicles of the simulated vehicle of the vehicle dynamics simulator, and also every vehicle can run with its own origin and destination. So these vehicles can act as surrounded vehicles.

This third module is a 3D-computer graphics road environment simulator. This simulator creates actual geographical conditions and road configurations in response to the vehicle location of the simulated

FIGURE 38.28 Modules of ITS simulator.

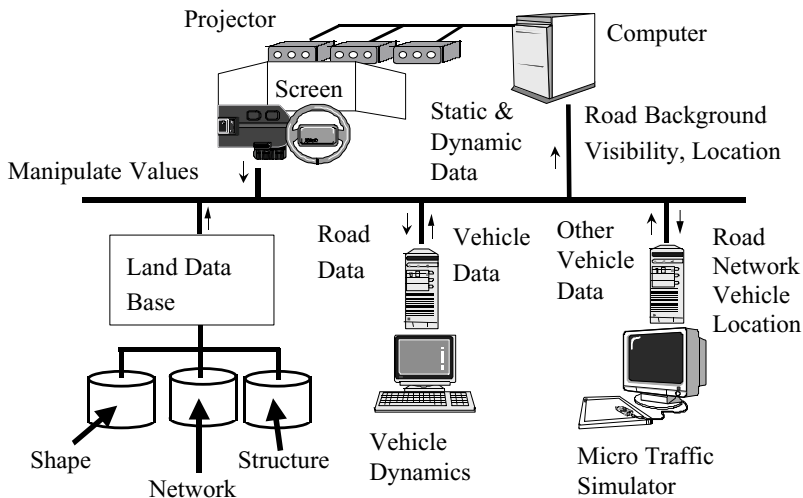

FIGURE 38.29 Physical architecture of ITS simulator.

vehicle. For these, various road data like width, gradient, numbers of lane, road shape, and so on are stored in the memories of this module. In response to the vehicle movement the stored road data are accessed to form virtual road environment with 3D graphics based on real road data.

The final module is to control the operation of the above three module and to make the total modules operate as the ITS simulator. A representative action is to synchronize other three modules because all time units to compute are different in each module.

Figure 38.29 shows an architecture and data flow among all four modules. The land database means the stored data as shown before. The upper right computer in Fig. 38.29 means system control module and 3D graphic processing of road environment simulator.

A simulation result on how congestion is formed by a blocking vehicle is shown in Fig. 38.30. The reader can easily understand a process of congestion due to a blocking vehicle in a circle. A driving simulator cannot simulate such a situation. The next simulation result is shown in Fig. 38.31. It simulates

A blocking vehicle

FIGURE 38.30 Generation of congestion due to accident.

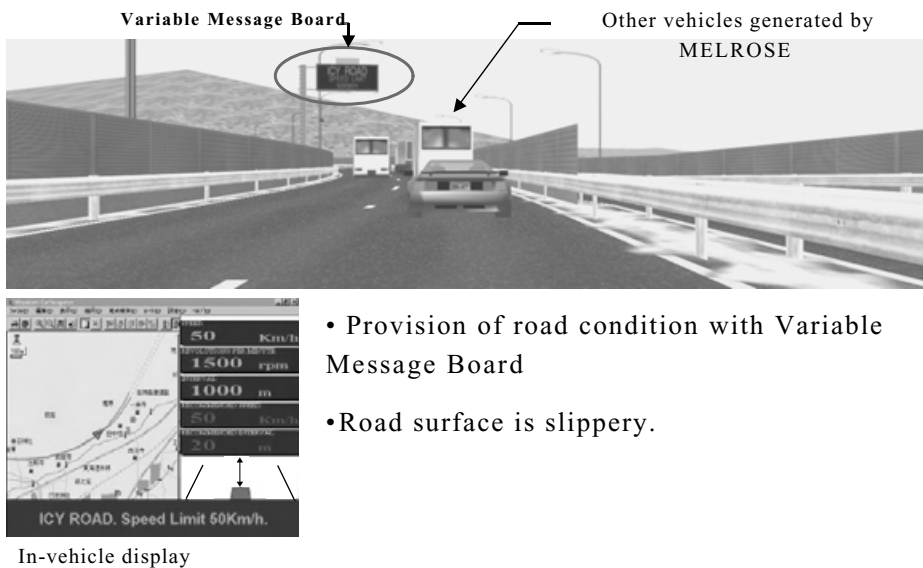

FIGURE 38.31 Simulation of effectiveness of AHS-i.

a kind of the interaction effects between provisions of traffic information and vehicles or drivers, that is, it simulates the differences of traffic flow rate with and without traffic information with a message board to drivers. For example, a roadside message board in the circle in Fig. 38.31 says that there is an icy road surface ahead, so please slow down. This message is also sent through road to vehicle communication to vehicle and shown in the in-vehicle display like in-vehicle navigation system in Fig. 38.31. Now a smart driver follows this advice to get smooth traffic flow. Some driver might not follow. As a result of this, congestion would occur to cause bad traffic flow. Therefore, traffic flow rates between these two cases are very different. ITS simulator can simulate such a situation and show the effectiveness of the provisions of traffic information.

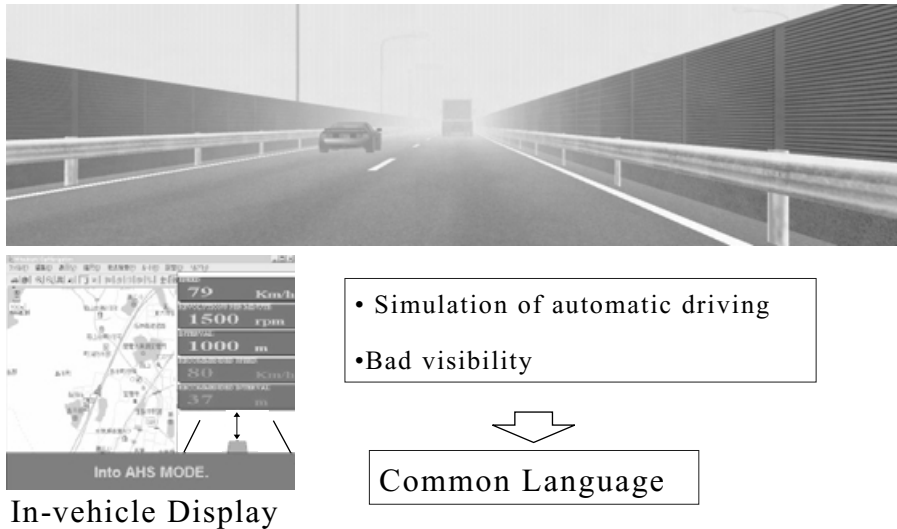

FIGURE 38.32 Simulation of effectiveness of AHS-a.

Figure 38.32 shows another example of the simulation with ITS simulator. A foggy situation with bad visibility is simulated. For example, a vehicle with an automatic driving system can run safely in spite of such a foggy condition. Though several modifications are needed, ITS simulator can simulate both every considerable traffic situation and considerable situation of use of control systems like automatic driving. As I mentioned earlier, this means that ITS simulator has a great advantage to show both the effects and the effectiveness of ITS deployment.

The microscopic traffic simulator, that is a part of the ITS simulator, alone can simulate several situations. For example, Fig. 38.17 shows the effects on congestion in front of a tollgate of a highway between with and without ETC. The upper case in Fig. 38.17 shows congestion in front of a tollgate with ETC. The lower shows the case without ETC. Each colored rectangle shows each vehicle. So the length of congestion is given by that of the row of the rectangles on each lane. You can easily see the difference between with and without ETC. Even people who suspect the effect of introducing ETC can understand the effect and would agree to the introduction of ETC.

## 38.6 Conclusion

We have the following conclusions:

1. In Japan in-vehicle navigation system are widespread and the VICS service to provide real-time traffic information is also widely spread. As for ETC, its service is about to start.
2. In the development of navigation software, adoption of both an hierarchical architecture and man machine builder into the development environment of navigation software is powerful enough to develop the software very quickly with high reliability.
3. ITS simulator is a powerful tool to solve the issues of ITS deployment.

## Acknowledgments

The author expresses his great thanks to Dr. Yukio Goto, Mr. Yoshihiko Utsui, Mr. Masahiko Ikawa, Mr. Akio Uekawa, Dr. Hiroyuki Kumazawa, Mr. Mitsuo Shimotani, Mr. Minoru Ozaki, Mr. Akira Sugimoto, and other many researchers and engineers at the Industrial Electronics and Systems Laboratory of Mitsubishi Electric Corporation, for their great assistance and encouragement.

## To Probe Further

In this field, there has been much rapid progress. So we cannot find comprehensive literature on Japanese ITS. Therefore, below is some literature about specific fields.

## 39.1 Instruction Set Architecture for Multimedia Signal Processing

---

*Ruby Lee*

### Introduction

Multimedia signal processing, or media processing [1], is the processing of digital multimedia information in a programmable processor. Digital multimedia information includes visual information like images, video, graphics, and animation, audio information like voice and music, and textual information like keyboard text and handwriting. With general-purpose computers processing more multimedia information, multimedia instructions for efficient media processing have been defined for the instruction set architectures (ISAs) of microprocessors. Meanwhile, digital processing of video and audio data in consumer products has also resulted in more sophisticated multimedia processors. Traditional digital signal processors (DSPs) in music players and recorders and mobile telephones are becoming increasingly sophisticated as they process multiple forms of multimedia data, rather than just audio signals. Video processors for televisions and video recorders have become more versatile as they have to take into account high-fidelity audio processing and real-time three-dimensional (3-D) graphics animations. This has led to the design

FIGURE 39.1 32-bit integer register made up of four 8-bit subwords.

of more versatile media processors, which combine the capabilities of DSPs for efficient audio and signal processing, video processors for efficient video processing, graphics processors for efficient 2-D and 3-D graphics processing, and general-purpose processors for efficient and flexible programming. The functions performed by microprocessors and media processors may eventually converge. In this chapter, some of the key innovations in multimedia instructions added to microprocessor ISAs are described, which have allowed high-fidelity multimedia to be processed in real-time on ubiquitous desktop and notebook computers. Many of these features have also been adopted in modern media processors and DSPs.

### Subword Parallelism

Workload characterization studies on multimedia applications show that media applications have huge amounts of data parallelism and operate on lower-precision data types. A pixel-oriented application, for example, rarely needs to process data that is wider than 16 bits. This translates into low computational efficiency on general-purpose processors where the register and datapath sizes are typically 32 or 64 bits, called the width of a word. Efficient processing of low-precision data types in parallel becomes a basic requirement for improved multimedia performance. This is achieved by partitioning a word into multiple *subwords*, each subword representing a lower-precision datum. A *packed data type* will be defined as data that consists of multiple subwords packed together. These subwords can be processed in parallel using a single instruction, called a *subword-parallel* instruction, a *packed* instruction, or a *microSIMD* instruction. SIMD stands for “single instruction multiple data,” a term coined by Flynn [2] for describing very large parallel machines with many data processors, where the same instruction issued from a single control processor operates in parallel on data elements in the parallel data processors. Lee [3] coined the term *microSIMD* architecture to describe an ISA—where a single instruction operates in parallel on multiple subwords within a single processor.

Figure 39.1 shows a 32-bit integer register that is made up of four 8-bit subwords. The subwords in the register can be pixel values from a grayscale image. In this case, the register is holding four pixels with values 0xFF, 0x0F, 0xF0, and 0x00. The same 32-bit register can also be interpreted as two 16-bit subwords, in which case, these subwords would be 0xFF0F and 0xF000. The subword boundaries do not correspond to a physical boundary in the register file; they are merely how the bits in the word are interpreted by the program. If we have 64-bit registers, the most useful subword sizes will be 8-, 16-, or 32-bit words. A single register can then accommodate 8, 4, or 2 of these different sized subwords, respectively.

To exploit subword parallelism, packed parallelism, or *microSIMD* parallelism in a typical word-oriented microprocessor, new subword-parallel or packed instructions are added. (The terms “subword-parallel,” “packed,” and “*microSIMD*” are used interchangeably to describe operations, instructions and architectures.) The parallel processing of the packed data types typically requires only minor modifications to the word-oriented functional units, with the register file and the pipeline structure remaining unchanged. This results in very significant performance improvements for multimedia processing, at a very low cost (see Fig. 39.2).

Typically, packed arithmetic instructions such as *packed add* and *packed subtract* are first introduced. To support subword parallelism efficiently, other classes of new instructions such as subword permutation instructions are also needed. Typical subword-parallel instructions are described in the rest of this chapter, pointing out interesting arithmetic or architectural features that have been added to support this style of *microSIMD* parallelism. In the subsection on “Packed Add and Packed Subtract Instructions,” *packed add* and *packed subtract* instructions described are, as well as several variants of these. These instructions can all be implemented on the basic Arithmetic Logical Units (ALUs) found in programmable processors, with minor modifications. Such partitionable ALUs are described in the subsection on “Partitionable ALUs.” *Saturation arithmetic*—one of the most interesting outcomes of

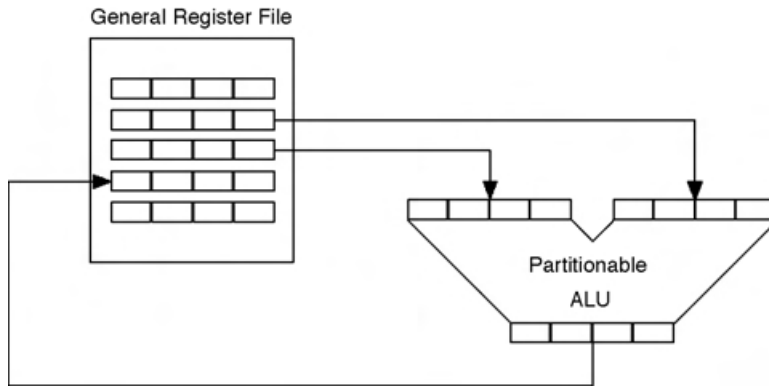

FIGURE 39.2 MicroSIMD parallelism uses packed data types and a partitionable ALU.

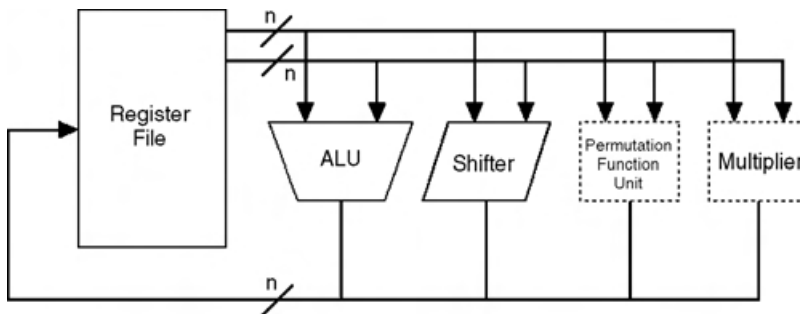

FIGURE 39.3 Typical datapaths and functional units in a programmable processor.

subword-parallel additions—for efficiently handling overflows and performing in-line conditional operations is also described. A variant of packed addition is the *packed average* instruction, where unbiased rounding is an interesting associated feature. Another class of packed instructions that can use the ALU is the *parallel compare* instruction where the results are the outcomes of the subword comparisons.

The subsection on “Packed Multiply Instruction” describes how packed integer multiplication is handled. Also described are different approaches to solving the problem of the products being twice as large as the subword operands that are multiplied in parallel. Although subword-parallel multiplication instructions generally require the introduction of new integer multiplication functional units to a microprocessor, the special case of multiplication by constants, which can be achieved very efficiently with *packed shift* and *add* instructions that can be implemented on an ALU with a small preshifter, is described.

The subsection on “Packed Shift and Rotate Operations” describes *packed shift* and *packed rotate* instructions, which perform a superset of the functions of a typical shifter found in microprocessors, in parallel, on packed subwords.

The subsection on “Subword Permutation Instruction” describes a new class of instructions, not previously found in programmable processors that do not support subword parallelism. These are subword permutation instructions, which rearrange the order of the subwords packed in one or more registers. These permutation instructions can be implemented using a modified shifter, or as a separate permutation function unit (see Fig. 39.3).

To provide examples and illustrations, the following first and second generation multimedia instructions in microprocessor ISAs are used:

- IA-64 [4,5], MMX [6,7], and SSE-2 [8] from Intel,
- MAX-2 [9,10] from Hewlett-Packard,

- 3DNow!<sup>1</sup> [11,12] from AMD,
- AltiVec [13] from Motorola.

## Historical Overview

The first generation multimedia instructions focused on subword parallelism in the integer domain. These are described and compared in [14]. The first set of multimedia extensions targeted at general-purpose multimedia acceleration, rather than just graphics acceleration, was MAX-1, introduced with the PA-7100LC processor in January 1994 [15,16] by Hewlett-Packard. MAX-1, an acronym for “multimedia acceleration extensions,” is a minimalist set of multimedia instructions for the 32-bit PA-RISC processor [17]. An application that clearly illustrated the superior performance of MAX-1 was MPEG-1 video and audio decoding with software, at real-time rates of 30 frames per second [18]. For the first time, this performance was made possible using software on a general-purpose processor in a low-end desktop computer. Until then, such high-fidelity, real-time video decompression performance was not achievable without using specialized hardware. MAX-1 also accelerated pixel processing in graphics rendering and image processing, and 16-bit audio processing.

Next, Sun introduced VIS [19], which was an extension for the UltraSparc processors. VIS was a much larger set of multimedia instructions. In addition to packed arithmetic operations, VIS provided very specialized instructions for accessing visual data, stored in predetermined ways in memory.

Intel introduced MMX [6,7] multimedia extensions in the dominant Pentium microprocessors in January 1997, which immediately legitimized the valuable contribution of multimedia instructions for ubiquitous multimedia applications.

MAX-2 [9] was Hewlett-Packard’s multimedia extension for its 64-bit PA-RISC 2.0 processors [10]. Although designed simultaneously with MAX-1, it was only introduced in 1996, with the PA-RISC 2.0 architecture. The subword permutation instructions introduced with MAX-2 were useful only with the increased subword parallelism in 64-bit registers. Like MAX-1, MAX-2 was also a minimalist set of general-purpose media acceleration primitives.

MIPS also described MDMX multimedia extensions and Alpha described a very small set of MVI multimedia instructions for video compression.

The second generation multimedia instructions initially focused on subword parallelism on the floating-point (FP) side for accelerating graphics geometry computations and high-fidelity audio processing. Both of these multimedia applications use single-precision, floating-point numbers for increased range and accuracy, rather than 8-bit or 16-bit integers. These multimedia ISAs include SSE and SSE-2 [8] from Intel and 3DNow! [11,12] from AMD. Finally, the PowerPC’s AltiVec [13] and the Intel-HP IA-64 [4,5] multimedia instruction sets are comprehensive integer and floating-point multimedia instructions. Today, every microprocessor ISA and most media and DSP ISAs include subword-parallel multimedia instructions.

## Packed Add and Packed Subtract Instructions

Packed add and packed subtract instructions are similar to ordinary add and subtract instructions, except that the operations are performed in parallel on the subwords of two source registers. Add (nonpacked) and packed add operations are shown in Figs. 39.4 and 39.5, respectively. The packed add in Fig. 39.5 uses source registers with four subwords each. The corresponding subwords from the two source registers are summed up, and the four sums are written to the target register. A packed subtract operation operates similarly.

## Partitionable ALUs

Very minor modifications to the underlying functional units are needed to implement packed add and packed subtract instructions. Assume that we have an ALU with 32-bit integer registers, and we want to extend this ALU to perform a packed add that will operate on four 8-bit subwords in parallel.

---

<sup>1</sup> 3DNow! may be considered as having two versions. In June 2000, 25 new instructions were added to the original 3DNow! specification. In this text, this extended 3DNow! architecture will be considered.

FIGURE 39.4 ADD  $R_c, R_a, R_b$  : Ordinary add instruction.

FIGURE 39.5 PADD  $R_c, R_a, R_b$  : Packed add instruction.

To achieve this, the carry propagation across the subword boundaries has to be blocked. Because each subword is interpreted as being independent of the neighboring subwords, by stopping the carry bits from affecting the neighboring subwords, the packed add operation can be realized.

In Fig. 39.6, the packed integer register  $R_a=[0xFF|0xF|0xF0|0x00]$  is being added to another packed register  $R_b=[0x00|0xFF|0xFF|0xF]$ . The result is written to the target register  $R_c$ . In an ordinary add instruction, the overflows generated by the addition of the second and third subwords will propagate into the first two sums. The correct sums, however, can be achieved easily by blocking the carry bit propagation across the subword boundaries, which are spaced 8-bits apart from one another.

As shown in Fig. 39.7, a 2-to-1 multiplexer placed at the subword boundaries of the adder can be used to control the propagation or the blocking of the carry bits. If the instruction is a packed add, the multiplexer control is set such that a zero is propagated into the next subword. If the instruction is an ordinary add, the multiplexer control is set such that the carry from the previous stage is propagated. By placing such a multiplexer at each subword boundary and adding the control logic, partitionable ALUs are achieved at insignificant cost.

By using 3-to-1 multiplexers instead of 2-to-1 multiplexers, we can also implement packed subtract instructions. The multiplexer control is set such that:

- For packed add instructions, zero is propagated into the next stage.
- For packed subtract instructions, one is propagated into the next stage.

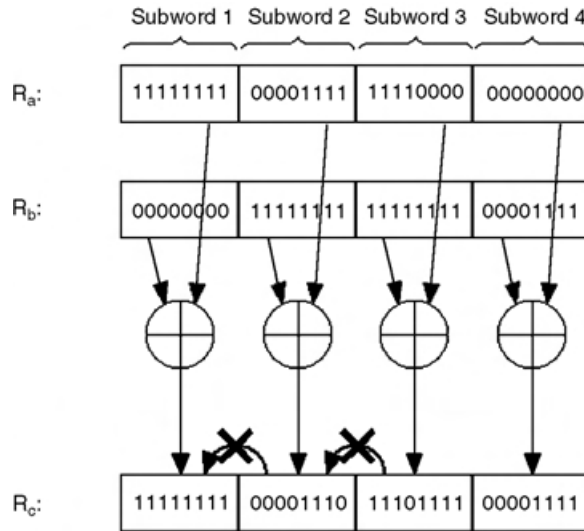

FIGURE 39.6 In the packed add instruction, the carry bits are not propagated.

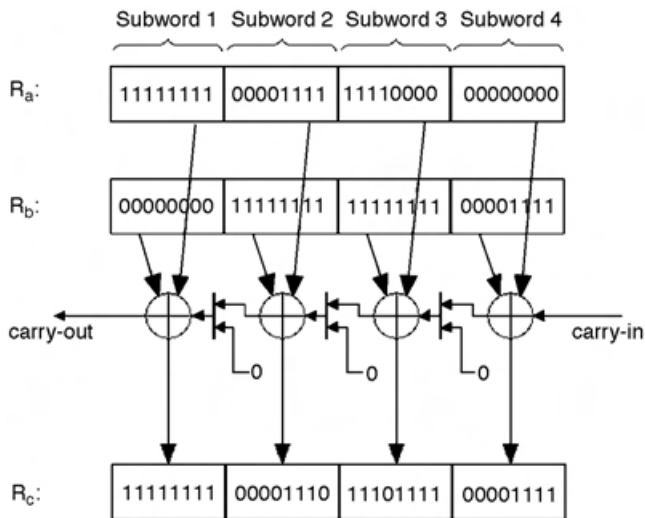

FIGURE 39.7 Partitionable ALU: In packed add instructions, the multiplexers propagate zero; in ordinary add instructions, the multiplexers propagate carry-out from the previous stage into the carry-in of the next stage.

- For ordinary add/subtract instructions, the carry/borrow bit from the previous stage is propagated into the next stage.

When a zero is propagated through the boundary into the next subword in the packed add instructions, we are essentially ignoring any overflow that might have been generated. Similarly, when a one is propagated through the boundary into the next subword in the packed subtract instructions, we are essentially ignoring any borrow that might have been generated. Ignoring overflows is equivalent to using modular arithmetic in add operations. Although modular arithmetic can be necessary or useful, other occasions arise when the carry bits should not be ignored and have to be handled differently.

## Handling Parallel Overflows

Overflows in packed `add/subtract` instructions can be handled in the following ways:

- The overflow may be ignored (modular arithmetic).
- A *flag* bit may be set if at least one overflow is generated.
- Multiple flag bits (i.e., one flag bit for each addition operation on the subwords) may be set.
- A software overflow trap can be taken.
- Saturation arithmetic: the results are limited to a certain range. If the outcome of the operation falls outside this range, the corresponding limiting value will be the result.

Most nonpacked integer `add/subtract` instructions choose to ignore overflows and perform modular arithmetic. In modular arithmetic, the numbers wrap around from the largest representable number to the smallest representable number. For example, in 8-bit modular arithmetic, the operation  $254+2$  will give a result of 0. The expected result, 256, is larger than the largest representable number, which is 255, and therefore is wrapped around to the smallest representable number, which is 0.

In multimedia applications, modular arithmetic frequently gives undesirable results. If the numbers in the previous example were pixel values in a grayscale image, by wrapping the values from 255 down to 0, white pixels would have converted into black ones. One solution to this problem is to use overflow traps, which are implemented in software.

A flag bit is an indicator bit that is set or cleared depending on the outcome of a particular operation. In the context of this discussion, an overflow flag bit is an indicator that is set when an `add` instruction generates an overflow. Occasions arise where the use of the flag bits are desirable. Consider a loop that iterates many times and in each iteration, executes many `add` instructions. In this case, it is not desirable to handle overflows (by taking overflow trap routines) as soon as they occur, because this would negatively impact the performance by interrupting the execution of the loop body. Instead, the overflow flag can be set when the overflow occurs, and the program flow continues as if the overflow did not occur. At the end of each iteration, however, this overflow flag can be checked and the overflow trap can be executed if the flag turns out to be set. This way, the program flow would not be interrupted while the loop body executes.

An overflow trap can be used to *saturate* the results so that the aforementioned problems would not occur. A result that is greater than the largest representable value is replaced by that largest value. Similarly, a result that is less than the smallest representable value is replaced by that smallest value. One problem with this solution will be its negative effects to performance. An overflow trap is handled in software and may take many clock cycles to resolve. This can be acceptable only if the overflows are infrequent. For nonpacked `add/subtract` instructions, generation of an overflow on a 64-bit register by adding 8-bit quantities will be rare, so a software overflow trap will work well. This is not the case for packed arithmetic operations. Causing an overflow in an 8-bit subword is much more likely than in a 64-bit register. Also, since a 64-bit register may hold eight 8-bit subwords, multiple overflows can occur in a single execution cycle. In this case, handling the overflows by software traps could easily negate any performance gains from executing packed operations. The use of saturation arithmetic solves this problem.

## Saturation Arithmetic

Saturation arithmetic implements in hardware the work done by the overflow trap described above. The results falling outside the allowed numeric ranges are saturated to the upper and lower limits by hardware. This can handle multiple parallel overflows efficiently, without operating system intervention. Two types of overflows for arithmetic operations are:

- A *positive overflow* occurs when the result is larger than the largest value in the defined range for that result
- A *negative overflow* occurs when the result is smaller than the smallest value in the defined range for that result

If saturation arithmetic is used in an operation, the result is clipped to the maximum value in its defined range if a positive overflow occurs, and to the minimum value in its defined range if a negative overflow occurs.

For a given instruction, multiple saturation options may exist, depending on whether the operands and the result are treated as signed or unsigned integers. For an instruction that uses three registers (two for source operands and one for the result), there can be eight different saturation options. Each one of the three registers can be treated as containing either a signed or an unsigned integer, which gives  $2^3$  possible combinations. Not all of the eight possible saturation options are equally useful. Only three of the eight possible saturation options are used in any of the multimedia ISAs surveyed:

- a) **sss** (signed result–signed first operand–signed second operand): In this saturation option, the result and the two operands are all treated as signed integers. The most significant bit is considered the sign bit. Considering  $n$ -bit subwords, the result and operands are defined in the range  $[-2^{n-1}, 2^{n-1} - 1]$ . If a positive overflow occurs, the result is saturated to  $2^{n-1} - 1$ . If a negative overflow occurs, the result is saturated to  $-2^{n-1}$ . In an addition operation that uses the **sss** saturation option, since the operands are signed numbers, a positive overflow is possible only when both operands are positive. Similarly, a negative overflow is possible only when both operands are negative.
- b) **uuu** (unsigned result–unsigned first operand–unsigned second operand): In this saturation option, the result and the two operands are all treated as unsigned integers. Considering  $n$ -bit integer subwords, the result and the operands are defined in the range  $[0, 2^n - 1]$ . If a positive overflow occurs, the result is saturated to  $2^n - 1$ . If a negative overflow occurs, the result is saturated to zero. In an addition operation that uses the **uuu** saturation option, since the operands are unsigned numbers, negative overflow is not a possibility; however, for a subtraction operation using the **uuu** saturation, negative overflow is possible, and any negative result will be clamped to zero as the smallest value.
- c) **uus** (unsigned result–unsigned first operand–signed second operand): In this saturation option, the result and the first operand are treated as unsigned numbers, and the second operand is treated as a signed number. Although this may seem like an unusual option, it proves useful because it allows the addition of a signed increment to an unsigned pixel. It also allows negative numbers to be clipped to zero. Its implementation has logical symmetry to the **sss** case.

In addition to the efficient handling of overflows, saturation arithmetic also facilitates several other useful computations. For instance, saturation arithmetic can also be used to clip results to arbitrary maximum or minimum values. Without saturation arithmetic, these operations could normally take up to five instructions for each pair of subwords. That would include instructions to check for upper and lower bounds and then to perform the clipping. Using saturation arithmetic, however, this effect can be achieved in as few as two instructions for all the pairs of packed subwords.

Saturation arithmetic can also be used for in-line conditional execution, reducing the need for conditional branches that can cause significant performance degradations in pipelined processors. Some examples are the packed maximum and packed absolute difference operations shown in Figs. 39.8(a, b).

Table 39.1 contains examples of operations that can be performed using saturation arithmetic [15]. All of the instructions in the table use three registers. The first register is the target register. The second and the third registers hold the first and the second operands respectively. PADD and PSUB denote packed add and packed subtract instructions. The three-letter field after the instruction mnemonic specifies which saturation option is to be used. If this field is empty, modular arithmetic is assumed. All the examples in the table operate on 16-bit integer subwords.

Table 39.2 contains a summary of the register and subword sizes and the saturation options found in different multimedia ISAs. Table 39.3 is a summary of the packed add/subtract instructions in several multimedia ISAs. The first column contains descriptions of common packed instructions. The symbols  $a_i$  and  $b_i$  represent the corresponding subwords from the two source registers. The symbol  $c_i$  represents the corresponding subword in the target register.

**FIGURE 39.8** (a) Packed maximum operation using saturation arithmetic. (b) Packed absolute difference operation using saturation arithmetic.

The IA-64<sup>2</sup> architecture has 64-bit integer registers. Packed add and packed subtract instructions are supported for subword sizes of 1, 2, and 4 bytes. Modular arithmetic is defined for all subword sizes whereas the saturation options (*sss*, *uuu*, and *uus*) exist for only 1 and 2-byte subwords.

The PA-RISC MAX-2 architecture also has 64-bit integer registers. Packed add and packed subtract instructions operate on only 2-byte subwords. MAX-2 instructions support modular arithmetic, and the *sss* and *uus* saturation options.

The IA-32 MMX architecture defines eight 64-bit registers for use by the multimedia instructions. Although these registers are referred to as separate registers, they are aliased to the registers in the FP data register stack. Supported subword sizes are 1, 2, and 4 bytes. Modular arithmetic is defined for all subword sizes whereas the saturation options (*sss* and *uus*) exist for only 1- and 2-byte subwords.

The IA-32 SSE-2 technology introduces a new set of eight 128-bit FP registers to the IA-32 architecture. Each of the 128-bit registers can accommodate four single-precision (SP) or two double-precision (DP) numbers. Moreover, these registers can also be used to accommodate packed integer data types. Integer subword sizes can be 1, 2, 4, or 8 bytes. Modular arithmetic is defined for all subword sizes whereas the saturation options (*sss* and *uus*) exist for only 1- and 2-byte subwords.

The PowerPC AltiVec architecture has thirty-two 128-bit registers for multimedia instructions. Packed add/subtract instructions are supported for 1-, 2-, and 4-byte subwords. Modular or saturation arithmetic (*uuu* or *sss*) can be used, although *sss* saturation is only supported for packed add.

<sup>2</sup>All the discussions in this chapter consider Intel's IA-64 as the base architecture. Evaluations of the other architectures are generally carried out by comparisons to IA-64.

**TABLE 39.1** Examples of Operations That are Facilitated by Saturation Arithmetic

Operation	Instruction Sequence	Notes
Clip $a_i$ to an arbitrary maximum value $v_{\max}$ , where $v_{\max} < 2^{15} - 1$ .	PADD.sss $R_a, R_a, R_b$	$R_b$ contains the value $(2^{15} - 1 - v_{\max})$ . If $a_i > v_{\max}$ , this operation clips $a_i$ to $2^{15} - 1$ on the high end.
	PSUB.sss $R_a, R_a, R_b$	$a_i$ is at most $v_{\max}$ .
Clip $a_i$ to an arbitrary minimum value $v_{\min}$ , where $v_{\min} > -2^{15}$ .	PSUB.sss $R_a, R_a, R_b$	$R_b$ contains the value $(-2^{15} + v_{\min})$ . If $a_i < v_{\min}$ , this operation clips $a_i$ to $-2^{15}$ at the low end.
	PADD.sss $R_a, R_a, R_b$	$a_i$ is at least $v_{\min}$ .
Clip $a_i$ to within the arbitrary range $[v_{\min}, v_{\max}]$ , where $-2^{15} < v_{\min} < v_{\max} < 2^{15} - 1$ .	PADD.sss $R_a, R_a, R_b$	$R_b$ contains the value $(2^{15} - 1 - v_{\max})$ . This operation clips $a_i$ to $2^{15} - 1$ on the high end.
	PSUB.sss $R_a, R_a, R_d$	$R_d$ contains the value $(2^{15} - 1 - v_{\max} + 2^{15} - v_{\min})$ . This operation clips $a_i$ to $-2^{15}$ at the low end.
	PADD.sss $R_a, R_a, R_c$	$R_c$ contains the value $(-2^{15} + v_{\min})$ . This operation clips $a_i$ to $v_{\max}$ at the high end and to $v_{\min}$ at the low end.
Clip the signed integer $a_i$ to an unsigned integer within the range $[0, v_{\max}]$ , where $0 < v_{\max} < 2^{15} - 1$ .	PADD.sss $R_a, R_a, R_b$	$R_b$ contains the value $(2^{15} - 1 - v_{\max})$ . This operation clips $a_i$ to $2^{15} - 1$ at the high end.
	PSUB.uus $R_a, R_a, R_b$	This operation clips $a_i$ to $v_{\max}$ at the high end and to zero at the low end.
Clip the signed integer $a_i$ to an unsigned integer within the range $[0, v_{\max}]$ , where $v_{\max} < 2^{16} - 1$ . $c_i = \max(a_i, b_i)$ Packed maximum operation	PADD.uus $R_a, R_a, 0$	If $a_i < 0$ , then $a_i = 0$ else $a_i = a_i$ . If $a_i$ was negative, it gets clipped to zero, else remains same.
	PSUB.uuu $R_c, R_a, R_b$	If $a_i > b_i$ , then $c_i = (a_i - b_i)$ else $c_i = 0$ .
$c_i =  a_i - b_i $ Packed absolute difference operation	PADD $R_c, R_b, R_c$	If $a_i > b_i$ , then $c_i = a_i$ else $c_i = b_i$ .
	PSUB.uuu $R_c, R_a, R_b$	If $a_i > b_i$ , then $e_i = (a_i - b_i)$ else $e_i = 0$ .
	PSUB.uuu $R_f, R_b, R_a$	If $a_i \leq b_i$ , then $f_i = (b_i - a_i)$ else $f_i = 0$ .
	PADD $R_c, R_c, R_f$	If $a_i > b_i$ , then $c_i =  a_i - b_i $ , else $c_i =  b_i - a_i $ .

Note:  $a_i$  and  $b_i$  are the subwords in the registers  $R_a$  and  $R_b$ , respectively, where  $i = 1, 2, \dots, k$ , and  $k$  denotes the number of subwords in a register. Subword size  $n$ , is assumed to be two bytes (i.e.,  $n = 16$ ) for this table.

**TABLE 39.2** Summary of the Integer Register, Subword Sizes, and Subtraction Options Supported by the Different Architectures

Architectural Feature	IA-64	MAX-2	MMX	SSE-2	Altivec
Size of integer registers (bits)	64	64	64	128	128
Supported subword sizes (bytes)	1, 2, 4	2	1, 2, 4	1, 2, 4, 8	1, 2, 4
Modular arithmetic	Y	Y	Y	Y	Y
Supported saturation options	sss, uuu, uus for 1, 2 byte	sss, uus for 2 byte	sss, uuu for 1, 2 byte	sss, uuu for 1, 2 byte	uuu, sss for 1, 2, 4 byte

### Packed Average

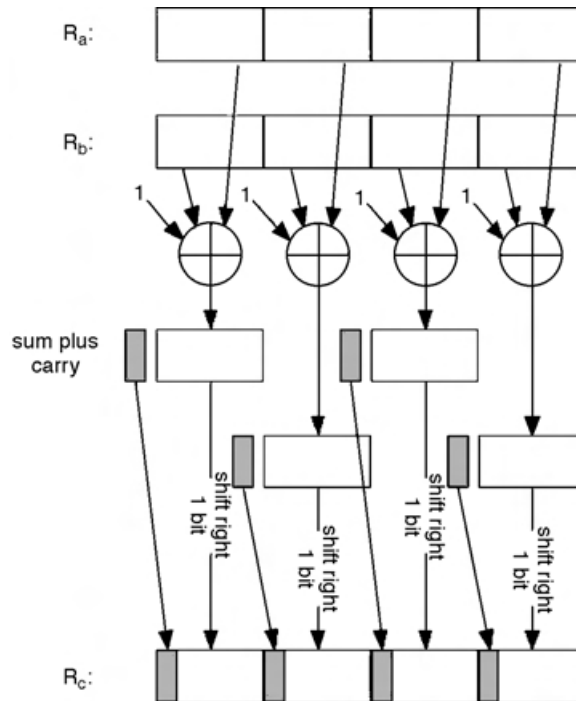

Packed average instructions are very common in media applications such as pixel averaging in MPEG-2 encoding, motion compensation, and video scaling. In a packed average, the pairs of corresponding subwords in the two source registers are added to generate intermediate sums. Then, the intermediate sums are shifted right by one bit, so that any overflow bit is shifted in on the left as the most significant bit. The beauty of the average operation is that no overflow can occur, and two operations (add followed by a one bit right shift) are performed in one operation. In a packed average instruction,  $2n$  operations are performed in a single cycle, where  $n$  is the number of subwords. In fact, even more operations are performed in a packed average instruction, if the rounding applied to the least significant end of the result is considered. Here, two different rounding options have been used:

**TABLE 39.3** Summary of the packed add and packed subtract Instructions and Variants

Integer Operations	IA-64	MAX-2	MMX	SSE-2	3DNow!	Altivec
$c_i = a_i + b_i$	√	√	√	√		√
$c_i = a_i + b_i$ (with saturation)	√	√	√			√
$c_i = a_i - b_i$	√	√	√	√		√
$c_i = a_i - b_i$ (with saturation)	√	√	√			√
$c_i = \text{average}(a_i, b_i)$	√	√		√	√	√
$c_i = \text{average}(a_i, -b_i)$	√					
$[c_{2i}, c_{2i+1}] = [a_{2i} + a_{2i+1}, b_{2i} + b_{2i+1}]$						√

$c = \sum  a_i - b_i $	√	√ <sup>a</sup>		√	√	

<sup>a</sup> This operation is realized by using saturation arithmetic.

**FIGURE 39.9** PAVG  $R_c, R_a, R_b$ : Packed average instruction using the *round away from zero* option.

- *Round away from zero*: A one is added to the intermediate sums, before they are shifted to the right by one bit position. If carry bits were generated during the addition operation, they are inserted into the most significant bit position during the shift right operation (see Fig. 39.9).
- *Round to odd*: Instead of adding one to the intermediate sums, a much simpler OR operation is used. The intermediate sums are directly shifted right by one bit position, and the last two bits of each of the subwords of the intermediate sums are ORed to give the least significant bit of the final result. This makes sure that the least significant bit of the final results are set to 1 (odd) if at least one of the two least-significant bits of the intermediate sums are 1 (see Fig. 39.10).

**FIGURE 39.10** PAVG  $R_c$ ,  $R_a$ ,  $R_b$ : Packed average instruction using the *round to odd* option. (From Intel, IA-Architecture Software Developer's Manual, Vol. 3, Instruction Set Reference, Rev. 1.1, July 2000. With permission.)

This rounding mode also performs *unbiased rounding* under the following assumptions. If the intermediate result is uniformly distributed over the range of possible values, then half of the time the bit shifted out is zero, and the result remains unchanged with rounding. The other half of the time the bit shifted out is one: if the next least significant bit is one, then the result loses  $-0.5$ , but if the next least significant bit is a zero, then the result gains  $+0.5$ . Because these cases are equally likely with a uniform distribution of the result, the *round to odd* option tends to cancel out the cumulative averaging errors that may be generated with repeated use of the averaging instruction.

### Accumulate Integer

Sometimes, it is useful to add adjacent subwords in the same register. This can, for example, facilitate the accumulation of streaming data. An `accumulate integer` instruction performs an addition of the subwords in the same register and places the sum in the upper half of the target register, while repeating the same process for the second source register and using the lower half of the target register (Fig. 39.11).

### Save Carry Bits

This instruction saves the carry bits from a packed add operation, rather than the sums. Figure 39.12 shows such a `save carry bits` instruction in AltiVec: a packed add is performed and the carry bits are written to the least significant bit of each result subword in the target register. A similar instruction saves the borrow bits generated when performing packed subtract instead of packed add.

### Packed Compare Instructions

Sometimes, it is necessary to compare pairs of subwords. In a `packed compare` instruction, pairs of subwords are compared according to the relation specified by the instruction. If the condition is true for a subword pair, the corresponding field in the target register is written with a 1-mask. If the condition is

FIGURE 39.11 ACC  $R_c$ ,  $R_a$ ,  $R_b$ : Accumulate integer working on registers with two subwords.

FIGURE 39.12 Save carry bits instruction.

false, the corresponding field in the target register is written with a 0-mask. Alternatively, a true or false bit is generated for each subword, and this set of bits is written into the least significant bits of the result register. Some of the architectures have compare instructions that allow comparison of two numbers for all of the 10 possible relations,<sup>3</sup> whereas others only support a subset of the most frequent relations. A typical packed compare instruction is shown in Fig. 39.13 for the case of four subwords.

When a mask of bits is generated as in Fig. 39.13, often a move mask instruction is also provided. In a move mask instruction, the most significant bits of each of the subwords are picked, and these bits are placed into the target register, in a right aligned field (see Fig. 39.14). In different algorithms, either the subword mask format generated in Fig. 39.13 or the bit mask format generated in Fig. 39.14 is more useful.

Two common comparisons used are finding the larger of a pair of numbers, or the smaller of a pair of numbers. In the packed maximum instruction, the greater of the subwords in the compared pair gets written to the corresponding subword in the target register (see Fig. 39.15). Similarly, in the packed minimum instruction, the smaller of the subwords in the compared pair gets written to the corresponding subword in the target register. As described in the earlier section on saturation arithmetic, instead of special instructions for packed maximum and packed minimum, MAX-2 performs packed maximum and

<sup>3</sup> Two numbers  $a$  and  $b$  can be compared for one of the following 10 possible relations: equal, less-than, less-than-or-equal, greater-than, greater-than-or-equal, not-equal, not-less-than, not-less-than-or-equal, not-greater-than, not-greater-than-or-equal. Typical notation for these relations are as follows respectively: =, <, <=, >, >=, !=, !<, !<=, !>, !>=.

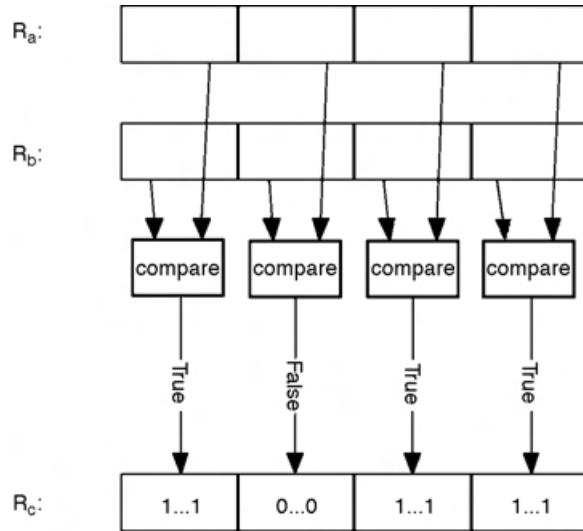

FIGURE 39.13 Packed compare instruction. Bit masks are generated as a result of the comparisons made.

FIGURE 39.14 Move mask  $R_b$ ,  $R_a$ .

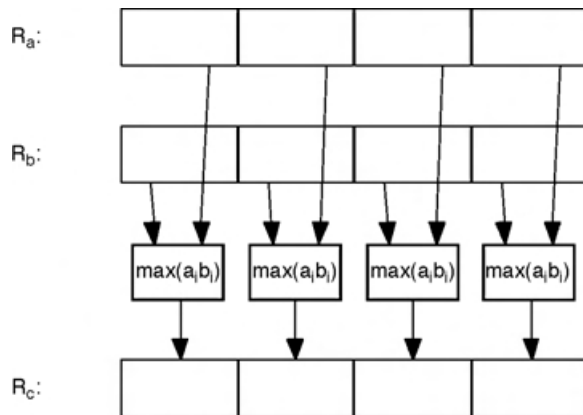

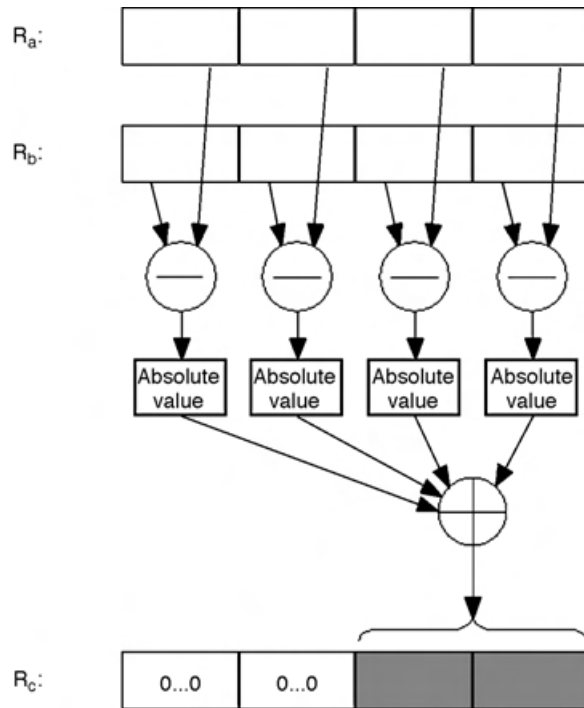

FIGURE 39.15 Packed maximum instruction.

**FIGURE 39.16** SAD  $R_c$ ,  $R_a$ ,  $R_b$ : Sum of absolute differences instruction.

packed minimum operations by using packed add and packed subtract instructions with saturation arithmetic (see Fig. 39.8). An ALU can be used to implement comparisons, maximum and minimum instructions with a subtraction operation; comparisons for equality or inequality is usually done with an exclusive-or operation, also available in most ALUs.

### Sum of Absolute Differences

A more complex, multi-cycle instruction is the sum of absolute differences (SAD) instruction (see Fig. 39.16). This is used for motion estimation in MPEG-1 and MPEG-2 video encoding, for example. In a SAD instruction, the two packed operands are subtracted from one another. Absolute values of the resulting differences are then summed up.

Although useful, the SAD instruction is a multi-cycle instruction with a typical latency of three cycles. This can complicate the pipeline control of otherwise single cycle integer pipelines. Hence, minimalist multimedia instruction sets like MAX-2 do not have SAD instructions. Instead, MAX-2 uses generic packed add and packed subtract instructions with saturation arithmetic to perform the SAD operation (see Fig. 39.8(b) and Table 39.1).

### Packed Multiply Instructions

#### Multiplication of Two Packed Integer Registers

The main difficulty with packed multiplication of two  $n$ -bit integers is that the product is twice as long as each operand. Consider the case where the register size is 64 bits and the subwords are 16 bits. The result of the packed multiplication will be four 32-bit products, which cannot be accommodated in a single 64-bit target register.

One solution is to use two packed multiply instructions. Figure 39.17 shows a packed multiply high instruction, which places only the more significant upper halves of the products into the target register.

FIGURE 39.17 Packed multiply high instruction.

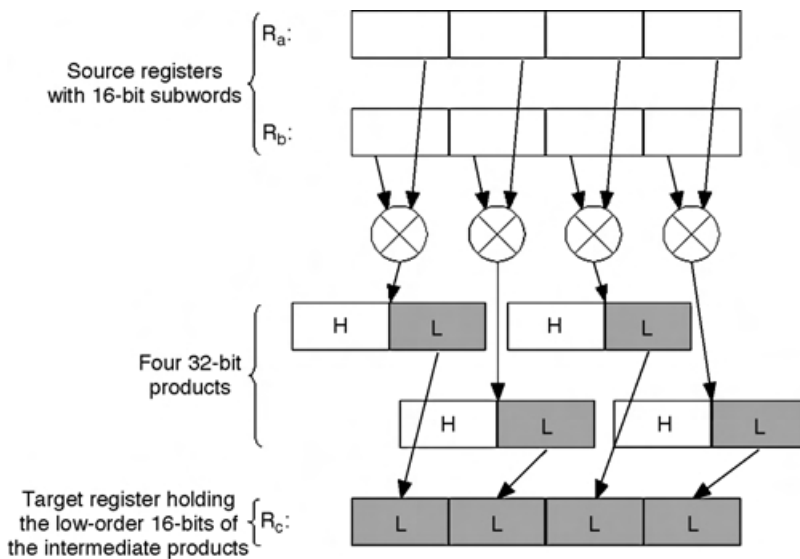

FIGURE 39.18 Packed multiply low instruction.

Figure 39.18 shows a packed multiply low instruction, which places only the less significant lower halves of the products into the target register.

IA-64 generalizes this with its packed multiply and shift right instruction (see Fig. 39.19), which does a parallel multiplication followed by a right shift. Instead of being able to choose either the upper or the lower half of the products to be put into the target register, it allows multiple<sup>4</sup> different 16-bit fields from each of the 32-bit products to be chosen and placed in the target register. Ideally, saturation

<sup>4</sup> In IA-64 the right-shift amounts are limited to 0, 7, 15, or 16 bits, so that only 2 bits in the packed multiply and shift right instruction are needed to encode the four shift amounts.

FIGURE 39.19 The generalized packed multiply and shift right instruction.

arithmetic is applied to the shifted products, to guard for the loss of significant “1” bits in selecting the 16-bit results.

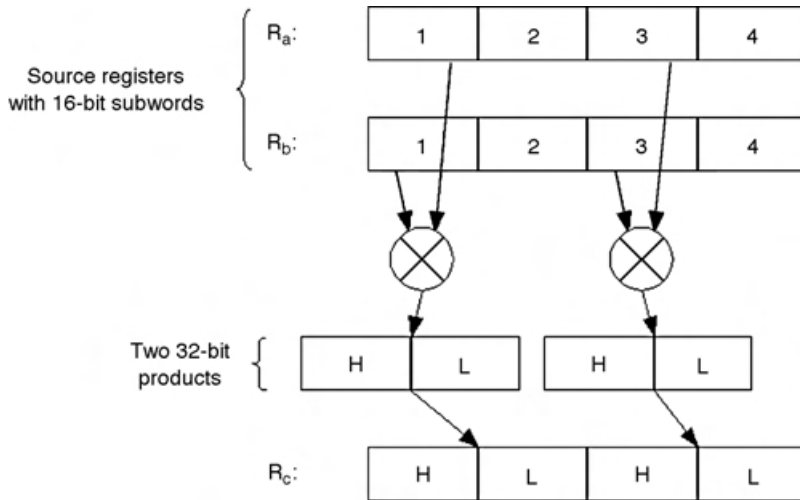

IA-64 also allows the full product to be saved, but for only half of the pairs of source subwords. Either the odd or the even indexed subwords are multiplied. This makes sure that only as many full products as can be accommodated in one target register are generated. These two variants, the *packed multiply left* and *packed multiply right* instructions, are depicted in [Figs. 39.20](#) and [39.21](#).

Another variant is the *packed multiply and accumulate* instruction. Normally, a multiply and accumulate operation requires three source registers. The *PMADDWD* instruction in MMX requires only two source registers by performing a packed multiply followed by an addition of two adjacent subwords (see [Fig. 39.22](#)).

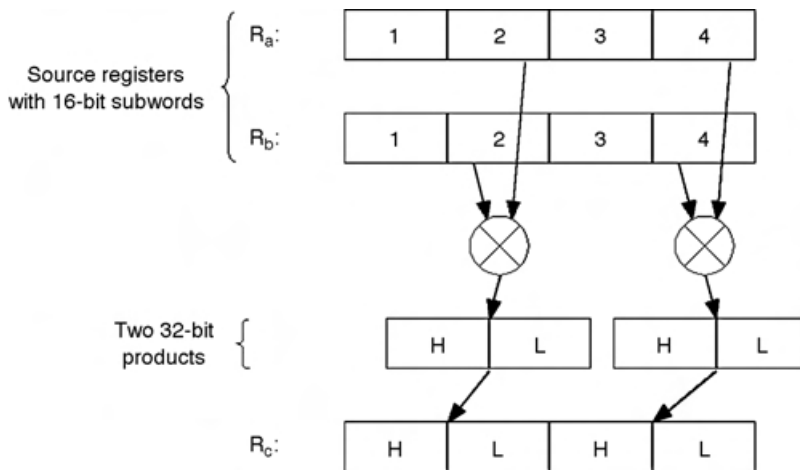

Instructions in the AltiVec architecture may have up to three source registers. Hence, AltiVec’s *packed multiply and accumulate* uses three source registers. In [Fig. 39.23](#), the instruction *packed multiply high and accumulate* starts just like a *packed multiply* instruction, selects the more significant halves of the products, then performs a *packed add* of these halves and the values from a third register. The instruction *packed multiply low and accumulate* is the same, except that only the less significant halves of the products are added to the subwords from the third register.

### Multiplication of a Packed Integer Register by an Integer Constant

Many multiplications in multimedia applications are with constants, instead of variables. For example, in the inverse discrete cosine transform (IDCT) used in the compression and decompression of JPEG images and MPEG-1 and MPEG-2 video, all the multiplications are by constants. This type of multiplication can be further optimized for simpler hardware, lower power, and higher performance simultaneously by using

**FIGURE 39.20** Packed multiply left instruction where only the odd indexed subwords of the two source registers are multiplied.

**FIGURE 39.21** Packed multiply right instruction where only the even indexed subwords of the two source registers are multiplied.

packed shift and add instructions [14,15,20]. Shifting a register left by  $n$  bits is equivalent to multiplying it by  $2^n$ . Since a constant number can be represented as a binary sequence of ones and zeros, using this number as a multiplier is equivalent to a left shift of the multiplicand of  $n$  bits for each  $n$ th position where there is a 1 in the multiplier and an add of each shifted value to the result register.

As an example, consider multiplying the integer register  $R_a$  with the constant  $C = 11$ . The following instruction sequence performs this multiplication. Assume  $R_a$  initially contains the value 6.

*Initial values:*  $C = 11 = 1011_2$  and  $R_a = 6 = 0110_2$

Instruction	Operation	Result
Shift left 1 bit $R_b, R_a$	$R_b = R_a \ll 1$	$R_b = 1100_2 = 12$
Add $R_b, R_b, R_a$	$R_b = R_b + R_a$	$R_b = 1100_2 + 0110_2 = 010010_2 = 18$
Shift left 3 bit $R_c, R_a$	$R_c = R_a \ll 3$	$R_c = 0110_2 * 8 = 110000_2 = 48$
Add $R_b, R_b, R_c$	$R_b = R_b + R_c$	$R_b = 010010_2 + 110000_2 = 1000010_2 = 66$

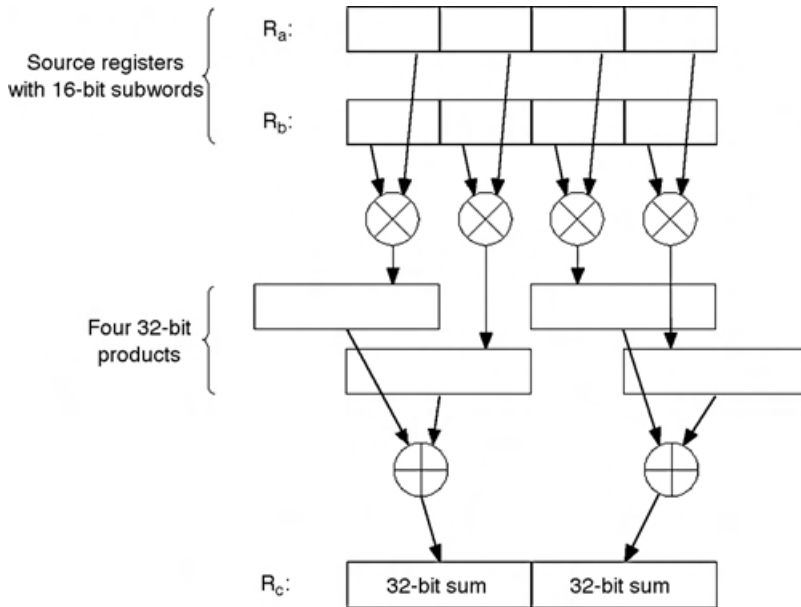

FIGURE 39.22 Packed multiply and accumulate instruction in MMX.

This sequence can be shortened by combining the shift left and the add instructions into one new shift left and add instruction. The following new sequence performs the same multiplication in half as many instructions and uses one less register.

*Initial values:*  $C = 11 = 1011_2$  and  $R_a = 6 = 0110_2$

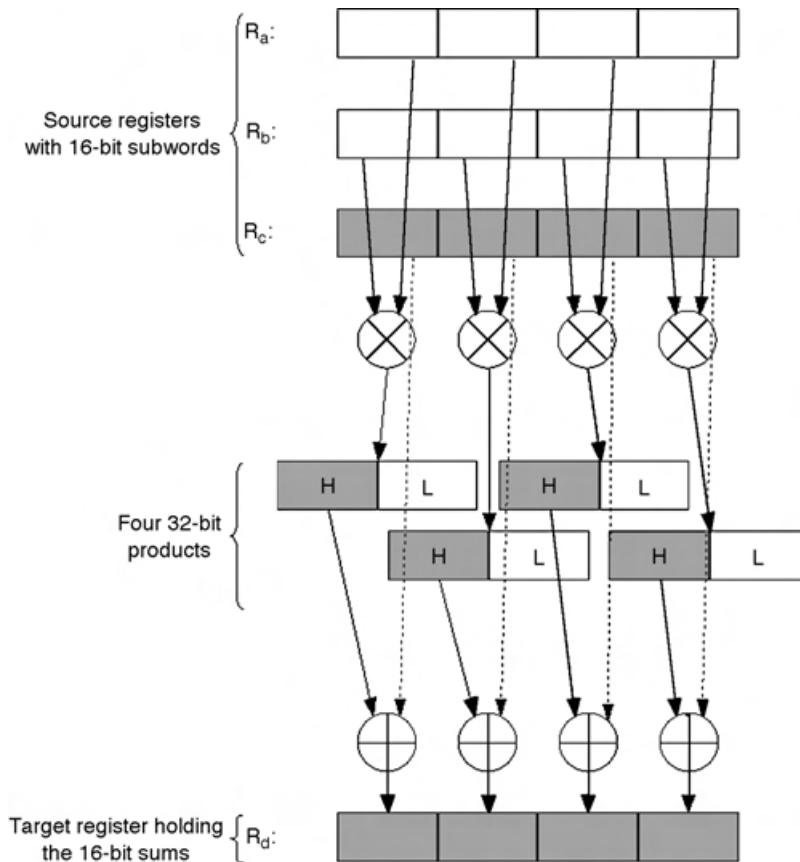

Instruction	Operation	Result
Shift left 1 bit and add $R_b, R_a, R_a$	$R_b = R_a \ll 1 + R_a$	$R_b = 18$
Shift left 3 bit and add $R_b, R_a, R_b$	$R_b = R_a \ll 3 + R_b$	$R_b = 66$

Multiplication of packed integer registers by integer constants uses the same idea. The shift left and add instruction becomes a packed shift left and add instruction to support the packed data types. As an example consider multiplying the subwords of the packed integer register  $R_a = [1|2|3|4]$  by the constant  $C = 11$ . The instructions to perform this operation are:

*Initial values:*  $C = 11 = 1011_2$  and  $R_a = [1|2|3|4] = [0001|0010|0011|0100]_2$

Instruction	Operation	Result
Shift left 1 bit and add $R_b, R_a, R_a$	$R_b = R_a \ll 1 + R_a$	$R_b = [3 6 9 12]$
Shift left 3 bit and add $R_b, R_a, R_b$	$R_b = R_a \ll 3 + R_b$	$R_b = [11 22 33 44]$

The same reasoning used for multiplication by integer constants applies to multiplication by fractional constants. Arithmetic right shift of a register by  $n$  bits is equivalent to dividing it by  $2^n$ . Using a fractional constant as a multiplier is equivalent to an arithmetic right shift of the multiplicand by  $n$  bits for each  $n$ th position where there is a 1 in the multiplier and an add of each shifted value to the result register. By using a packed arithmetic shift right and add instruction, the shift and the add instructions can be combined into one to further speed such computations. For instance, multiplication of a

**FIGURE 39.23** In the packed multiply high and accumulate instruction in AltiVec, only the high-order bits of the intermediate products are used in the addition.

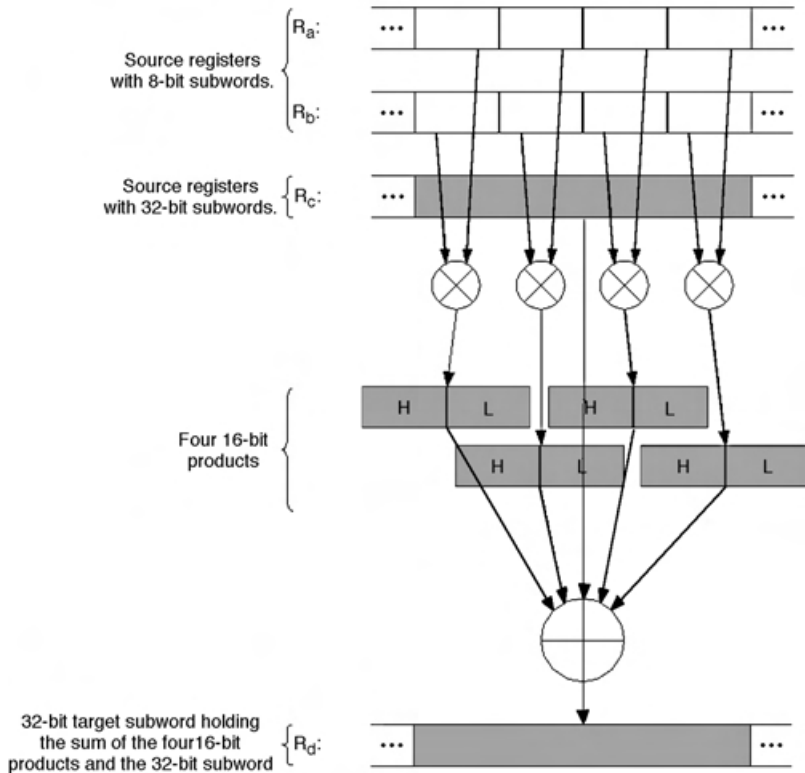

packed register by the fractional constant  $0.011_2 (=0.375)$  can be performed by using just two packed arithmetic shift right and add instructions.

*Initial values:*  $C = 0.375 = 0.011_2$  and  $R_a = [1|2|3|4] = [0001|0010|0011|0100]_2$

Instruction	Operation	Result
Arithmetic shift right 3 bit and add $R_b, R_a, 0$	$R_b = R_a \gg 2 + 0$	$R_b = [0.125 0.25 0.375 0.5]$
Arithmetic shift right 2 bit and add $R_b, R_a, R_b$	$R_b = R_a \gg 2 + R_b$	$R_b = [0.375 0.75 1.125 1.5]$

Only two single-cycle instructions are required to perform the multiplication of four subwords by a constant, in this example. This is equivalent to an effective rate of two multiplications per cycle. Without subword parallelism, the same operations would take at least four integer multiply instructions. Furthermore, the packed shift and add instructions use a simple ALU with a small preshifter, whereas the integer multiply instructions need a more complex multiplier functional unit. In addition, each multiplication operation takes at least three cycles of latency compared to one cycle of latency for a preshift and add operation. Hence, for this example, the speedup for multiplying four subwords by a constant is six times faster ( $4 \times 3/2$ ), comparing implementations with one subword multiplier versus one partitionable ALU with preshifter.

MAX-2 in PA-RISC and IA-64 are the only multimedia ISAs surveyed that have these efficient packed shift left and add instructions and packed shift right and add instructions. The preshift

**FIGURE 39.24** AltiVec’s VSUMMBM instruction: only one-fourth of the instruction is shown. Each box represents a byte. This process is carried out for each 32-bit word in the 128-bit source registers.

amounts allowed are by one, two, or three bits, and the arithmetic is performed with signed saturation, for 16-bit subwords.

### Vector Multiplication

So far, this chapter has examined relatively simple packed multiply instructions. These instructions all take about the same latency as a single multiply instruction, which is typically 3–4 cycles compared to an add instruction normalized to one cycle latency. For better or worse, some multimedia ISAs have included very complex, multiple-cycle operations. For example, AltiVec has a packed vector multiply and accumulate instruction, using three 128-bit packed source operands and a 128-bit target register (see Fig. 39.24). First, all the pairs of bytes within a 32-bit subword in two of the source registers are multiplied in parallel and 16-bit products are generated. Then, four 16-bit products are added to each other to generate a “sum of products” for every 32 bits. A 32-bit subword from the third source register is added to this “sum of products.” The resulting sum is placed in the corresponding 32-bit subword field of the target register. This process is repeated for each of the four 32-bit subwords. This is a total of sixteen 8-bit integer multiplies, twelve 16-bit additions, and four 32-bit additions, using four 128-bit registers, in a single VSUMMBM instruction. This can perform a  $4 \times 4$  matrix times a  $4 \times 1$  vector multiplication, where each element is a byte, in a single instruction, but this single complex instruction takes many cycles of latency. While a multiplication of a  $4 \times 4$  matrix with a  $4 \times 1$  vector is a very frequent operation in graphics geometry processing, the precision required is usually that of 32-bit single-precision floating-point numbers, not 8-bit integers. Whether the complexity of such a compound VSUMMBM instruction is justified depends on the frequency of such  $4 \times 4$  matrix-vector multiplications of bytes. Table 39.4 summarizes the packed integer multiplication instructions described.

**TABLE 39.4** Packed Integer Multiplication Instructions

### Packed Shift and Rotate Operations

Most microprocessors have one or more shifters in addition to one or more ALUs (see Fig. 39.3). Just as the ALU is partitionable, so is the shifter, for subword-parallel operation. A packed shift instruction performs blocking shifts of the subwords packed in a register. Any bits shifted to the left are blocked from affecting the adjacent subword on the left; any bits shifted to the right are blocked from affecting the adjacent subword on the right.

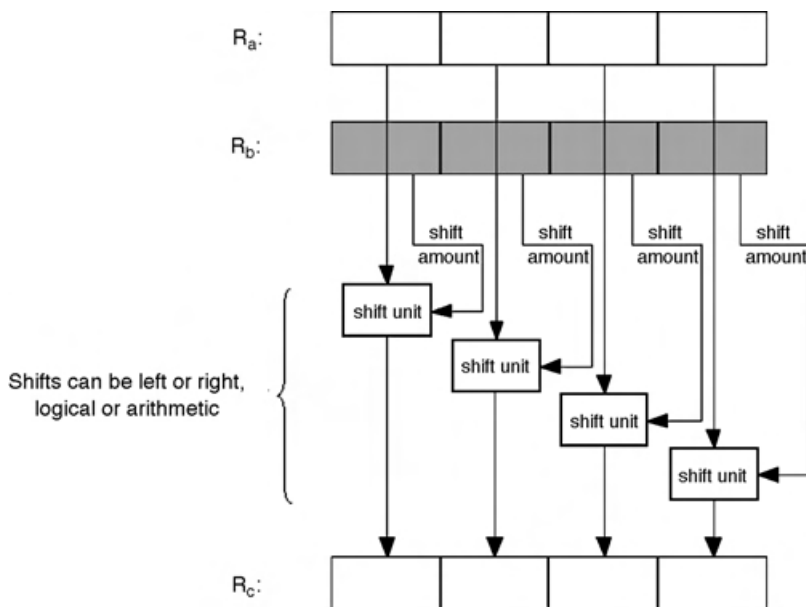

For the packed shift instruction, the shift can be logical (zeros substituted for vacated bits) or arithmetic (zeros substituted for vacated bits on the right and sign-bit replicated for vacated bits on the left). The shift amount can be given by an immediate operand or by a register operand. When the shift amount is given by a register, each subword is usually shifted by the same amount, given by the least significant  $\log_2 n$  bits of a second source register, for shifting the  $n$  bits of a first source register (see Fig. 39.25). In a more complicated, but more versatile form, each subword in a packed register can be shifted by a different amount (see Fig. 39.26).

Similarly, the packed rotate instruction performs rotations on each subword in parallel. The amount to be rotated can be specified by an immediate in an instruction, by a single rotate amount in a register, or by different rotate amounts for each subword (see Fig. 39.27). Data-dependent rotations, where the single rotate amount is given in a register, have been proposed for symmetric cryptography algorithms like RC5.

Packed shift instructions may also be used to multiply or divide subwords by a constant that is a power of two. When used in this way, it may be necessary to apply saturation arithmetic with parallel left shifts used for multiplication. It may also be desirable to apply rounding with parallel arithmetic right shifts. Such saturation and rounding complicate the circuitry for the shifter functional unit, and is not implemented by any of the current multimedia ISAs. Hence, packed shift instructions should be used for multiplication or division only when no overflow can occur on left shifts, and sufficient precision can be preserved on right shifts. For multiplication by an integer or fractional constant, packed shift and add instructions, described in the subsection on “Multiplication of a Packed Integer Register by an Integer Constant,” are preferable. These can better control accuracy in the multiplication.

**FIGURE 39.25** Packed shift instruction. Shift amount is given in the second operand. Each subword is shifted by the same amount.

**FIGURE 39.26** Packed shift instruction. Shift amount is given in the second operand. Each subword can be shifted by a different amount.

Table 39.5 summarizes the multimedia instructions involving packed shift and packed rotate operations. In the table,  $n$  is used to represent a shift or rotate amount that is specified in the immediate field of an instruction. For example, in the operation denoted as  $c_i = a_i \ll n$ , each subword of  $c$  is shifted to the left by the amount given in the immediate field of the corresponding instruction. Similarly, in the operation  $c_i = a_i \ll b$ , each subword of  $c$  is shifted to the left by the amount specified in the source register  $b$ . In  $c_i = a_i \ll b_b$ , each subword of  $c$  is shifted to the left by the amount specified in the corresponding subword of the source register  $b$ . Shift left is represented by  $\ll$ , shift right by  $\gg$ , and rotate by  $\ll\ll$ .

## Subword Permutation Instructions

Initially, the rearrangement of subwords in registers manifested only as packing and unpacking operations. MAX-2 first introduced general-purpose subword permutation instructions for more versatile reordering of subwords packed into one or more registers.

### Pack Instructions

Pack instructions convert from larger subwords to smaller subwords. If the value in the larger subword is greater than the maximum value that can be represented by the smaller subword, saturation arithmetic is performed, and the resulting subword is set to the maximum value of the smaller subword. Figure 39.28 shows how a register with smaller packed subwords can be created from two registers with subwords that are twice as large. Pack instructions differ in the size of the supported subwords and in the saturation options used.

### Unpack Instructions

Unpack instructions are used to convert smaller packed data types to larger ones. The subwords in the two source operands are written sequentially to the target register in alternating order. Because, only one-half of each of the source registers can be used, the unpack instructions come with two variants

FIGURE 39.28 Pack instruction converts larger subwords to smaller ones.

FIGURE 39.29 Unpack high instruction.

FIGURE 39.30 Unpack low instruction.

unpack high or unpack low. The high/low unpack instructions select and unpack the high or low order subwords of a source register, when used with register zero as the second source register.<sup>5</sup>

### Subword Permutation Instructions

Ideally, it is desirable to be able to perform all possible permutations on packed data. This is only possible for small numbers of subwords. When the number of subwords increases, the number of control bits required to specify arbitrary permutations becomes too large to be encoded in an instruction. For the case of  $n$  subwords, the number of control bits used to specify a particular permutation of these  $n$  subwords

<sup>5</sup>Register zero gives a constant value of “zero” when used as a source register.

**TABLE 39.6** Number of Control Bits Required to Specify an Arbitrary Permutation

2	2
4	8
8	24
16	64
32	160
64	384
128	896

**FIGURE 39.31** Arbitrary permutation on a register with four subwords.

is  $n \log_2(n)$ . Table 39.6 shows how many control bits are required to specify any arbitrary permutation for different numbers of subwords. When the number of subwords is 16 or greater, the number of control bits exceeds the number of the bits available in the instruction, which is typically 32 bits. Therefore, it becomes necessary to use a second register<sup>6</sup> to contain the control bits used to specify the permutation. By using this second register, it is possible to get any arbitrary permutation of up to 16 subwords in one instruction.

Because AltiVec instructions have three 128-bit source registers, a subword permutation can use two registers to hold data, and the third register to hold the control bits. This allows any arbitrary selection and re-ordering of 16 of the 32 bytes in the two source registers in a `vperm` instruction.

Only a small subset of all the possible permutations is achievable with one subword permutation instruction, so it is desirable to select permutations that can be used as primitives to realize other permutations. A `permute` instructions can have one or two source registers as operands. In the latter case, only half of the subwords in the two source operands may actually appear in the target register. Examples of these two cases are the `mux` and `mix` instructions respectively, in both IA-64 and MAX-2.

`Mux` in IA-64 operates on one source register. It allows all possible permutations of four packed 16-bit subwords, with and without repetitions (see Fig. 39.31). An 8-bit immediate field is used to select one of the 256 possible permutations. This is the same operation performed by the `permute` instruction in the earlier MAX-2.

In IA-64, the `mux` instruction can also permute eight packed 8-bit subwords. For the 8-bit subwords, `mux` has five variants, and only the following permutations are implemented in hardware (see Fig. 39.32):

- `Mux.rev` (reverse): Reverses the order of bytes.
- `Mux.mix` (mix): Performs the `Mix` operation (see below) on the bytes in the upper and lower 32-bit halves of the 64-bit source register.

<sup>6</sup>This second register needs to be at least 64-bits wide to fully accommodate the 64 control bits needed for 16 subwords.

**FIGURE 39.32** Mux instruction of IA-64 has five permutation options for 8-bit subwords. (From Intel, IA-Architecture Software Developer's Manual, Vol. 3, Instruction Set Reference, Rev. 1.1, July 2000. With permission.)

- `Mux.shuf` (shuffle): Performs a perfect shuffle on the bytes in the upper and lower halves of the register.
- `Mux.alt` (alternate): Selects first the even<sup>7</sup> indexed bytes, placing them in the upper half of the result register, then selects the odd indexed bytes, placing them in the right half of the result register.
- `Mux.brcst` (broadcast): Replicates the least significant byte into all the byte locations of the result register.

`Mix` is a very useful permutation operation on two source registers. A `mix left` instruction picks even subwords alternately from the two source registers and places them into the target register (see Fig. 39.33). A `mix right` instruction picks odd subwords alternately from the two source registers and places them into the target register (see Fig. 39.34).

The versatility of `Mix` is demonstrated [9, 14], for example, in performing a matrix transpose. `Mix` can also be used to perform an unpacking function similar to that done by `Unpack High` and `Unpack Low`. The usefulness of `Mix` and `Mux` (or `Permute`) has also been validated in [21] as general-purpose subword permutation primitives for processing of two-dimensional data in microSIMD architectures.

### Extract, Deposit, and Shift Pair Instructions

A more sophisticated shifter can also perform `extract` and `deposit` bit-field operations, as in PA-RISC [17, 10]. An `extract` instruction picks an arbitrary contiguous bit-field from the source operand and places it right aligned into the result register (Fig. 39.35). `Extract` instructions may be limited to work

<sup>7</sup>The bytes indexed from 0 to 7. 0 corresponds to the most significant byte, which is on the left end of the registers.

FIGURE 39.33 Mix left instruction.

FIGURE 39.34 Mix Right instruction.

FIGURE 39.35 Extract bit-field instruction.

FIGURE 39.36 Extract subword instruction.

on subwords instead of bit-fields (Fig. 39.36). Extract instructions clear the upper bits of the target register.

A deposit instruction picks a right-aligned contiguous bit-field from the source register and patches it into an arbitrary location in the target register (Fig. 39.37). The unpatched bits of the target register remain unchanged. Alternatively, they are cleared to zeros in a zero and deposit instruction [17]. Deposit instructions may be limited to work on subwords instead of arbitrarily long bit-fields and arbitrary patch locations (Fig. 39.38).

FIGURE 39.37 Deposit bit-field instruction.

FIGURE 39.38 Deposit subword instruction.

FIGURE 39.39 Shift pair instruction in IA-64.

A very useful instruction for rearranging subwords from two registers is the `shift pair` instruction in IA-64 (see Fig. 39.39). This instruction, which was first introduced in the PA-RISC ISA [10,17], is essentially a `shift` instruction for bit-strings that span more than one register. `Shift pair` concatenates the two source registers to form a 128-bit intermediate value, which is shifted to the right by  $n$  bits. The least significant 64 bits of the shifted value is written to the result register. If the same register is specified for both operands, the result is a `rotate` operation. Rotates can be realized this way, so IA-64 does not have a separate `rotate` instruction. This `shift pair` instruction is more general than a `rotate`, allowing flexible combination of two bit-fields from separate registers. Table 39.7 summarizes the subword permutation instructions on packed data types.

### Floating-Point MicroSIMD Instructions

High-fidelity audio and graphics geometry processing require the higher precision and range of floating-point numbers. Usually, single-precision (32-bit) floating-point (FP) numbers are sufficient, but 16-bit integers or fixed-point numbers are not. Double-precision (64-bit) floating-point numbers are not really needed for such multimedia computations.

Because floating-point registers are at least 64-bits wide in microprocessors to support double-precision (DP) FP numbers, it is possible to pack two single-precision (SP) FP numbers in a 64-bit register, to support subword parallelism, or packed parallelism, or microSIMD parallelism on the FP

**TABLE 39.7** Subword Permutation Instructions

functional units and registers. The precision levels supported by different ISAs are shown in [Table 39.8](#). SP and DP numbers are 32 and 64 bits long, respectively, as defined by the IEEE-754 FP number standard. Only SSE-2 supports packed DP FP numbers. MAX-2 and MMX do not support packed FP instructions.

## Packed Floating-Point Arithmetic Instructions

### *Packed FP Add*

[Figure 39.40](#) shows a packed FP add, where four pairs of single-precision FP numbers in two 128-bit registers are added using floating-point addition. Packed FP subtract instructions are similar. While the packed FP instruction looks very similar to the packed integer equivalents (see [Fig. 39.5](#)), implementation of packed FP add is not as simple as blocking carries at the subword boundary as in packed integer addition (see [Fig. 39.7](#)). It is much more difficult to partition a FP functional unit for subword parallelism because of the nature of FP arithmetic acting on FP numbers represented in sign, mantissa, and exponent format. Another difference is that in floating-point number representation, considerations like modular arithmetic or saturation arithmetic are not applicable.

### *Packed FP Multiplication*

Multiplication of two packed FP registers involves multiplication of corresponding FP subwords from the source registers, where the products are written to the corresponding subword in the target register (see [Fig. 39.41](#)). In multiplication of two single-precision numbers, the product is also single-precision, and hence the same width. Therefore, packed FP multiply does not have the problem associated with packed integer multiply instructions, where the product is twice the width of the operands.

FIGURE 39.40 PFPADD  $R_c, R_a, R_b$ : Packed FP add instruction.

FIGURE 39.41 PFPMUL  $R_c, R_a, R_b$ : Packed FP multiply instruction.

### Packed FP Multiply and Add

The most important FP operation in audio, graphics, and digital signal processing is the FP multiply and accumulate operation. Recognizing this, many ISAs have implemented this as the basic FP operation, needing three source registers. For example, IA-64 implements packed FP multiply and add (FPMA), packed FP multiply and subtract (FPMS), and packed FP negative multiply and add (FPNMA). It then realizes packed FP add, packed FP subtract, and packed FP multiply operations by using FPMA and FPMS instructions. IA-64 architecture specifies 128 FP registers, which are numbered FR0 through FR127. Of these registers, FR0 and FR1 are special. FR0 always returns the value +0.0 when sourced as an operand, and FR1 always reads +1.0. When FR0 or FR1 are used as source operands, the FPMA and FPMS instructions can be used to realize packed FP add or packed FP subtract operations and packed FP multiply operations (see Table 39.9).

The format of the FPMA (Fig. 39.42) instruction is FPMA  $R_d, R_a, R_b, R_c$  and the operation it performs is  $R_d = R_a * R_b + R_c$ . If FR1 is used as the first or the second source operand, a packed FP add operation is realized. Similarly, a FPMS instruction can be used to realize a packed FP subtract operation. Using FR0 as the third source operand in FPMA or FPMS results in a packed FP multiply operation.

Table 39.10 is a summary of the packed FP instructions supported by multimedia ISAs. Several packed FP instructions operate like their packed integer equivalents, except that they operate on packed FP subwords

**TABLE 39.9** IA-64 uses FPMA and FPMS Instructions for packed FP add, packed FP subtract, and packed FP multiply

IA-64 Instruction	Operation	Equivalent Instruction
FPMA $R_d, FR1, R_b, R_c$ (packed FP multiply and add)	$R_d = FR1 * R_b + R_c$ $= 1.0 * R_b + R_c$ $= R_b + R_c$	Packed FP add
FPMS $R_d, FR1, R_b, R_c$ (packed FP multiply and subtract)	$R_d = FR1 * R_b - R_c$ $= 1.0 * R_b - R_c$ $= R_b - R_c$	Packed FP subtract
FPMA $R_d, R_a, R_b, FR0$ (packed FP multiply and add)	$R_d = R_a * R_b + FR0$ $= R_a * R_b + 0.0$ $= R_a * R_b$	Packed FP multiply

**FIGURE 39.42** Packed FP multiply and add instruction in IA-64.

rather than packed integer (or fixed-point) subwords. These include packed FP add, packed FP subtract, packed FP multiply, packed FP negate, packed FP absolute value, packed FP compare, packed FP maximum, and packed FP minimum. IA-64 also has the packed FP maximum absolute value and the packed FP minimum absolute value. These put the larger or smaller of the absolute values of the pairs of FP subwords into the result subwords in the target register, respectively.

### ***Packed FP Compare***

The packed FP compare instruction compares pairs of FP subwords according to the relation specified by the instruction. If the condition is true for a subword pair, the corresponding field in the target register is written with a 1-mask. If the condition is false, the corresponding field in the target register is written with a 0-mask. The only difference is that two additional relations, ordered and unordered, are possible for floating-point numbers in addition to the 10 relations already specified for comparing integers (see

subsection “Packed Compare Instruction”). Some ISAs have packed FP compare instructions that allow all the 12 possible relations,<sup>8</sup> whereas others support a more limited subset of relations.

### Packed FP Compare Bounds

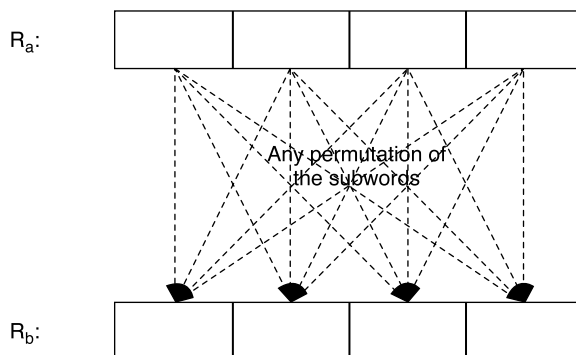

An interesting comparison instruction is the packed FP compare bounds (VCMPEFB) instruction of AltiVec. This instruction compares corresponding FP subwords from the two source registers, and depending on the relation between the compared numbers, it generates a two-bit result, which is written to the target register. The resulting two-bit field indicates the relation between the two compared FP numbers. For instance, in VCMPEFB  $R_c, R_a, R_b$ , the FP number pairs  $(a_i, b_i)$  are compared, and a two-bit field is written into  $c_i$  such that:

- Bit 0 of the two-bit field is cleared if  $a_i \leq b_i$ , and is set otherwise.
- Bit 1 of the two-bit field is cleared if  $a_i \geq (-b_i)$ , and is set otherwise.
- Both bits are set if any of the compared FP numbers is a NaN.

<sup>8</sup>Two floating-point numbers  $a$  and  $b$  can be compared for one of the following 12 possible relations: equal, less-than, less-than-or-equal, greater-than, greater-than-or-equal, unordered, not-equal, not-less-than, not-less-than-or-equal, not-greater-than, not-greater-than-or-equal, ordered. Typical notation for these relations are as follows respectively: =, <, <=, >, >=, ?, !=, !<, !<=, !>, !>=, !?.

**TABLE 39.11** Result of the VCMPEFP Instruction for Different Input Pairs

Input		Output	
$a_i$	$b_i$	Bit 0	Bit 1
3.0	5.0	0	0
-8.0	5.0	0	1
8.0	5.0	1	0
3.0	-5.0	1	1

**FIGURE 39.43** FP permute  $R_b, R_a$ : FP permute instruction.

The two-bit result field is written to the high-order two bits of  $c_i$ ; the remaining bits of  $c_i$  are cleared to 0. Table 39.11 gives examples of input pairs that result in each of the four different possible outputs for this instruction.

The SSE-2 architecture also includes a packed FP square root instruction. This instruction operates on packed single-precision or double-precision numbers and computes the square roots to SP or DP accuracy. IA-64 has the packed FP reciprocal square root instruction and the packed FP reciprocal instruction. Both are very useful for graphics computations.

## Subword Permutation Instructions

### FP Permutation Instructions

SSE-2 has an FP permute (see Fig. 39.43) instruction that allows any arbitrary permutation of the four 32-bit SP subwords in one of its 128-bit multimedia registers. This operates just like the permute instruction in MAX-2 and the mux instruction (2-byte subword version) in IA-64 (see Fig. 39.31).

IA-64 only has two single-precision subwords in its packed format, so all possible permutations of two subwords can be achieved with a much simpler operation, FP swap. This instruction just exchanges the two subwords. IA-64 also allows two variants of this: after swapping the subwords, the sign of either the left or the right FP value is negated.

FP mix is a useful operation that performs a permutation on two packed FP registers. A FP mix instruction picks alternating subwords from two source registers and places them into the target register. FP mix in IA-64 appears in three variants. The first one (Fig. 39.44) is called the FP mix left and uses the odd indexed FP subwords of the source registers in the permutation, starting from the leftmost subword. The second variant, FP mix right (Fig. 39.45) uses the even indexed FP subwords of the source registers, ending with the rightmost subword. The third variant, FP mix left right (Fig. 39.46) uses the odd indexed FP subword of the first source register, and the even indexed subword of the second

**FIGURE 39.44** FP mix left  $R_c, R_b, R_a$ : FP mix left instruction in IA-64.

**FIGURE 39.45** FP mix right  $R_c, R_b, R_a$ : FP mix right instruction in IA-64.

**FIGURE 39.46** FP mix left right  $R_c, R_b, R_a$ : FP mix left right instruction in IA-64.

source register. These three FP mix instructions, together with the Shift Pair instruction described earlier, allow any one of the four combinations of the SP subwords packed into two IA-64 registers to be achieved with only one instruction.

### ***FP Unpack***

Packing and unpacking subwords has a different interpretation for FP numbers than for integers. In general, there is sufficient precision in single-precision numbers, and there is no need to unpack it to a double-precision number; however, the FP unpack can be regarded as a useful subword permutation instruction like FP mix. It performs a shuffle by interleaving the subwords from two registers. The FP unpack instructions operate just like the equivalent integer unpack instructions (see Figs. 39.29 and 39.30). They come in two “flavors”: FP unpack high and FP unpack low. Note that the SSE-2 employs FP unpack, after unpack in MMX, and IA-64 employs FP mix, after mix in MAX-2.

### ***FP Pack***

In the integer domain, pack instructions are used to create smaller packed data types from larger data types. The FP pack instruction in IA-64 creates two packed SP numbers from two 82-bit source registers. All IA-64 FP registers are 82-bit extended precision FP format with two extra guard bits for computational accuracy. First, the two 82-bit numbers are converted to standard 32-bit SP representation. These two SP numbers are then concatenated and the result is stored in the significand field (which is 64 bits) of the 82-bit target FP register. The exponent field of the target register is set to the biased exponent for  $2.0^{63}$ , which indicates a packed FP format, and the sign bit is set to zero, indicating a positive number.

## **Conclusions**

Section 39.1 described multimedia instructions for programmable processors by broad classes according to the functional units used, first in the integer domain then in the floating-point domain. For integer subwords, packed add and packed subtract instructions, and different variants of these, use the ALU. Packed multiply instructions use the multiplier functional unit, although very efficient multiplication by constants can be implemented with packed shift and add instructions, which only need an ALU with a preshifter. Packed shift and packed rotate instructions use the shifter. Packed subword permutation instructions can either be implemented on a modified shifter or in a new permutation unit. For packed floating-point subwords, less leverage of hardware seems possible. The basic functional units are a floating-point adder, multiplier, and FP subword permutation unit. IA-64 combines the FP adder and multiplier into an FP multiply-add unit. For each of these instruction classes, interesting multimedia instructions introduced in current microprocessors were described, for example, in the IA-64, MMX, and SSE-2 from Intel; MAX-2 from Hewlett-Packard; 3DNow! from AMD; and AltiVec from Motorola.

The key feature in these multimedia instructions is the concept of subword parallelism, also called packed parallelism or microSIMD parallelism. This is implemented for packed integers or fixed-point numbers in the integer datapaths, and for packed floating-point numbers in the floating-point datapaths. Visual multimedia data like images, video, graphics rendering and animation involve pixel processing, which can fully exploit subword parallelism on the integer datapath. Higher-fidelity audio processing and graphics geometry processing require single-precision floating-point computations, which exploit subword parallelism on the floating-point datapath. Typical DSP operations such as multiply and accumulate have also been added to the multimedia repertoire of general-purpose microprocessors. These multimedia instructions have embedded DSP and visual processing capabilities into general-purpose microprocessors, providing native signal processing (sometimes referred to as NSP) for multimedia data. In fact, most DSPs and media processors have also adopted subword parallelism in their architectures, as well as other features often first introduced in microprocessors for multimedia signal processing.

More unusual computer arithmetic issues arising from subword-parallel multimedia instructions in microprocessors are saturation arithmetic, integer rounding alternatives, integer multiplication problems and solutions, and subword permutation instructions.

Some of the multimedia ISAs introduced in microprocessors adhere to the “less is more” minimalist architecture approach, defining as few instructions as necessary for high-performance, with each instruction executable in a single pipeline cycle. Others embody the “more is better” approach, where complex sequences of operations are represented by a single multimedia instruction, with such an instruction taking many cycles for execution. An example is the packed vector multiply and accumulate instruction in AltiVec (Fig. 39.24). These two trends represent different stylistic preferences, akin to reduced instruction set computer (RISC) and complex instruction set computer (CISC) architectural preferences. In fact, sometimes, RISC-like multimedia instructions have been added to CISC processor ISAs, and CISC-like multimedia instructions to RISC processor ISAs. The remarkable fact is that subword-parallel multimedia instructions have achieved such rapid and pervasive adoption in both RISC and CISC microprocessors, DSPs and media processors, attesting to their undisputed cost-effectiveness in accelerating multimedia processing in software.

To simplify software compatibility and interoperability of multimedia software across different processors, it is highly desirable to refine the best ideas from the different multimedia ISAs into a coherent set of subword-parallel instructions. If this is a small yet powerful set, it is more likely to be implemented in all future microprocessors and media processors, allowing algorithm and compiler optimizations to exploit microSIMD parallelism with confidence that benefits would be realized across almost all processors. While slight differences in multimedia instructions across processors may not affect the potential performance provided by each ISA, they make it difficult to design an optimal algorithm and a set of compiler optimizations that achieve the best multimedia performance for every processor. The challenge for the next phase of multimedia ISA design is to understand which ISA features are truly effective for multimedia signal processing, and encapsulate these insights into the design of third-generation multimedia ISA for both microprocessors and media processors.

## 39.2 DSP Platform Architecture for SoC Products

---

*Gerald G. Pechanek*

### Introduction

The development of wireless, networking, communications, video, and consumer products has shifted toward low-power high-functionality systems-on-chip (SoC) semiconductors [1]. Driving this development is the availability of deep sub-micron technology allowing more complete system designs to be embedded in silicon. Some of these improvements include increasing on-chip memory capacity, the use of more fully programmable solutions using DSPs, and the inclusion of specialized interfaces and functions.

To make these high-value SoC products widely available at low cost requires the use of standard design practices that allow them to be fabricated at multiple semiconductor suppliers. This means that custom designed SoCs, optimized to a particular manufacturing process, cannot be used. Consequently, as the complexity and functionality of SoC products continues to increase with stringent power requirements, the standard approach of increasing clock speed on an existing design to meet higher performance requirements is infeasible.

The need to support multiple standards, and to quickly adapt to changing standards, has become a product requirement [2]. To satisfy this need, programmable DSPs and control processors are being increasingly used as the central SoC design component. These processors form the basis of the SoC product platform and permeate the overall system design including the on-chip memory, DMA, internal busses, etc. Consequently, choosing a flexible and efficient processor, which can be manufactured by multiple semiconductor suppliers, is arguably the most important intellectual property (IP) decision that needs to be made in the creation of an SoC product.

In recent years, a class of high-performance programmable processor IP has emerged that is appropriate for use in high-volume embedded applications such as digital cellular, networking, communications, and console gaming [3,4]. Section 39.2 briefly describes the ManArray thread coprocessor as an example of the architectural features needed for demanding SoC requirements. The next subsection provides a brief description of the ManArray thread coprocessor architecture. The subsection "The ManArray Thread

FIGURE 39.47 ManArray architectural elements.

Coprocessor Platform” describes how the ManArray architecture fulfills SoC application requirements, with focus on the implementation, compiler, and tools. “Performance Evaluation” presents performance results, and last subsection concludes the chapter section.

## The ManArray Thread Coprocessor Architecture

In numerous application environments there is a need to significantly augment the signal processing capabilities of a MIPS, ARM, or other host processor. In addition, many applications require low power consumption at very high performance levels to accomplish the tasks of emerging applications, such as wireless LAN (i.e., 802.11a) for battery-powered Internet devices. The BOPS SoC cores provide streamlined coprocessor attachment to MIPS, ARM, or other hosts for this purpose. Through selectable parallelism, the ManArray SoC cores achieve high performance at low clock rates, which minimizes power requirements. The compiler or programmer can select from packed data, indirect VLIW, PE array SIMD, and multiple threaded forms of parallelism to provide the best product solution. Further, BOPS provides a complete solution by providing a comprehensive top-down design methodology for delivering the SoC solutions.

The ManArray processor is an array processor using a sequence processor (SP) array controller and an array of distributed indirect VLIW processing elements (PEs) (see Fig. 39.47). By varying the number of PEs on a core, an embedded scalable design is achieved with each core using a single architecture. This embedded scalability makes it possible to develop multiple products that provide a linear increase in performance and maintain the same programming model by merely adding array processor elements as needed by the application. As the processing capability is increased, the memory-to-PE bandwidth is increased, and the system DMA bandwidth may be increased as well. Embedded scalability drastically reduces development costs for future products because it allows for a single BOPS software development kit (SDK) to support a wide range of products.

In addition to the embedded scalability, ManArray cores are configurable in the number and type of cores included on a chip, instruction subsetting for application optimization, the sizes of each SP’s instruction memory, the distributed iVLIW memories, the PE/SP data memories, and the I/O buffers, selectable clock speed, choice of on-chip peripherals, and DMA bus bandwidth. The ManArray cores provide a lower cost, more optimized signal processing solution than reconfigurable processors designed using FPGA technology [5]. Multiple ManArray cores provide optimized scalable multiprocessing by including multiple BOPS cores on an SoC product. These multiple ManArray cores can be organized to provide data pipeline processing between SP/PE-array cores and the parallelization of sub-application tasks (thread parallelism) with a centralized host-based control to be described later in this chapter section.

Generally speaking, the ManArray processor combines PEs in clusters that also contain a SP, uniquely merged into the PE array, and a cluster-switch, Fig. 39.47. The SP provides program control, contains the instruction and data address generation units, and dispatches instructions to the processor array. In this manner, the ManArray processor is designed for scalability with a single architecture definition and a common tool set. The processor and supporting tools are designed to optimize the needs of a SoC platform by allowing a designer to balance an application’s sequential control requirements with the application’s inherent data parallelism. This is accomplished by having a scalable architecture that begins

FIGURE 39.48 ManArray 1 × 2 core elements.

with a simple uniprocessor model and continues through multi-array processor implementations. In the design flow we ensured that the ManArray architecture supported a reasonably large array processor as well as a simple stand-alone uniprocessor that could act as an array controller. In more detail, a SP merged with PE0 (SP/PE0) and an additional PE (PE1), referenced as a 1 × 2, are shown in Fig. 39.48.

The ManArray architecture uses a distributed register file model where the SP and each PE contain their own independent register space, up to eight execution units (five shown), a distributed very long instruction word memory (VIM), local SP instruction memory, local data memories, and an application-optimized DMA and bus I/O control unit. In the Manta™ core, an available 2 × 2 implementation of the ManArray architecture, and its 1 × 1 and 1 × 2 subsets (available by software masking of selected PEs), a 64-entry register file space is used in the SP and each PE. The register space consists of a reconfigurable compute register file (CRF), which can act as a 32 × 32-bit or 16 × 64-bit register file for the execution units on a cycle-by-cycle basis, totally integrated into the instruction set architecture, an 8 × 32-bit address register file (ARF), and a 24 × 32-bit miscellaneous register file (MRF).

In the ManArray architecture, the address registers are separated from the compute register file. This approach maximizes the number of registers for compute operations and guarantees a minimum number of dedicated address registers. This approach does not require any additional ports from the compute register file to support the load and store address generation functions, and it still allows independent PE memory addressing for such functions as local data dependent table lookups. The Manta chip supports both 32-bit data types including quad byte, dual halfword, and word; and 64-bit data types including octal byte, quad halfword, dual word, and double word. The balanced architectural approach taken for the compute register file provides the high performance features needed by many applications. It supports octal byte and quad halfword operations in a logical 16 × 64-bit register file space without sacrificing the 32-bit data type support in the logical 32 × 32-bit register file. Providing both allows optimum usage of the register file space and minimum overhead in manipulating packed data items. By adding PEs, the packed data support grows such that a 1 × 2 effectively provides 128-bit packed data support, a 2 × 2 provides 256-bit packed data support, etc., growing the level of parallelism needed by appropriate choice of the selected core.

The ManArray instruction set is partitioned into four groups using the high two bits of the instruction format—a control group, an arithmetic group, a load/store group, and a reserved proprietary instruction group. Figure 39.49 shows 32-bit simplex instructions in groupings that represent the five execution unit slots of the Manta chip, the first ManArray implementation, plus a control group (01). The execution units include store and load units, an arithmetic logic unit (ALU), a multiply accumulate unit (MAU), and a data select unit (DSU). The load and store instructions support base plus displacement, direct, indirect, circular, and table addressing modes. The ALU, MAU, and DSU support basic add/subtract, multiply,

Control	Store	Load	ALU	MAU	DSU
Group 01	Group 10	Group 10	Group 11	Group 11	Group 11
Call	Base+Disp.	Base+Disp.	ADD/SUB	ADD/SUB	Copy
Jump	Direct	Direct	Butterfly	Butterfly	Shift/Rotate
EventPoint Loops	Indirect	Indirect	Compare	MPY/MPYA	Permute
Return	Circular	Circular	AbsoluteDiff	MPYCmplx	Bit operations
Load VLIW	Table	Table	Min/Max	MPYCmplxA	Divide
Execute VLIW	ARF group	ARF group	Logicals	SUM2P/SUM2PA	Communications PEExchange
		Immediate			
		Broadcast			

FIGURE 39.49

and data type manipulations such as shift, rotate, and permute, respectively. In addition, many application specific instructions are used for improved signal processing efficiency. An example of this are the multiply complex instructions for improved FFT performance described in reference [6].

The control and branch instructions are executed by the SP. It is also capable of indirectly executing VLIWs that are local to the SP and in each PE. To minimize the effects of branch latencies, a short variable pipeline is used consisting of Fetch, Decode, Execute, and ConditionReturn for non-iVLIWs and Fetch, PreDecode, Decode, Execute, and ConditionReturn for iVLIWs. The PreDecode pipeline stage is used to indirectly fetch VLIWs from their local VIMs. Note that VLIWs are stored locally in VIMs in each PE and in the SP and are fetched by a 32-bit execute VLIW (XV) instruction. In addition, an extensive scalable conditional execution approach is used in each PE and the SP to minimize the use of branches.

All loads/stores and arithmetic instructions execute in one or two cycles with no hardware interlocks. Further, all arithmetic and load/store instructions can be combined into VLIWs, stored locally in the SP and in each PE, and can be indirectly selected for execution from the small distributed VLIW memories (VIMs). Using the load iVLIW (LV) instruction, the programmer or compiler loads individual instruction slots with the 32-bit simplex instructions optimized for the algorithm being programmed. These VLIWs are used for algorithm performance optimization, are re-loadable, and require only the use of a 32-bit execute VLIW (XV) instructions in the program stored in the SP instruction memory.

A dedicated bit in all instruction formats controls whether an instruction is executed in parallel across the array of PEs or sequentially in the SP. To more optimally support a multiple PE array containing the distributed register files, the ManArray network is integrated into the architecture providing single-cycle data transfers within PE clusters and between orthogonal clusters of PEs. The DSU communications instructions can also be included into VLIWs, thereby overlapping communications with computation operations, which in effect reduces the communication latency to zero. The ManArray network operation is independent of background DMA operations, which provide a data streaming path to peripherals, such as a global memory.

The inherent scalability of the ManArray processor is obtained in part through the advanced ManArray network which interconnects the PEs. Consider by way of example, a two-dimensional (2D)  $4 \times 4$  torus and the corresponding embedded 4D hypercube, written as a  $4 \times 4$  table with both row, column, and hypercube node labels. (See Fig. 39.50A.)

In Fig. 39.50A, the  $PE_{i,j}$  cluster nodes are labeled in gray-code as follows:  $PE_{G(i),G(j)}$  where  $G(x)$  is the gray code of  $x$ . First, columns 2, 3, and 4 are rotated one position down. Next, the same rotation is repeated with columns 3 and 4, and then with column 4. The resulting 4D ManArray table is shown in Fig. 39.50B.

Notice that the row elements in Fig. 39.50B, for example  $\{(1,0), (0,1), (3,2), (2,3)\}$ , contain the transpose PE elements. By grouping the row elements in clusters of four PEs each, and completely interconnecting the four PEs, connectivity among the transpose elements can be obtained. Notice also that, in the new matrix of PEs, the east and south wires, as well as the north and west wires, are connected between adjacent clusters. For example, using Fig. 39.50A note that node (2,3) connects to the east node (2,0) with wraparound

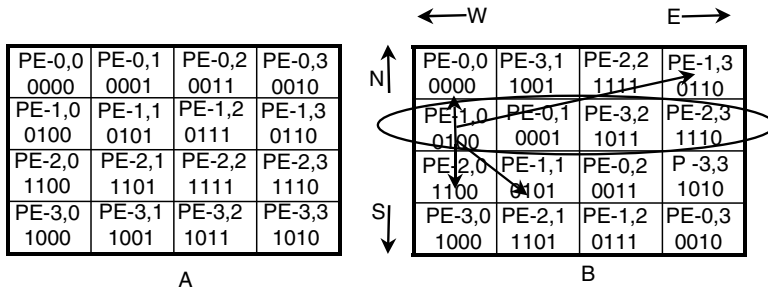

FIGURE 39.50 Hypercube interconnection scheme.

wires in a torus arrangement. Node (2,3) also connects to the south node (3,3). Now, using Fig. 39.50B, note that nodes (2,0) and (3,3) are both in the same cluster adjacent to the cluster containing node (2,3). This same pattern occurs for all nodes in the new matrix. This means that the east and south wires can be shared and, in a similar manner, the west and north wires can be shared between all clusters. This effectively cuts the wiring in half as compared to a standard torus, and without affecting the performance of any SIMD array algorithm.

The rotating algorithm maintains the connectivity between the PEs, so the normal hypercube connections still remain as shown in one example in Fig. 39.50B as PE (1,0/0100) can communicate to its nearest hypercube nodes {(0000), (0101), (0110), (1100)} in a single step. Note also that the longest paths in a hypercube, where each bit in the node address changes between two nodes, are all contained in the completely connected clusters of processors nodes. For example, the circled cluster contains node pairs {(0100), (1011)} and {(0001), (1110)}, which would take four steps to communicate between each pair in previous hypercube processors, takes only one step to communicate in the new ManArray network. These properties are maintained in higher dimensional ManArray networks containing higher dimensional tori, and thus hypercubes, as subsets of the ManArray connectivity matrix. We have also shown that the complexity of the ManArray network is small and that the diameter, the largest distance between any pair of nodes, is 2 for all  $d$  where  $d$  is the dimension of the subset hypercube [7].

Application-specific instructions are included in the various execution units, such as multiply complex [6] and other video, graphics, and communications unique instructions. Any of the four groups of instructions can be mixed on a cycle-by-cycle basis. The single ManArray instruction set architecture supports the entire ManArray family of cores from the single merged SP/PE0  $1 \times 1$  to any of the highly parallel multi-processor arrays ( $1 \times 2$ ,  $2 \times 2$ ,  $2 \times 4$ ,  $4 \times 4$ , etc.), for more details see references [8] and [9].

## The ManArray Thread Coprocessor Platform

The ManArray thread coprocessors are designed to act as independent coprocessors to ARM, MIPS, or other hosts. The programmer's view is a shared memory sequentially coherent model where multiple processors operate on independent processes. With this model, an SoC developer can quickly utilize the signal processing capabilities of the ManArray core subsystem since the operating system already runs on the host processors. In its role as a digital signal coprocessor, the ManArray core is subservient to the host processor. A core driver running on the host operating system manages all the DSP resources on the core. The ManArray system interface allows multiple BOPS cores to be attached to a single host processor as shown, for example, in Fig. 39.51. For wireless and media processing applications the  $1 \times 1$  MOCARay-I mobile communications accelerator and the  $1 \times 2$  MICORay-I imaging communications engine are designed to work separately or jointly, as shown in Fig. 39.51, to provide ultra low-power baseband and media DSP services for 3G mobile products. Figure 39.51 shows a multimode Smart Phone or PDA with MOCARay-I providing the GPRS/EDGE and/or UMTS mode while MICORay-I provides support for video MPEG-4, JPEG 2000 photo imaging, speech decode/encode, sprite-based rendering in a gaming mode, audio processing MP3, etc.

FIGURE 39.51 Application of multiple BOPS cores to 3G wireless.

FIGURE 39.52 Application of multiple BOPS cores to VoIP.

Another example of the use of BOPS cores as thread coprocessors is in voice-over-Internet protocol (VoIP) products. For this application, an integrated dual  $1 \times 2$  arrangement with a common DMA controller is used as the basic platform unit. One, two, or four of these dual  $1 \times 2$  units are provided as an SoC DSP “farm” with an on-board host engine, e.g. MIPS.

Figure 39.52 illustrates the configuration with eight  $1 \times 2$  cores. This system arrangement allows the workload to be partitioned appropriately allowing extant applications to run on existing host OSs in the MIPS controller. This lowers the risk of migrating an existing code base, and no new OS ports are required to support the ManArray cores. To complement the configurable hardware, there is a BOPS library of both DSP and control software routines to perform the desired VoIP gateway functions. In addition,

**FIGURE 39.53** Host DSP software layers.

existing host optimized compilers are used for the sequential code that remains resident on the host allowing the parallel code to be optimized for the ManArray cores.

A driver API allows host applications to initialize, control, and communicate with multiple ManArray coprocessors attached to the host. A standard message interface exists for all coprocessors to/from the host. Specifically, the ManArray core DSPs are described as thread coprocessors because the host processor dispatches entire threads of execution to the cores. The host driver loads programs, schedules context switches, and manages data streams into and out of the various coprocessors. The high-performance DMA engine, scaled appropriately for the application, autonomously transfers data streams to and from the host. In addition, data streams can be “pushed/pulled” from one coprocessor to another, or to/from peripherals (such as an H.100 interface) and coprocessors, without host intervention, using the ManArray DMA-to-DMA interconnection protocol.

The DMA subsystem consists of the DMA controller, a ManArray control bus (MCB), and a ManArray data bus (MDB). The MDB provides the high-bandwidth data interface between the cores and other system peripherals including system memory. The MDB consists of multiple identical lanes and is scalable by increasing the number of lanes and/or increasing the width of the lanes. Specifically, the MDB uses time division multiplexing of multiple independent buses or lanes to transfer data. The MCB is a low latency coprocessor-to-coprocessor/peripheral messaging bus, which runs independently and in parallel with the MDB. This system of multiple independent application task-optimized cores is designed to have each core run an independent thread supported by the programmable DMA engines [10].

Figure 39.53 illustrates the host-DSP software layers. The multiple ManArray cores support the multiple independent program threads that are managed by the host OS through remote procedure calls (RPC) scheduled by the RTOS driver running in the host. The BOPS channel processing API provides a standard interface for allocating voice channel processing to the multiple  $1 \times 2$  cores. On the ManArray core side, a thin DSP nano-kernel supports thread load/unload with DMA transfers overlapping computation. The RPC and DMA drivers provide standard host-DSP communication and data transfer support.

Supporting this scalable platform for VoIP solutions is BOPS SoC design flow as shown in Fig. 39.54. Four parallel processes are shown supporting both hardware and software design efforts for the thread coprocessors, peripherals, host software, and DSP software developments.

Once the SoC functional specification and a basic system design is determined the next development steps can be done in parallel. The ManArray core RTL and other peripheral RTL are done in parallel, being designed to the ManArray interface specifications. At the same time, due to the use of a cycle accurate system simulator and other supporting tools, the host CPU software and DSP software development are done in parallel.

To streamline development, verification and debug, BOPS provides a range of modeling and prototyping platforms to support system modeling, and software and hardware system development including:

- a cycle-accurate C-simulator, which can be used to develop ManArray DSP and system software. This can be used directly with other C simulations, or with control processor tools and bus models to provide a software simulation model of an entire system;
- a software development toolkit (SDK) including the BOPS ANSI-C Halo™ parallelizing C compiler;
- the Jordan™/Manta™ PCI card, which can be used to model and test DSP software at 100 MHz processor speeds and under actual DMA I/O conditions;

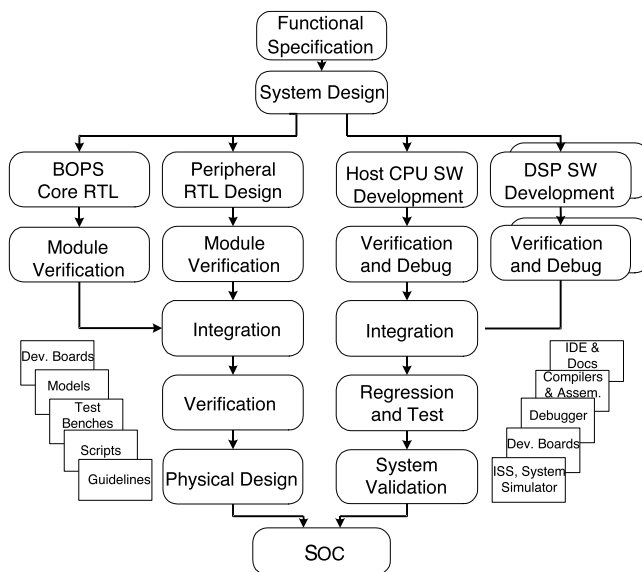

FIGURE 39.54 BOPS SoC design flow.

- the Travis™/ Manta™ prototyping board, which can be used to prototype entire SoC systems at actual speeds;
- the Xemuator™ emulation board, which can be used to model RTL emulations of an entire SoC system.

The same DSP debugging GUI is shared by the C-simulator, Jordan, Travis, and Xemuator boards. The Jordan development and Travis prototyping boards are provided using a  $2 \times 2$  Manta core that contains features needed in many applications. The Travis system prototyping board uses the standard configurations available on Manta cores  $1 \times 1$ ,  $1 \times 2$ , and  $2 \times 2$ . All of the normal fixed resources such as host microcontroller, oscillators, memories, power supplies, configuration controls, debug, peripheral and PCI interfaces are also on board. In addition, a large FPGA accommodates all unique logic circuits allowing for rapid design, testing, and debug. The Jordan board with the Manta chip provides real time operation of standard cores in a MIPS host system with off board system prototyping. Also included on the Jordan board is a MIPS microcontroller with interrupts and boot ROM. With these development boards the software can be integrated and tested. BOPS also provides verification tools and supporting scripts and guidelines for the physical design.

The SoC emulator board, the Xemuator, allows MHz speed emulation in FPGAs of the many possible RTL hardware and software configurations of the scalable ManArray architecture. This is useful when bus sizes, bus protocols, and external interfaces are changed from the standard core configurations. Likewise, I/O and DMA controllers may need to be altered for certain applications. Additions, subsetting, and other changes to the instruction set can be explored on the Xemuator by modifying the downloaded core's FPGA description.

## Performance Evaluation

To illustrate the power of the highly parallel ManArray architecture, a simple example is presented: Two vectors are to be added and the result stored in a third vector.

$$\text{for } (i = 0; i < 256; i++)$$

$$A[i] = B[i] + C[i]$$

Benchmark	Data Type	Performance
256 pt. Complex FFT (2x2)	16-bit real & imaginary	383 cycles
256 pt. Complex FFT (1x1)	16-bit real & imaginary	1115 cycles
1024 pt. Complex FFT (2x2)	16-bit real & imaginary	1513 cycles
1024 pt. Complex FFT (1x1)	16-bit real & imaginary	5221 cycles
2048 pt. Complex FFT (2x2)	16-bit real & imaginary	3182 cycles
2D 8x8 IEEE IDCT [11] (2x2)	8-bit	34 cycles
2D 8x8 IEEE IDCT (1x1)	8-bit	176 cycles
256 tap Real FIR filter, M samples (2x2)	16-bit	16*M + 81 cycles
256 tap Real FIR filter, M samples (1x1)	16-bit	64*M + 78 cycles
4x4 Matrix * 4x1 vector (2x2)	IEEE 754 Floating Point	2 cycles / output vector
3x3 Correlation (720col) (2x2)	8-bit	271 cycles
3x3 Median Filter (720col) (2x2)	8-bit	926 cycles
8x8 Block Motion Est. (H=64, V=32) (2x2)	8-bit	4611 cycles
Horizontal Wavelet (N Rows = 512) (2x2)	16-bit	1029 cycles

FIGURE 39.55 Manta 2 × 2 thread coprocessor benchmarks.

In a sequential-only implementation there would be required a loop of four instructions, two loads to move a  $B$  and a  $C$  element to registers, an add of the elements, and a store of the result to register  $A$ . The sequential implementation takes  $(4 \times 256)$  iterations = 1024 cycles, assuming single cycle load, add, and store instructions.

Assuming the data type is 16-bits and quad 16-bit packed data instructions are available, the vector sum would require  $(4 \times 64)$  iterations = 256 cycles.

Further assuming an array processor of four PEs where each PE is capable of the packed data operations, then the function can be partitioned between the four PEs and run in parallel requiring  $(4 \times 16)$  iterations = 64 cycles.

Finally, assuming a VLIW processor such as the ManArray processor, a software pipeline technique can be used with the VLIWs to minimize the instructions issued per iteration such that  $(2 \times 16)$  iterations = 32 cycles are required. This represents a 32x improvement over the sequential implementation.

ManArray architecture allows a programmer or compiler to select the level of parallelism appropriate for the task at hand. This selectable parallelism includes packed data operations ( $4 \times 16$ -bits and  $8 \times 8$ -bits in one 64-bit operation on the Manta core), parallel array PEs (performance scales linearly with the addition of PEs), and instruction level parallelism (iVLIW concurrent store/load, ALU, MAU, and DSU instructions).

By use of the three levels of parallelism available on each core, including the use of single-cycle PE communications, scalable conditional execution, and background data streaming DMA, the following benchmarks, Fig. 39.55, can be obtained on the Manta 2 × 2 thread coprocessor, which can also function as subset array 1 × 1 and 1 × 2 array processors.

## Conclusions and Future Extensions

The pervasive use of processor IP in embedded SoC products for consumer applications requires a stable design point based on a scalable processor architecture to support future needs with a complete set of hardware and software development tools. The ManArray cores are highly scalable, using a single architecture definition that provides low power and high performance. Target SoC designs can be optimized to a product by choice of core type, 1 × 1, 1 × 2, 2 × 2, ... and by number of cores. The BOPS tools and SoC development process provides a fast path to delivering verified SoC products. Future plans include architectural extensions, representing a superset of the present design, which greatly improve performance in the intended applications.

## Acknowledgments

The author thanks Dr. Steve Walsh, Dr. Dave Strube, Dr. Sergei Larin, and Carl Lewis for their comments in preparing this paper. The author also thanks the BOPS, Inc. development team for their drive, excitement, and creative technical skills in developing the ManArray processor, tools, and their supporting functions, as well as for making BOPS, Inc. a fun place to work.

## 39.3 Digital Audio Processors for Personal Computer Systems

---

*Thomas C. Savell*

### Introduction

The audio subsystem of the personal computer (PC), once an almost unnecessary component, has become an integral part of the operating systems and applications software that run on them. The evolution of the PC itself has led to a complex audio system; requiring simultaneous playback and recording while applying advanced signal processing. The best PC audio systems employ one or more specialized digital audio processors to offload the main processor and guarantee artifact-free audio.

FIGURE 39.56 Simplified schematic of IBM-PC speaker circuit.

## Brief History and Evolution

The early PCs could only generate simple tones and beeps. In the early 1980s, the system designers of the original IBM-PC used the Intel 8253 digital timer to generate a series of pulses at a regular rate, usually a square wave within the audio range of less than 20 kHz. The output of this chip drove the base of a transistor to switch on and off a small speaker as shown in the schematic of Fig. 39.56. This simple, cost-effective solution effectively offloaded the 4.77 MHz Intel 8088 main processor from the task of generating a tone. The 8253 timer had three independent channels, and the system designers used channel 0 to keep track of the time of day and channel 1 to generate DRAM refresh cycles. Thus, the otherwise unused timer channel 2 provided an essentially cost-free audio processor.

Although the most common use of this primitive audio system was to alert the user to an event, clever programmers were able to play simple melodies using it. Eventually, they discovered how to use pulse-width modulation coupled with the reactance of the circuit to create a low-quality digital-to-analog converter (DAC), enabling the playback of digitally sampled waveforms. Audio created using this method, however, was very noisy and presented a significant load on the main processor.

Later in the 1980s, add-in cards appeared with an integrated music synthesizer capable of playing back polyphonic music. One such early card, the Adlib soundcard, used a form of music synthesis known as frequency modulation (FM) synthesis. As John Chowning described in 1973, FM synthesis creates complex sounds using simple sine waves to modulate the frequency of other sine waves [1]. The Adlib soundcard used the simple Yamaha OPL2 FM synthesis chip, which used only two sine waves per voice to synthesize complex waveforms. It could create satisfactory, yet unrealistic synthesis of natural musical instruments, as well as a limited spectrum of special sound effects.

The immensely popular Adlib-compatible SoundBlaster® (Creative Technology, Ltd.) was introduced in 1989 by Creative Labs. In addition to Adlib's FM synthesis capabilities, it added a simple method of playing and recording digital audio encoded as a pulse code modulated (PCM) stream. Perhaps as important to its success, Creative Labs provided software development support to computer game developers free of charge, resulting in widespread software support for the SoundBlaster. The new PCM audio capabilities added the possibility of using any sound as an effect in a game. This important enhancement led to the requirement for PCM audio on all future soundcards.

PCM audio was transferred to and from the soundcard using the Intel 8237 direct memory access (DMA) controller on the main system motherboard, as shown in Fig 39.57. The early SoundBlaster cards could only transfer 8-bit PCM audio, resulting in a dynamic range of only about 48 dB. Later, the SoundBlaster 16 card added support for 16-bit PCM audio with a much better 96 dB dynamic range, using the 16-bit DMA controller of the newer computers.

As time progressed, wavetable synthesis replaced FM synthesis. Wavetable synthesis is capable of synthesizing musical instrument sounds that are nearly indistinguishable from real instruments except to the trained ear. It works by triggering digital recordings of notes played on actual instruments in response to keys played on a keyboard. To synthesize the sound of a piano, the wavetable synthesizer stores a series of digital recordings of a real piano, and plays them back on command. Although the sound

FIGURE 39.57 Slave DMA using the Intel 8237 DMA controller.

quality is far superior to that produced by the earlier FM soundcards, the high price of the early wavetable implementations was prohibitive to widespread market acceptance. The normal market forces eventually drove the price down, and soundcards that could only produce FM became obsolete.

An important force in the evolution of both graphics and audio in PCs is the computer game. The continually increasing realism of game graphics, with players able to navigate through virtual three-dimensional (3-D) environments, created demand for more realistic game audio. This demand led to the advent of 3-D positional audio, allowing accurate placement of sound sources within a virtual 3-D environment rendered on stereo speaker systems. It ultimately led to full environmental simulation, with the ability to simulate a sound in various environments such as a carpeted room, a large hall, and even underwater.

A 3-D audio experience is difficult to achieve using two speakers. The smallest head movement of the listener can often destroy the effect. Movie theaters overcame this problem using multi-speaker sound systems that placed speakers to the sides and rear of the listener. It eventually migrated to home theater systems and finally to computer gaming systems.

The best systems now have a 5.1 channel audio system such as Dolby Digital<sup>®</sup> (Dolby Laboratories) coupled to a 3-D rendering soundcard with environmental simulation capabilities. These systems provide an audio experience that immerses the listener in the environment, helping to create the illusion of realism.

## Today's System Requirements

Today's systems use a layered approach, with applications able to produce audio with little or no knowledge of the underlying hardware. Layers of software hide most of the hardware-specific features. Applications use a query mechanism to determine which features are present, enabling considerable freedom in hardware implementation. Many features of the audio system can also be rendered in software, guaranteeing the application developer a minimum feature set and performance level, nearly independent of the installed hardware. Thus, today's architecture is scalable, allowing the user to choose hardware acceleration for better performance, or software emulation for lowest cost.

Audio on a PC can be divided into several general categories, including operating system interaction, music, gaming, and voice applications. Each of these categories has unique properties, but with proper architecture, a single solution can apply to all of them.

Operating system interaction is generally limited to alerting the user to various events, such as starting up the system, selecting an invalid choice, or receiving new e-mail messages. In the early days of PCs, simple beeps communicated all of these items. Now, these events can be associated with any sound recording, and each association can be unique. Whenever an event occurs, the operating system instructs the soundcard to play back the associated sound recording.

Music applications are much more complex. The soundcard is required to provide a wavetable synthesizer responsive to musical instrument digital interface (MIDI) commands [2]. In addition, it must be able to play back streaming audio in various formats including PCM, MP3 (MPEG-1 Layer 3 Audio), and Dolby Digital (5.1-channel home theater audio). Finally, it must be capable of recording in CD quality, or 16-bit stereo PCM at a sample rate of 44.1 kHz. Each of these major features must be independent and operate simultaneously.

Gaming applications often require a very sophisticated audio system. Many games place sound sources in a virtual 3-D space. The user expects the system to render this 3-D space on any number of speaker systems, ranging from headphones to stereo speakers to 5.1-channel home theater systems. The virtual 3-D space includes not only positional cues, but environmental cues as well. A game player must be able to move a character from an open outdoor space into a small wooden room and seamlessly hear the environmental cues such as the short reverberation of a small room. Objects in motion produce the well-known Doppler effect increasing the apparent frequencies of the sounds emitted by objects moving toward the listener and decreasing those of objects moving away [3]. The most sophisticated audio systems can reproduce the Doppler effect on both the objects in motion and their reflections.

Voice applications, although not new, have yet to gain the widespread availability of operating system, music, and gaming applications. Because of the large memory requirements, voice recognition algorithms are better suited to the main processor and use limited, if any, preprocessing by the soundcard in the record path. Moreover, automatic voice recognition is still unreliable, except when restricted to isolated words from a limited vocabulary. Another class of voice applications is voice communication. The emergence of the Internet has brought with it the promise of low-cost worldwide telephony. The implementation of Internet telephony requires sophisticated noise-cancellation and echo-cancellation algorithms that are often best suited to run on the sound card.

## Hardware Architecture

The hardware of the PC audio system satisfies these system requirements with a simple model. Much like the entire computer system, it consists of three major subsystems: storage, processing, and input/output (I/O). The storage subsystem can include local memory, system memory, and disk storage such as hard drives and compact discs, but the audio processor does not usually interface directly with a disk storage device. The processing subsystem includes both the main processor and a processor located on the soundcard to provide hardware acceleration. The I/O subsystem usually consists of an analog interface such as the Audio CODEC '97 (AC97) standardized DAC and ADC. In addition, digital interfaces such as the Sony/Philips digital interface (S/PDIF) are often included. By dividing the audio system into three logical blocks, the system designer faces the simplified task of creating each block while optimizing the interfaces between them. The audio processor designer is concerned with the processing capabilities of the chip as well as the I/O system interface and the memory bus interface.

## Memory

Local memory connects directly to the audio processor. This includes both ROM and RAM of various types located on the soundcard, generally used to store wavetables for wavetable synthesis and digital delay lines for environmental simulation algorithms. Local memory provides the highest system performance for wavetable synthesis and environmental simulation since it need not share bandwidth with the main processor and other hardware such as disk, video, and networking interfaces; however, local memory costs money, and cost is often a major consideration in market driven engineering. The emergence of the RAM-less soundcard, which stores audio in system memory rather than local memory, is primarily due to the need to decrease costs.

Creation of a RAM-less soundcard requires that system memory store most audio data. A relatively small amount of RAM is still required on the audio processor chip for algorithms that require high-bandwidth access to memory. System memory connects to the main processor of the PC through bus bridging logic, and stores the programs and data that make up the operating system and application programs. When the audio processor requires access to system memory, it generates a memory access request on the add-in card bus. If the main processor or any other device is currently accessing system memory, the audio processor must wait.

The early PCs used a relatively low-performance add-in card bus known as ISA, or Industry Standard Architecture. The soundcards that plugged into the ISA bus accessed system memory through the Intel 8237 DMA controller. The 8237 DMA controller contains auto-incrementing address registers and uses

a request/acknowledge handshake protocol to communicate with requesting devices. Because it generates the memory address and controls the direction of the transfer, it is the bus master.

The soundcard operates as a slave to the 8237 DMA controller, which is limited to a single address per requesting device and only performs single-word transfers. In addition, certain channels of the DMA controller are limited to 8-bit transfers, and others can perform 16-bit transfers. The soundcards that could support 16-bit samples had to allocate two DMA channels, one for 8-bit audio, and the other for 16-bit audio. These limitations were acceptable for soundcards that did not require system memory to store wavetables or digital delay lines. These soundcards either had local memory or supported only FM synthesis. They used this slave DMA system for streaming audio, which is generally a recording of music or other sounds.

Applications such as games that create virtual environments generate a continuous stream of audio; however, it is not as simple as playing a static recording. The content of the stream changes based on the actions of the user. As the user interacts with the virtual environment, virtual objects move in relation to the listener, and the sounds they produce may change over time. Each sound an object can make is usually stored as a short recording. The process of creating the continuous audio stream that represents the virtual environment entails summing all the sound sources within the listener's range. The use of slave DMA for these types of applications requires software to create the continuous audio stream. The software for positioning objects in a virtual 3-D space is nontrivial, so the applications generally simplify the problem when using an ISA bus soundcard.

A better solution is to place a powerful DMA controller directly on the soundcard. When the soundcard contains a DMA controller, it becomes the bus master, and can overcome the limitations of the 8237A DMA controller. For example, it can have a large number of independent address generators, enabling both wavetable synthesis and 3-D hardware acceleration for audio stored in system memory. A soundcard that supports wavetable synthesis or environmental simulation using system memory must have a bus mastering DMA controller.

The audio processor designer must consider the memory bandwidth requirements, bus bandwidth availability, and bus transfer latency to determine whether bus-mastering DMA is a viable design choice. Given the number of simultaneous audio channels, the sample rate of each channel, and the number of bytes in each sample, the designer can easily calculate the memory bandwidth requirements. For example, a processor supporting 64 audio channels with a sample rate of 48 kHz and 2 bytes (16-bit) per sample requires 6,144,000 bytes/s. The available bus bandwidth must be greater than that for it to be a viable design choice.

Calculating available bus bandwidth is much more difficult. It depends on the bus bandwidth capability, the reserved bandwidth for other transactions on the bus, and any transaction overhead not accounted for in the bus bandwidth capability. The bus bandwidth capability is straightforward to calculate. The simplest method is to use the data transfer rate times the bus width. For example, a 33.33 MHz PCI bus is 4-bytes wide, leading to a bus bandwidth capability of approximately 133 Mbytes/s.

This, however, ignores the per-transaction overhead required to arbitrate for the bus and begin a bus cycle. For example, a transaction with a single data transfer typically requires about five clocks to complete. If all transactions are single data transfers, the available bus bandwidth is only about 27 Mbytes/s. Burst data transfers reduce the effect of the per-transaction overhead. If 16 data transfers occur in a burst transaction that requires 20 clocks to complete, the available bus bandwidth increases to about 106 Mbytes/s. Computers represent a waveform as an array of numeric values in memory, so audio is well suited to burst transactions. Even so, the available bandwidth is generally much less than these theoretical amounts due to system overhead such as DRAM refresh and CPU cache access to main memory.

The least quantified of all the factors is the reserved bandwidth for other transactions on the bus. This includes bandwidth required by other devices on the bus and the bandwidth needed to program the audio processor itself. The bandwidth required by other devices is unknown since it depends on the add-in cards in each user's individual system. Even the bandwidth needed to program the audio processor is difficult to quantify, since it depends on the peculiarities of the software device driver, the operating

system, and the application programs that ultimately generate the audio. Any method of determining the amount to reserve seems entirely arbitrary since variable quantities determine the optimal amount.

Instead of relying on an arbitrary decision based on a guess, one could make measurements of the bus bandwidth used by other devices on the bus in a typical system. Although measurements are by no means a guarantee that any particular system will provide enough bandwidth, one can assume that a similarly equipped typical system will provide a similar amount of bandwidth. The designer can also estimate the bandwidth needed to program the audio processor. Clearly, there is a known overhead to start up a single channel of audio. The bandwidth needed to program the processor includes at least this overhead multiplied by the number of channels. There is additional bandwidth required to maintain a channel of audio. For example, if an object in a virtual 3-D environment moves, the processor must reprogram the portion of the audio processor that positions the object. Numerous other facets are part of this problem, and the audio processor designer should consult with the software engineers to obtain a reasonable estimate of the true bandwidth needed to program the processor.

Given estimates of the memory bandwidth required for audio data transfer and the available bus bandwidth, the designer can determine the limits at which the system will fail. Based on this information, the processor implementation or the target system requirements may need to change.

### Mixing Multiple Sources

The basic system requirements and user expectations require that the sound system sum together multiple audio sources with an independent level control for each source. The audio term for this summation process is mixing. The operating system usually provides software for a simple audio mixer that enables the user to control the relative levels of the compact disc, line in, microphone, and various internally generated sound sources. The system often uses a small digitally programmable analog mixer for the analog sources such as line in and microphone; however, the wavetable synthesizer and 3-D gaming applications require mixing a relatively large number of channels under real-time software control, as shown in Fig. 39.58. These applications use an all-digital mixer due to the large number of channels.

On the surface, a digital audio mixer sounds like a trivial exercise in multiply-accumulate operations; however, in order to sum together sampled waveforms, they must all have the exact same sample rate. Consider two sampled waveforms, each 1-second in length. The first has a sample rate of 48 kHz and the second has a sample rate of 24 kHz. Although they both represent 1-second of time, the first waveform consists of 48000 points, and the second waveform consists of 24000 points. In order to mix them, they must have the same number of points representing the same amount of time.

The solution is to use a sample rate converter before the mixer. The sample rate converter has a fixed output sampling-rate and a variable input sampling-rate. This allows the digital mixer to operate on multiple waveforms of different sample rates. The software programs the sample rate converter with the ratio of input to output, also known as the pitch. Pitch is a musical term that relates to the frequency of

FIGURE 39.58 Mixing a large number of sound sources under software control.

a note. A higher pitch corresponds to a higher frequency. The sample rate converter performs a double duty as a pitch shifter, enabling a single recorded note to reproduce many notes on the instrument. This provides effective data compression by reducing the number of recordings required to reproduce the sound of an instrument. In addition, it enables a variety of musical effects such as vibrato, pitch bend, and portamento. Finally, the pitch shifting effect of the sample rate converter emulates the Doppler effect needed by 3-D environmental audio. Thus, the sample rate converter is a fundamental building block used by nearly all facets of the digital audio system in the PC.

### Sample Rate Converters

Sample rate converters come in several varieties, offering different levels of conversion quality. Higher quality conversion requires more computation, and comes at a correspondingly higher cost. Drop-sample converters require almost no computation to implement and offer the lowest quality. Linear interpolation converters require more computation and offer reasonably good quality, especially for downward pitch shift. Multi-point interpolation converters require the most computation and memory bandwidth, but provide the highest quality; however, there can be considerable variation in the quality of multi-point interpolation converters.

To understand sample rate conversion, it is necessary to understand discrete-time sampling theory as described by Nyquist and Shannon [4,5]. In order to sample a signal properly, the sample rate must be at least twice the highest frequency component in the signal. The Nyquist frequency is one-half the sample rate, and indicates the highest frequency component that a particular sample rate can represent. Sampling of frequency components above the Nyquist frequency results in aliases in the sampled waveform that are not present in the original signal. Sampling systems such as digital recorders typically use a low-pass filter at the input of the analog to digital converter to avoid aliasing.

The relationship between the frequencies of the aliases and those of the original out-of-band signal is simple. A sine wave at a frequency  $F$  between the Nyquist,  $N$ , and the sample rate,  $2N$ , will alias to a frequency of  $2N - F$ . Consider a signal consisting of two sine waves, one at 28,000 Hz and another at 45,000 Hz. Using a sample rate of 48,000 Hz, the resulting sampled waveform would consist of an alias of the 28,000 Hz sine wave at 20,000 Hz, and an alias of the 45,000 Hz sine wave at 3000 Hz. The sampling process has lost the original signal and created a new signal. Figure 39.59 illustrates the frequency domain spectrum of the original signal and the aliases created by sampling at too low of a rate.

In-band signals also create a type of alias, known as an image. Images and aliases are the converse of one another. A properly sampled sine wave at frequency  $F$  has an image at  $2N - F$ . It also has images at  $2N + F$ ,  $4N - F$ ,  $4N + F$ , and so on up to infinity. Consider a signal consisting of two sine waves, one at 20,000 Hz, and the other at 3000 Hz. The spectrum of this signal is identical to the one generated by sampling sine waves at 28,000 Hz and 45,000 Hz, as shown in Fig. 39.60. One cannot determine by inspection whether the sampled waveform represents true in-band signals, aliases of out-of-band signals, or some combination of the two.

The images are quite important when performing sample rate conversion. At the original sample rate, the images fold back into the passband at exactly the same frequencies of the in-band signal; however, changing the sample rate causes the images to fold back onto different frequencies in the passband, creating

FIGURE 39.59 Aliasing caused by sampling at too low a rate.

FIGURE 39.60 Images above the Nyquist frequency.

FIGURE 39.61 Aliases and images from sample rate conversion.

FIGURE 39.62 Simple time series that deceptively appears to represent a square wave.

aliasing distortion. Figure 39.61 illustrates the effect of changing the sample rate on the images of the in-band signal. The sample rate converter must remove these images in order to obtain high quality conversion.

It is easy to deceive a naïve observer by a sampled waveform. Consider the following time series:

$$0.707 \quad 0.707 \quad -0.707 \quad -0.707 \quad 0.707 \quad 0.707 \quad -0.707 \quad -0.707$$

As shown in Fig. 39.62, the waveform might appear to represent a square wave of peak magnitude 0.707 at exactly one-half the Nyquist frequency. This is incorrect. A true square wave consists of an infinite

**FIGURE 39.63** True signal represented by simple time series.

series of frequencies at  $F, 3F, 5F, 7F, \dots, (2n + 1)F$ , where  $n$  goes to infinity. However, the first partial,  $3F$ , is above the Nyquist frequency. Therefore, this must represent a sine wave. However, its peak magnitude is not 0.707, but is instead equal to 1.0, as shown in Fig. 39.63.

The ultimate goal of sample rate conversion is to create a new time series at a new sample rate that correctly represents the true original signal. An ideal sample rate converter creates a time series that is indistinguishable from that derived by resampling the original signal. Because it requires an infinite-length time series, no real sample rate converter achieves this ideal; however, it is possible to come arbitrarily close, given enough computation.

To create a new time series at a new sample rate, it is necessary to interpolate values between the input samples. To do this, the sample rate converter maintains an output phase that represents the time index of the output samples relative to the input samples. It maintains the phase by accumulating the pitch. To double the number of output samples, use a pitch of 0.5. On each output sample period, the sample rate converter adds the pitch to the phase accumulator. If the initial value for the phase accumulator is 0.0, the resulting phase over time will be the following:

$$0.0 \quad 0.5 \quad 1.0 \quad 1.5 \quad 2.0 \quad 2.5 \quad 3.0 \quad 3.5 \quad \dots$$

The integer portion of the phase accumulator is the address of the input sample(s) to convert, and the fractional portion is the interpolation factor that indicates how far between input samples to generate an output sample. In the previous example phase accumulator, the fraction alternates between 0.0 and 0.5. The fraction of 0.5 indicates that the output sample should be halfway between two input samples. This definition is somewhat imprecise when using multi-point interpolation, but in a logical sense, it still applies.

Usually, a hardware implementation of a sample rate converter uses a fixed-point representation for both the pitch and the phase accumulator. The fixed-point representation enables very simple extraction of both the integer and fractional portions, and minimizes the size of the adder used to maintain the phase accumulator. The number of integer bits in the phase accumulator limits the amount of memory addressable by the sample rate converter. Integer widths of at least 24-bit are common.

The number of integer bits required for the pitch is much smaller than the number required for the phase accumulator. Upward pitch shifting, which is equivalent to conversion to a lower sample rate requires filtering to a lower cutoff frequency than downward pitch shifting. Often, much more distortion occurs when performing upward pitch shifting. The additional filtering and distortion of upward pitch

**FIGURE 39.64** Address generator for drop-sample interpolator.

shifting place limits on its usefulness. Upward pitch shifts of more than three octaves extend into the realm of special effects. When viewed as pure sample rate conversion, a three octave upward shift is equivalent to converting from a 48 to a 6 kHz sample rate. The lowest sample rate commonly used for audio is 8 kHz. Thus, it is usually acceptable to limit the number of integer bits in the pitch to two or three, providing a 2- to 3-octave upward shift capability.

The magnitude of the least-significant bit (LSB) of the pitch fraction, indicated by the number of fractional bits, determines the frequency ratio resolution. For example, the LSB of a 12-bit fraction is equal to  $1/4096$ . The perceptual unit of measurement for pitch is cents, or  $1/100$  of a semitone. This is equal to a ratio of  $2^{1/1200}$  or 1.00058. The just-noticeable-difference (JND) for pitch is around 8 cents, or 1.0046, indicating the acceptable frequency error [3]. Given this, it would seem that a 12-bit fraction is sufficient and even generous, since the ratio  $4097/4096$  is equal to 1.00024, much better than the JND of 1.0046; however, an effective method of data compression for sampled waveforms is to lower the sample rate such that the highest frequency of interest in the signal is near the Nyquist frequency of the lower sample rate. Consider a sine wave consisting of only four points. When played back at unity pitch on a system with a 48 kHz output rate, the frequency of the sine wave is 12 kHz. A more useful frequency in the human hearing range is 125 Hz. To generate this, the pitch must be 0.0104. The closest available ratio with 12-bits of fraction is 0.0105, generating a frequency ratio error of 1.0078, more than the JND. In practice, a minimum of 14-bits of fraction is required for acceptable results across a wide range of input rates and pitches. Ideally, the number of fractional bits in both the phase accumulator and the pitch should match.

### ***Drop-Sample Interpolation***

Drop-sample interpolation, sometimes called nearest-neighbor interpolation, is the simplest type of sample rate converter. The drop-sample interpolator simply rounds the phase accumulator to the nearest integer and chooses the input sample at the resulting integer address to be the output sample. This requires very little hardware as illustrated in Fig. 39.64. It also requires access to only a single input sample to create an output sample, whereas all other forms of sample rate conversion require access to more than one input sample to create a single output sample, but the result can be very poor quality.

### ***Linear Interpolation***

Linear interpolation may be the most common type of sample rate converter. The quality is good, and the cost is relatively low. It requires access to two input samples to create a single output sample. The computational cost is one multiply, one add, and one subtract. It is possible to implement the entire linear interpolator with a single adder, using a shift and add approach to the multiply. This is feasible as long as the clock rate is high enough to support the desired channel count and fractional accuracy. The following equation describes the linear interpolation process, where  $x$  is the input waveform,  $y$  is the output sample,  $n$  is the integer part of the phase accumulator, and  $f$  is the fractional part of the phase accumulator:

$$y = x_n + f \times (x_{n+1} - x_n)$$

One can clearly see that when the fraction is zero, the output sample is equal to the input sample at the address indicated by the phase accumulator. As the fraction approaches 1.0, the output follows a

FIGURE 39.65 Linear interpolation of simple time series.

straight line drawn between adjacent input samples. Figure 39.65 illustrates the result of linearly interpolating a sine wave. The quality is quite good if the frequency of the sine wave is low relative to the Nyquist, but the quality deteriorates significantly as the frequency approaches the Nyquist. The linear interpolator has a low pass filtering effect that becomes noticeable above one half the Nyquist frequency. In addition, the alias rejection is not very good for the images of signals above one-half the Nyquist frequency. Thus, linear interpolation affects the quality in both the frequency response and aliasing distortion for high frequencies.

### Multi-Point Interpolation

Multi-point interpolation can produce much better quality than linear interpolation in both frequency response and aliasing distortion. The ideal interpolator has a frequency response that is perfectly flat within the passband and attenuates all other frequencies to zero. Convolution of the input waveform with a *sinc* function that runs from negative to positive infinite time produces such a frequency response. Unfortunately, we must work within the limits of finite time to build a real interpolator. In 1984, Gossett and Smith showed an efficient way to use a finite-length, windowed *sinc* function as a finite-impulse-response (FIR) filter for sample rate conversion over a wide range of pitches [6]. The definition of the *sinc* function is  $\text{sinc}(t)$ .

The convolution equation is  $\sum_{n=0}^{N-1} a_n x_{T-n}$ , where  $x$  is the input waveform and  $a$  is a selected set of coefficients, possibly a windowed *sinc* function.

The hardware implementation of a Gossett-Smith sample rate converter consists of a read-only-memory (ROM) containing the filter coefficients, a linear interpolator to increase the resolution of the filter coefficient set, and a multiply-accumulate unit to perform the convolution. Figure 39.66 shows a block diagram of a typical Gossett-Smith interpolation system. Because the *sinc* function and other low-pass FIR filters are symmetric about their centers, it is only necessary to store half of the points in the ROM. Simple address mirroring makes the ROM appear to contain all the points.

Perceived quality is often more important than measured quality. That is, it is more important to sound good to humans than to measure low distortion on laboratory instruments. Using a perceptual approach, one can design sample-rate conversion filters that sound better [7]. For example, humans cannot hear above 20 kHz, yet a 48 kHz sample-rate can represent frequencies up to 24 kHz. A filter that allows distortion within this guardband between 20 and 24 kHz can achieve better quality within the audible range of 20 Hz to 20 kHz.

FIGURE 39.66 Gossett–Smith interpolator block diagram.

### Address Looping

The phase accumulator of the sample rate converter must have some provision for looping back to a lower address. Clearly, it cannot continue to increment to infinity. The finite number of bits used to represent the integer part of the phase precludes that possibility. In addition, it is not useful simply to rely on binary wraparound of the address from its maximum value back to zero. This would imply all channels of sample rate conversion are reading from the same input waveform. At a minimum, the phase accumulator contains a loop address and loop size for each channel. When the value of the phase accumulator crosses the loop address, it loops back by the loop size and continues from the beginning of the loop. This enables both streaming audio and wavetable synthesis.

Many natural musical instrument sounds can be characterized by an attack phase, sustain phase, and release phase. The attack phase is often a primary cue to the listener as to the identity of the instrument. Usually, it consists of a rapidly changing and nonrepeating waveform. Conversely, the sustain phase is often a steady state that can be easily described by a repeating waveform. This is also true of the release phase. During sustain and release phases, the phase accumulator can loop to create the repeating waveform, saving considerable memory. Besides, the length of the sustain phase is usually unknown because it is controlled by the length of time the musician presses the key.

When streaming audio, the software fills a circular buffer with a continuous waveform to play. The phase accumulator loops at the boundaries of the circular buffer and plays the stream. The software must be careful not to overwrite audio that the sample rate converter has not yet played.

### Envelopes and Modulation

It is often necessary to control various aspects of a sound, such as pitch, amplitude, and filter cutoff frequency with time-varying signals called envelopes. The audio system may use these envelopes to simulate the changes in sound that occur when a 3-D sound source moves, or as an integral part of the music synthesis process.

A typical music synthesizer envelope generator has four segments designated attack, decay, sustain, and release (ADSR) as shown in Fig. 39.67. These four segments are a reasonable approximation of the amplitude envelopes of real musical instruments. The first two segments are attack and decay, and are usually a fixed duration. During these segments, the sound is changing rapidly, often containing transients and wideband noise corresponding to the initial strike of a drum, or pluck of a string. The decay segment leads to the sustain segment, a variable duration, steady state corresponding to the portion of a note that is held for a length of time. The final segment, release, occurs after the musician releases the note.

FIGURE 39.67 ADSR envelope.

FIGURE 39.68 Frequency response of lowpass resonant filter.

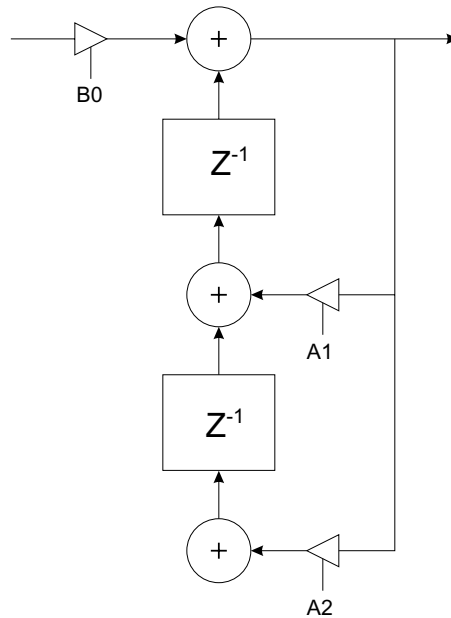

Envelopes used for 3-D sound positioning do not have such a clearly defined set of segments. Instead, 3-D positional audio is often interactive. It is not possible to predict the movements of the user in advance. For these applications, a fixed segment envelope generator may not be useful. A more useful method is to set a target value to which the hardware will smoothly ramp from the current value, enabling the software to be event driven.

In addition to the ADSR envelopes used for music synthesis and ramp-to-target envelopes used for 3-D positioning, a complete system requires a low frequency oscillator, or LFO. The system uses the LFO to create slowly modulating effects such as vibrato and tremolo.

The final control signal is usually a weighted sum of one or more ADSR envelopes and one or more LFOs. The scaling applied to the envelopes and LFOs are often time varying signals as well. This enables, for example, vibrato to slowly increase during the sustain segment of a synthesized violin sound. It is important to note that the scaling and summation occurs in perceptual units such as decibels and pitch cents, not physical units such as voltage and Hertz. This means that the result of the summation goes through a perceptual to physical units transform function before it is useful to the destination process. Example transform functions are  $10^{x/20}$  for decibels and  $2^{x/1200}$  for pitch cents.

### Filters

The most common filters in music synthesis are low-pass resonators. The frequency response of these filters is generally flat from 0 Hz up, with a characteristic resonance just below the low-pass cutoff frequency, as shown in Fig. 39.68. It is most common to build these filters with an infinite impulse response, or IIR structure, such as that illustrated in Fig. 39.69. The software specifies the cutoff frequency and resonant

**FIGURE 39.69** Two-pole IIR filter block diagram.

gain of the filter. It is possible to sweep these parameters in real time, so it is important to ensure filter stability under time-varying conditions. Stability criteria are outside the scope of this discussion, but it is not difficult to drive IIR filters to instability when varying coefficients in the presence of an input signal.

Three-dimensional positional audio and environmental simulation also demand the use of filters; however, low-pass resonators are not the ideal choice. The head-related transfer function (HRTF) describes the filtering performed by the shape of the human head, ear lobes, and ear canal [8]. In addition to loudness and inter-aural time delay, the brain uses cues provided by this filtering to determine the position of sound emitting objects. The most common implementation of an HRTF uses a FIR structure such as the Gossett–Smith interpolator filters; however, both the impulse response and the usage of HRTF filters are much different from that of Gossett–Smith interpolator filters.

Obstruction and occlusion are other filtering effects that occur when sound sources move in relation to other objects. For example, obstruction is the effect caused by an obstacle between the listener and a sound source in the same room. This applies a low-pass filtering effect on the direct sound, but not on the reverberation. In contrast, occlusion is the effect caused by a sound source located outside the same room as the listener. This applies a low-pass filtering effect on both the direct sound and the reverberation. Low-pass IIR filters are appropriate for these applications, although resonance is neither needed nor desired. The system can simulate these effects with the low-pass resonators used for music synthesis, but the typical  $-12$  dB per octave attenuation slope is generally too steep. A gentle  $-3$  or  $-6$  dB per octave slope is more appropriate.

The audio system of the PC also performs the role of a typical component stereo system, playing prerecorded music from CD or other sources. Thus, the software distributed with soundcards often includes equalization, such as tone controls and graphic equalizers. Simple tone controls, such as bass and treble, often use shelving filters as shown in Fig. 39.70. Graphic equalizers can use a bank of either band-pass filters or parametric equalizers into a summation matrix.

It is the designer’s choice whether to implement the filter types required by the digital audio system of the PC in hardware or software. The system often includes a programmable digital signal processor (DSP), enabling a software implementation. As the required filter count increases, it often becomes more

FIGURE 39.70 Bass and treble tone control filter shapes.

FIGURE 39.71 Delay line with feedback implementing a repeating echo.

efficient to implement them in hardware, especially if multiple filter types can use the same filter structure. Moreover, while FIR and IIR filter structures are quite different, a clever designer may find opportunities to reuse the same basic arithmetic hardware for both. For example, both structures can use a multiply-accumulate arithmetic unit. If each structure requires only one-half the available bandwidth, they can share the same math unit by time-division multiplexing the inputs. Because arithmetic units are generally costly, techniques such as this can significantly reduce the system cost.

### Effects

Music synthesis applications use effects such as reverb, delay, and chorus as sweeteners. They are not required, but tend to make the music sound more pleasing. In contrast, 3-D positional and environmental simulation applications require delay and reverb to achieve realistic results. The fundamental unit of many digital audio effects is the digital delay line. A simple echo effect may use only one delay line, whereas a reverb effect may use 20 or more delay lines. Even modulation effects such as chorus and flange use delay lines. Digital delay lines require one memory location per sample period of delay, an address generator, and arithmetic units to scale the inputs and outputs of the delay line. Figure 39.71 illustrates a typical delay line implementing a repeating echo through the use of feedback.

An obvious method of implementing a set of delay lines is to allocate memory buffers for each delay line and maintain circular address counters for each indicating the read and write locations. The delay time is equal to the difference between the read and write pointers, modulo buffer size. Maintaining circular address counters can easily use a large percentage of the total instruction bandwidth of a DSP. Many DSP implementations provide special instructions or self-maintaining address registers to reduce the load on the DSP.

To provide maximum flexibility in implementation of effects, most PC audio systems include a programmable DSP. The designer may choose to purchase an off-the-shelf DSP, either as a separate chip or

as a core to integrate onto the same silicon as the rest of the solution. An alternative is to design a custom DSP to fit the particular needs of the system. The advantages of a custom design are the freedom to add or reduce features, easier integration, and often a lower cost. The disadvantages include possible increased time to market and the lack of standard development tools such as compilers.

## Digital Audio I/O

Eventually, the system must present the processed audio to the listener. A DAC outputs an analog voltage proportional to the value of a word of digital data written to it. The analog output voltage drives the input to an amplifier, and eventually the sound comes from a speaker. A DAC generally accepts serial digital data rather than parallel, so the processor must first perform a parallel to serial conversion. A DAC is usually stereo, so it accepts a time-multiplexed serial stream alternating between left and right channels. The serial protocols are usually synchronous, and come in a few varieties. The most common in use today are AC97 and I<sup>2</sup>S, both of which are easily available and inexpensive.

In addition to audio output, the system must be capable of recording audio from microphones and external line-level devices such as CD players and tape decks. An ADC outputs digital data proportional to the magnitude of an analog voltage presented to its input. As in the case of a DAC, an ADC usually generates serial digital data consisting of time-multiplexed left and right channel data. The AC97 standard developed by Intel specifies a monolithic CODEC containing both a stereo DAC and a stereo ADC [9]. An AC97 implementation can sometimes be the most cost effective. Generally, devices that use the I<sup>2</sup>S protocol are of a higher quality but do not include both a stereo ADC and a stereo DAC.

For digital transmission of audio between the computer and an external device, the Sony/Philips Digital Interface (S/PDIF) protocol as specified in IEC-958 is the connection of choice [10]. It is a robust protocol intended for transmission over a 75-ohm coaxial cable. It uses Manchester encoding for the data, thus embedding a clock and making it insensitive to logical inversion. The ground is isolated, preventing hum and noise due to ground loops. Many consumer stereo components now have S/PDIF or its optical counterpart TOS-Link as integral connections.

## Emerging Applications

The basic digital audio system of a PC operates in stereo at 44.1 or 48 kHz sample rate with 16 bits of resolution. The current trend of audiophile systems is moving to a multichannel 96 kHz sample rate with 24 bits of resolution. Often, these audiophile trends trickle down to the mainstream systems as the cost comes down and demand rises. From a strict psycho-acoustical point of view, there is little value in increasing the sample rate to 96 kHz, since the range of human hearing is generally restricted to 20–20 kHz. In addition, a 96-kHz waveform requires twice the storage and twice the computation of the equivalent waveform at 48 kHz; however, there is some benefit to processing audio at 96 kHz, primarily in the response of filters over the human hearing range. It is easy to trade channel count for the higher sample rate. A system that can process 128 channels at 48 kHz can only process 64 channels at 96 kHz. The designer should weigh the cost versus the benefit, but often the market drives the decision. If the market demands 96 kHz, the designer must deliver it.

There is, however, a very real benefit to using 24 bits of resolution. The maximum dynamic range of human hearing is around 130–140 dB. The 96 dB dynamic range of 16-bit resolution is insufficient to cover this range. A 24-bit waveform has a dynamic range of 144 dB, more than sufficient to cover the range of human hearing. The design impact of 24 bits versus 16 bits is additional storage and larger arithmetic units, resulting in higher cost.

Likewise, there is a real benefit to multichannel audio beyond stereo. A real environment produces sounds from all directions instead of than only two points as in a stereo speaker system. But the processor should still support stereo as a minimum baseline system, since the majority of audio systems are stereo. To achieve this, the processor must have more than two separate outputs and be capable of sending different audio to the multiple outputs.

Data rate reduction is another important trend in digital audio processing. The majority of the popular techniques in use, including Dolby Digital and MP3, process the signal in the frequency domain.

FIGURE 39.72 Audio processor block diagram.

They employ a perceptual model that attempts to determine which frequency components are not perceivable by the human hearing system. By removing those components, the encoding process can reduce the amount of data required to represent the signal. For example, the MP3 encoding process achieves about a 10:1 compression ratio while maintaining a quality level high enough to satisfy most people.

## Conclusion

A digital audio processor for PCs consists of only a few components: a memory and host interface coupled to sample rate converters, filters, envelope generators, a mixer, and a programmable DSP. These components, as illustrated in Fig. 39.72, interact in various ways to become a variable-rate playback engine, a wavetable synthesizer, a 3-D positional audio processor, and an environmental audio simulator.

However, a digital audio system consists of both hardware and software. Given the wide range of possibilities, the designer has considerable freedom in choosing an implementation to meet particular market needs and price points. To meet the lowest price point, the designer chooses software implementations whenever possible. To achieve the highest performance, the designer chooses hardware; however, a hardware implementation may limit the flexibility of the end system. The task of partitioning the system into hardware and software components is one of the greatest hurdles to overcome. It requires a coordinated effort of strategic marketing with hardware and software engineering early in the design process. A proprietary chip is expensive to design and can take a long time from concept to production. The early involvement of strategic marketing and software engineering helps ensure the success of any new hardware design.

The customer purchases an audio system, not a chip. Thus, the designer must be aware of, yet look beyond the technical aspects of digital audio processors to create a system that provides the proper functionality at the right price.

## 39.4 Modern Approximation Iterative Algorithms and Their Applications in Computer Engineering

---

*Sadiq M. Sait and Habib Youssef*

### Introduction

This chapter section discusses one class of combinatorial optimization algorithms: approximation iterative algorithms. We shall limit ourselves to four of these algorithms, which are, in order of their popularity among the engineering community: (1) simulated annealing (SA), (2) genetic algorithm (GA), (3) tabu search (TS), and (4) simulated evolution (SimE).

GA and SimE are evolutionary algorithms, a term used to refer to any probabilistic algorithm whose design is inspired by evolutionary mechanisms found in biological species. Evolutionary algorithms, SA and TS have been found very effective and robust in solving numerous problems from a wide range of application domains. Furthermore, they are even suitable for ill-posed problems where some of the parameters are not known beforehand. These properties are lacking in all traditional optimization techniques. The four algorithms share the following properties:

1. They are approximation algorithms, i.e., they do not guarantee finding an optimal solution. Actually, they are blind, in that they do not know when they reached an optimal solution. Therefore, they must be told when to stop.
2. They are neighborhood search algorithms, which start from one suboptimal solution (or a population of solutions) and perform a partial search of the solution space for better solutions.
3. They are all “general.” They are not problem-specific and, practically, they can be tailored to solve any combinatorial optimization problem.
4. They all strive to exploit domain specific heuristic knowledge to bias the search toward “good” solution subspace. The quality of subspace searched depends to a large extent on the amount of heuristic knowledge used.
5. They are easy to implement. All that is required is to have a suitable solution representation, a cost function, and a mechanism to traverse the search space.
6. They have *hill climbing* property, i.e., they occasionally accept uphill (bad) moves.

The goal in this chapter section is to briefly introduce these four powerful algorithms. It is organized into nine sections. In the next four subsections, an intuitive discussion of each of the four iterative algorithms is provided. The remaining sections briefly address convergence aspects of the heuristics, their parallel implementation, and examples of applications. The final subsection concludes the chapter section with a comparison among the heuristics and a glimpse at the notion of hybrids. This chapter section does not provide a full account of any of this important class of heuristics. For more details, readers should consult the numerous references cited in the body of this work.

### Simulated Annealing

*Simulated Annealing* (SA) is one of the most well-developed and widely used iterative techniques for solving optimization problems. It is a general adaptive heuristic and belongs to the class of nondeterministic algorithms [1]. It has been applied to several combinatorial optimization problems from various fields

FIGURE 39.73 Local vs. global optima.

of science and engineering. The term *annealing* refers to heating a solid to a very high temperature (whereby the atoms gain enough energy to break the chemical bonds and become free to move), and then slowly cooling the molten material in a controlled manner until it crystallizes. By cooling the metal at a proper rate, atoms will have an increased chance to regain proper crystal structure with perfect lattices. During this annealing procedure, the free energy of the solid is minimized.

In the early 1980s, a correspondence between annealing and combinatorial optimization was established, first by Kirkpatrick, Gelatt and Vecchi [2] in 1983, and independently by Černý [3] in 1985. These scientists observed that a solution in combinatorial optimization is equivalent to a state in the physical system and the cost of the solution is analogous to the energy of that state. As a result of this analogy, they introduced a solution method in the field of combinatorial optimization. This method is thus based on the simulation of the physical annealing process, and hence the name *simulated annealing* [2,3].

Every combinatorial optimization problem may be discussed in terms of a *state space*. A *state* is simply a configuration of the combinatorial objects involved. For example, consider the problem of partitioning a graph of  $2n$  nodes into two equal sized subgraphs such that the number of edges with vertices in both subgraphs is minimized. In this problem, any division of  $2n$  nodes into two equal sized blocks is a configuration. A large number of such configurations exists. Only some of these correspond to global optima, i.e., states with optimum cost.

An iterative improvement scheme starts with some given state, and examines a *local neighborhood* of the state for better solutions. A local neighborhood of a state  $S$ , denoted by  $N(S)$ , is the set of all states which can be reached from  $S$  by making a small change to  $S$ . For instance, if  $S$  represents a two-way partition of a graph, the set of all partitions which are generated by swapping two nodes across the partition represents a local neighborhood. The iterative improvement algorithm moves from the current state to a state in the local neighborhood if the latter has a better cost. If all the local neighbors have larger costs, the algorithm is said to have *converged* to a *local optimum*. This is illustrated in Fig. 39.73. Here, the states are shown along the  $x$ -axis, and it is assumed that two consecutive states are local neighbors. It is further assumed that we are discussing a *minimization* problem. The cost curve is *nonconvex*, i.e., it has multiple minima. A greedy iterative improvement algorithm may start off with an initial solution such as  $S$  in Fig. 39.73, then slide along the curve and find a local minimum such as  $L$ . There is no way such an algorithm can find the global minimum  $G$  of Fig. 39.73, unless it “climbs the hill” at the local minimum  $L$ . In other words, an algorithm that occasionally accepts inferior solutions can escape from getting trapped in a local optimum. SA is such a hill-climbing algorithm.

During annealing, a metal is maintained at a certain temperature  $T$  for a pre-computed amount of time, before reducing the temperature in a controlled manner. The atoms have a greater degree of freedom to move at higher temperatures than at lower temperatures. *The movement of atoms is analogous to the generation of new neighborhood states in an optimization process.* In order to simulate the annealing process,

```

Algorithm SimulatedAnnealing( $S_0, T_0, \alpha, \beta, M, Maxtime$ );
  (* $S_0$  is the initial solution *)
  (*BestS is the best solution *)
  (* $T_0$  is the initial temperature *)
  (* $\alpha$  is the cooling rate *)
  (* $\beta$  a constant *)
  (* $Maxtime$  is the total allowed time for the annealing process *)
  (* $M$  represents the time until the next parameter update *)

  Begin
     $T = T_0$ ;
     $CurS = S_0$ ;
     $BestS = CurS$ ; /* BestS is the best solution seen so far */
     $CurCost = Cost(CurS)$ ;
     $BestCost = Cost(BestS)$ ;
     $Time = 0$ ;
    Repeat
      Call Metropolis( $CurS, CurCost, BestS, BestCost, T, M$ );
       $Time = Time + M$ ;
       $T = \alpha T$ ;
       $M = \beta M$ 
    Until ( $Time \geq MaxTime$ );
    Return ( $BestS$ )
  End. (*of SimulatedAnnealing*)

```

```

Algorithm Metropolis( $CurS, CurCost, BestS, BestCost, T, M$ );
  Begin
    Repeat
       $NewS = Neighbor(CurS)$ ; /* Return a neighbor from  $aleph(CurS)$  */
       $NewCost = Cost(NewS)$ ;
       $\Delta Cost = (NewCost - CurCost)$ ;
      If ( $\Delta Cost < 0$ ) Then
         $CurS = NewS$ ;
        If  $NewCost < BestCost$  Then
           $BestS = NewS$ 
        EndIf
      Else
        If ( $RANDOM < e^{-\Delta Cost/T}$ ) Then
           $CurS = NewS$ ;
        EndIf
      EndIf
       $M = M - 1$ 
    Until ( $M = 0$ )
  End. (*of Metropolis*)

```

FIGURE 39.75 The Metropolis procedure.

much flexibility is allowed in neighborhood generation at higher “temperature,” i.e., many “uphill” moves are permitted at higher temperatures. The temperature parameter is lowered gradually as the algorithm proceeds. As the temperature is lowered, fewer and fewer uphill moves are permitted. In fact, at absolute zero, the SA algorithm turns greedy, allowing only downhill moves.

The SA algorithm is shown in Fig. 39.74. The core of the algorithm is the *Metropolis* procedure, which simulates the annealing process at a given temperature  $T$  (Fig. 39.75) [4]. The *Metropolis* procedure receives as input the current temperature  $T$ , and the current solution  $CurS$ , which it improves through local search. Finally, Metropolis must also be provided with the value  $M$ , which is the amount of time for which annealing must be applied at temperature  $T$ . The procedure *Simulated\_annealing* simply invokes *Metropolis* at decreasing temperatures. Temperature is initialized to a value  $T_0$  at the beginning of the procedure and is reduced in a controlled manner (typically in a geometric progression); the parameter

$\alpha$  is used to achieve this cooling. The amount of time spent in annealing at a temperature is gradually increased as temperature is lowered. This is done using the parameter  $\beta > 1$ . The variable *Time* keeps track of the time being expended in each call to the *Metropolis*. The annealing procedure halts when *Time* exceeds the allowed time.

The *Metropolis* procedure is shown in Fig. 39.75. It uses the procedure *Neighbor* to generate a local neighbor *NewS* of any given solution *S*. The function *Cost* returns the cost of a given solution *S*. If the cost of the new solution *NewS* is better than the cost of the current solution *CurS*, then the new solution is accepted, and we do so by setting  $CurS = NewS$ . If the cost of the new solution is better than the best solution (*BestS*) seen thus far, then *BestS* must be replaced by *NewS*. If the new solution has a higher cost in comparison to the original solution *CurS*, *Metropolis* will accept the new solution on a *probabilistic* basis. A random number is generated in the range 0 to 1. If this random number is smaller than  $e^{-\Delta Cost/T}$ , where  $\Delta Cost$  is the change in costs, ( $\Delta Cost = Cost(NewS) - Cost(CurS)$ ), and  $T$  is the current temperature, the uphill solution is accepted. This criterion for accepting the new solution is known as the *Metropolis criterion*. The *Metropolis* procedure generates and examines  $M$  solutions.

The probability that an inferior solution is accepted by the *Metropolis* is given by  $P(RANDOM < e^{-\Delta Cost/T})$ . The random number generation is assumed to follow a *uniform distribution*. Remember that  $\Delta Cost > 0$  because it is assumed that *NewS* is uphill from *CurS*. At very high temperatures (when  $T \rightarrow \infty$ ),  $e^{-\Delta Cost/T} \approx 1$ , and, hence, the above probability approaches 1. When  $T \rightarrow 0$ , the probability  $e^{-\Delta Cost/T}$  falls to 0.

In order to implement SA, a suitable cost function needs to be formulated for the problem being solved. In addition, as in the case of local search techniques, the existence of a neighborhood structure is assumed, and the *perturb* operation or *Neighbor* function needs to generate new states (neighborhood states) from current states. And finally, a control parameter is needed to play the role of temperature and a random number generator. The actions of SA are best illustrated with the help of an example. For the solution of the two-way partitioning problem using SA, please refer to [5].

A quality SA implementation requires the careful setting of a set of parameters that govern the convergence of the algorithm, namely (a) the initial value of temperature, (b) the number of iterations of the inner loop, (c) the rate of temperature decrease, and (d) the number of global iterations (the stopping criterion or the final value of temperature). This set of parameters is commonly referred as the “cooling schedule” [2,6,7]. It is customary to determine the cooling schedule by trial and error. However, some researchers have proposed cooling schedules that rely on some mathematical rigor. For a discussion on cooling schedule, and SA requirements the reader is referred to [8].

## Genetic Algorithms

Genetic Algorithm (GA), is a powerful, domain-independent search technique that was inspired by Darwinian theory. It emulates the natural process of evolution to perform an efficient and systematic search of the solution space to progress toward the optimum. It is an *adaptive* learning heuristic that is based on the theory of *natural selection* that assumes that individuals with certain characteristics are more able to survive, and hence pass their characteristics to their offspring. Several variations of the basic algorithm (modified to adapt to the problem at hand) exist. Subsequently, this set will be referred to as genetic algorithms (in plural).

GAs were invented by John Holland and his colleagues [9] in the early 1970s. Holland incorporated features of natural evolution to propose a *robust*, computationally simple, and yet powerful technique for solving difficult optimization problems. The structure that encodes how the organism is to be constructed is called a *chromosome*. One or more chromosomes may be associated with each member of the population. The complete set of chromosomes is called a *genotype* and the resulting organism is called a *phenotype*. Similarly, the representation of a solution to the optimization problem in the form of an encoded string is termed as a *chromosome*. In most combinatorial optimization problems a single chromosome is generally sufficient to represent a solution, i.e., the genotype and the chromosome are the same. The symbols that make up a chromosome are known as *genes*. The different values a gene can take are called *alleles*.

The fitness value of an individual (genotype or a chromosome) is a *positive* number that is a measure of its goodness. When the chromosome represents a solution to the combinatorial optimization problem, the fitness value indicates the cost of the solution. In the case of a minimization problem, solutions with lower cost correspond to individuals that are more fit.

GAs operate on a *population* (or set) of *individuals* (or solutions) encoded as strings. These strings represent points in the search space. In each iteration, referred to as a generation, a new set of strings that represent solutions (called offspring) is created by crossing some of the strings of the current generation [10]. Occasionally, new characteristics are injected to add diversity. GAs combine information exchange along with *survival of the fittest* among individuals to conduct the search.

When employing GAs to solve a combinatorial optimization problem one has to find an efficient representation of the solution in the form of a chromosome. Associated with each chromosome is its *fitness value*. If we simulate the process of natural reproduction, combined with the biological principle of survival of the fittest, then, as each generation progresses, better and better individuals (solutions) with higher fitness values are expected to be produced.

Because GAs work on a population of solutions, an initial population constructor is required to generate a certain predefined number of solutions. The quality of the final solution produced by a genetic algorithm depends on the size of the population and how the initial population is constructed. The initial population generally comprises random solutions.

The population of chromosomes evolves from generation to the next through the use of two types of genetic operators: (1) unary operators such as mutation and *inversion*, which alter the genetic structure of a single chromosome, and (2) higher order operator, referred to as *crossover*, which consists of obtaining new individual by combining genetic material from two selected parent chromosomes. The resulting individuals produced when genetic operators are applied on the parents are termed as *offspring*. Then the new population is selected out of the individuals of the current population and its offspring.

The choice of parents for crossover from the set of individuals that comprise the population is probabilistic. In keeping with the ideas of natural selection, we assume that stronger individuals, i.e., those with higher fitness values, are more likely to mate than the weaker ones. One way to simulate this is to select parents with a probability that is directly proportional to their fitness values. Larger the fitness, the greater is chance of an individual being selected as one of the parents for crossover [10].

Several crossover operators have been proposed in the literature. Depending on the combinatorial optimization problem being solved some are more effective than others. One popular crossover that will also help illustrate the concept is the *simple crossover*. It performs the “cut-catenate” operation. It consists of choosing a *random* cut point and dividing each of the two chromosomes into two parts. The offspring is then generated by catenating the segment of one parent to the left of the cut point with the segment of the second parent to the right of the cut point.

*Mutation* ( $\mu$ ) produces incremental random changes in the offspring by randomly changing allele values of some genes. In case of binary chromosomes it corresponds to changing single bit positions. It is not applied to all members of the population, but is applied probabilistically only to some. Mutation has the effect of perturbing a certain chromosome in order to introduce *new* characteristics not present in any element of the parent population. For example, in case of binary chromosomes, toggling some selected bits produces the desired effect.

*Inversion* is the third operator of GA and like mutation it also operates on a single chromosome. Its basic function is to laterally invert the order of alleles between two randomly chosen points on a chromosome.

A *generation* is an iteration of GA where individuals in the current population are selected for crossover and offspring are created. Due to the addition of offspring, the size of population increases. In order to keep the number of members in a population fixed, a constant number of individuals are selected from this set that consists of both the individuals of the initial population, and the generated offspring. If  $M$  is the size of the initial population and  $N_0$  is the number of offspring created in each generation, then, before the beginning of next generation,  $M$  new parents from  $M + N_0$  individuals are selected. A greedy

## Tabu Search

The previous subsection discussed simulated annealing, which was inspired by the cooling of metals, and genetic algorithms, which imitate the biological phenomena of evolutionary reproduction. In this section we present a more recent optimization method called tabu search (TS), which is based on selected concepts of artificial intelligence (AI).

Tabu search was introduced by Fred Glover [11–14] as a general iterative heuristic for solving combinatorial optimization problems. Initial ideas of the technique were also proposed by Hansen [15] in his *steepest ascent mildest descent* heuristic. TS is conceptually simple and elegant. It is a form of local neighborhood search. Each solution  $S \in \Omega$  has an associated set of neighbors  $N(S) \subseteq \Omega$ . A solution  $S' \in N(S)$  can be reached from  $S$  by an operation called a *move* to  $S'$ . Normally, the neighborhood relation assumed symmetric. That is, if  $S'$  is a neighbor of  $S$  then  $S$  is a neighbor of  $S'$ . At each step, the local neighborhood of the current solution is explored and the best solution in that neighborhood is selected as the new current solution. Unlike local search that stops when no improved new solution is found in the current neighborhood, tabu search continues the search from the best solution in the neighborhood even if it is worse than the current solution. To prevent cycling, information pertaining to the most recently visited solutions are inserted in a list called *tabu list*. Moves to tabu solutions are not allowed. The tabu status of a solution is overridden when certain criteria (aspiration criteria) are satisfied. One example of an aspiration criterion is when the cost of the selected solution is better than the best seen so far, which is an indication that the search is actually not cycling back, but rather moving to a new solution not encountered before.

Tabu search is a *metaheuristic*, which can be used not only to guide the search in complex solution spaces, but also to direct the operations of other heuristic procedures. It can be superimposed on any heuristic whose operations are characterized as performing a sequence of moves that lead the procedure from one trial solution to another. In addition to several other characteristics, the attractiveness of tabu search comes from its ability to escape local optima.

Tabu search differs from SA or GA, which are *memoryless*, and also from branch-and-bound, A\* search, etc., which are rigid memory approaches. One of its features is its systematic use of *adaptive*

FIGURE 39.77 The tabu list can be visualized as a window over accepted moves.

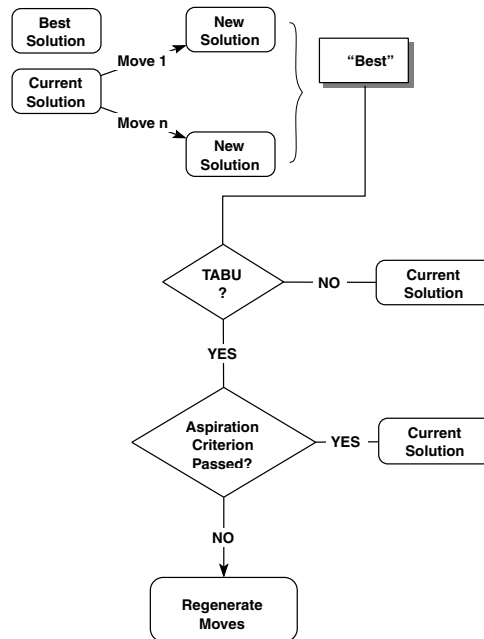

FIGURE 39.78 Flow chart of the tabu search algorithm.

(flexible) memory. It is based on very simple ideas with a clever combination of components, namely [16,17]:

1. A short-term memory component; this component is the core of the tabu search algorithm.
2. An intermediate-term memory component; this component is used for regionally **intensifying** the search.
3. A long-term memory component; this component is used for globally **diversifying** the search.

The central idea underlying tabu search is the exploitation of the above three memory components. Using the short-term memory, a *selective history*  $\mathbf{H}$  of the states encountered is maintained to guide the search process. Neighborhood  $N(S)$  is replaced by a modified neighborhood, which is a function of the history  $\mathbf{H}$ , and is denoted by  $N(\mathbf{H}, S)$ . History determines which solutions may be reached by a move from  $S$ , since the next state  $S$  is selected from  $N(\mathbf{H}, S)$ . The short-term memory component is implemented through a set of *tabu* conditions and the associated *aspiration criterion*.

The major idea of the short-term memory component is to classify certain search directions as tabu (or *forbidden*). By doing so we avoid returning to previously visited solutions. Search is therefore forced away from recently visited solutions, with the help of a short-term memory (*tabu list*  $\mathbf{T}$ ). This memory contains *attributes* of some  $k$  most recent moves. The size of the tabu list denoted by  $k$  is the number of iterations for which a move containing that attribute is forbidden after it has been made. The tabu list can be visualized as a window on accepted moves as shown in Fig. 39.77. Moves, which tend to undo previous moves within this window, are forbidden. A flow chart illustrating the basic short-term memory tabu search algorithm is given in Fig. 39.78. An algorithmic description of a simple implementation of the tabu search is given in Fig. 39.79.

$\Omega$  : Set of feasible solutions.  
 $S$  : Current solution.  
 $S^*$  : Best admissible solution.  
 $Cost$  : Objective function.  
 $\mathfrak{N}(S)$  : Neighborhood of  $S \in \Omega$ .  
 $V^*$  : Sample of neighborhood solutions.  
 $T$  : Tabu list.  
 $AL$  : Aspiration Level.

```

Begin
1. Start with an initial feasible solution  $S \in \Omega$ .
2. Initialize tabu lists and aspiration level.
3. For fixed number of iterations Do
4.     Generate neighbor solutions  $V^* \subset \mathfrak{N}(S)$ .
5.     Find best  $S^* \in V^*$ .
6.     If move  $S$  to  $S^*$  is not in  $T$  Then
7.         Accept move and update best solution.
8.         Update tabu list and aspiration level.
9.         Increment iteration number.
10.    Else
11.        If  $Cost(S^*) < AL$  Then
12.            Accept move and update best solution.
13.            Update tabu list and aspiration level.
14.            Increment iteration number.
15.        EndIf
16.    EndIf
17. EndFor
End.
  
```

**FIGURE 39.79** Algorithmic description of short-term tabu search (TS).

Intermediate-term and long-term memory processes are used to intensify and diversify the search, respectively, and have been found to be very effective in increasing both quality and efficiency [18,19].

The basic tabu search algorithm based on the short-term memory component is discussed first. Following this is a discussion on uses of intermediate and long-term memories.

Referring to Fig. 39.79, initially the current solution is the best solution. Copies of the current solution are perturbed with moves to get a set of new solutions. The best among these is selected and if it is not tabu then it becomes the current solution. If the move is tabu, its aspiration criterion is checked. If it passes the aspiration criterion, it becomes the current solution. If the move to the next solution is accepted, the move or some of its attributes are stored in the tabu list. Otherwise, moves are regenerated to get another set of new solutions. If the current solution is better than the best seen thus far, the best solution is updated. Whenever a move is accepted the iteration number is incremented. The procedure continues for a fixed number of iterations, or until some pre-specified stopping criterion is satisfied.

Tabu restrictions and aspiration criterion have a symmetric role. The order of checking for tabu status and aspiration criterion may be reversed, though most applications check if a move is tabu before checking for aspiration criterion. For more discussion on move attributes, types of tabu Lists and the various tabu restrictions, the data structure to handle tabu-lists, and other aspiration criteria, the reader is referred to [8].

In many applications, the short-term memory component by itself has produced solutions superior to those found by alternative procedures, and usually the use of intermediate-term and long-term memory is bypassed; however, several studies have shown that intermediate and long-term memory components can improve solution quality and/or performance [19–22].

The basic role of the intermediate-term memory component is to *intensify* the search. By its incorporation, the search becomes more aggressive. As the name suggests, memory is used to intensify the search.

Intermediate-term memory component operates as follows. A selected number  $m \gg |T|$  (recall that  $|T|$  is the size of tabu list) of best trial solutions generated during a particular period of search are chosen and their features are recorded and compared. These solutions may be  $m$  consecutive best ones, or  $m$  local optimal solutions reached during the search. Features common to most of these are then taken and new solutions that contain these features are sought. One way to accomplish this is to restrict/penalize moves that remove such attributes. For example, in the TSP problem with moderately dense graphs, the number of different edges that can be included into any tour is generally a fraction of the total available edges (Why?). After some number of initial iterations, the method can discard all edges not yet incorporated into some tour. The size of the problem and the time per iteration now become smaller. The search therefore can focus on possibilities that are likely to be attractive, and can also examine many more alternatives in a given span of time.

The goal of long-term memory component is to *diversify* the search. The principles involved here are just the *opposite* of those used by the intermediate-term memory function. Instead of more intensively focusing the search with regions that contain previously found good solutions, the function of this component is to drive the search process into new regions that are different from those examined thus far.

Diversification using long-term memory in tabu search can be accomplished by creating an evaluator whose task is to take the search to new starting points [11]. For example, in the traveling salesman problem (TSP), a simple form of long-term memory is to keep a count of the number of times each edge has appeared in the tours previously generated. Then, an evaluator can be used to penalize each edge on the basis of this count; thereby favoring the generation of *other, hopefully good* starting tours that tend to avoid those edges most commonly used in the past. This sort of approach is viewed as a **frequency**-based tabu criterion in contrast to the **recency**-based (tabu list) discussed earlier. Such a long-term strategy can be employed by means of a long-term tabu list (or any other appropriate data structure) that is periodically activated to employ tabu conditions of increased stringency, thereby forcing the search process into new territory [23].

It is easy to create and test the short-term memory component first, and then incorporate the intermediate/long components for additional refinements.

Let a matrix entry  $Freq(i, j)$  ( $i$  and  $j$  be movable or swappable elements) store the number of times swap  $(i, j)$  was made to take the solution from current state  $S$  to a new state  $S^*$ . We can then use this information to define a move evaluator  $\varepsilon(H, S)$ , which is a function of both the cost of the solution, and the frequency of the swaps stored. Our objective is to diversify the search by giving more consideration to those swaps that have not been made yet, and to penalize those that frequently occurred, that is given them less consideration [24]. Taking the above into consideration, the evaluation of the move can be expressed as follows:

$$\varepsilon(H, S^*) = \begin{cases} Cost(S^*) & Cost(S^*) \leq Cost(S) \\ Cost(S^*) + \alpha \times Freq(i, j) & Cost(S^*) > Cost(S) \end{cases}$$

$\alpha$  is a constant which depends on the range of the objective function values, the number of iterations, the span of history considered, etc. Its value ( $\alpha$ 's) is such that cost and frequency are appropriately balanced.

## Simulated Evolution (SimE)

The simulated evolution algorithm (SimE) is a general search strategy for solving a variety of combinatorial optimization problems. The first paper describing SimE appeared in 1987 [25]. Other papers by the same authors followed [26–28].

SimE assumes that there exists a population  $P$  of a set  $M$  of  $n$  (movable) elements. In addition, there is a cost function  $Cost$  that is used to associate with each assignment of movable element  $m$  a cost  $C_m$ .

```

ALGORITHM Simulated_Evolution(M, L);
/* M: Set of movable elements; */
/* L: Set of locations; */
/* B: Selection bias; */
/* Stopping criteria and selection bias can be automatically adjusted; */
INITIALIZATION;
Repeat
  EVALUATION:
    ForEach m ∈ M Do  $g_m = \frac{O_m}{C_m}$  EndForEach;

  SELECTION:
    ForEach m ∈ M Do
      If Selection(m,B) Then  $P_s = P_s \cup \{m\}$ 
      Else  $P_r = P_r \cup \{m\}$ 
      EndIf;
    EndForEach;
    Sort the elements of Ps;

  ALLOCATION:
    ForEach m ∈ Ps Do Allocation(m) EndForEach;
Until Stopping-criteria are met;
Return (BestSolution);
End Simulated_Evolution.

```

**FIGURE 39.80** Simulated evolution algorithm.

The cost  $C_m$  is used to compute the goodness (fitness)  $g_m$  of element  $m$ , for each  $m \in M$ . Furthermore, Usually additional constraints must be satisfied by the population as a whole or by particular elements. A general outline of the SimE algorithm is given in Fig. 39.80.

SimE algorithm proceeds as follows. Initially, a population<sup>1</sup> is created at random from all populations satisfying the environmental constraints of the problem. The algorithm has one main loop consisting of three basic steps, *Evaluation*, *Selection*, and *Allocation*. The three steps are executed in sequence until the population average *goodness* reaches a maximum value, or no noticeable improvement to the population *goodness* is observed after a number of iterations. Another possible stopping criterion could be to run the algorithm for a prefixed number of iterations (see Fig. 39.80). Some details of the steps of the SimE algorithm are presented in the next subsection.

### Evaluation

The *Evaluation* step consists of evaluating the goodness of each individual  $i$  of the population  $P$ . The *goodness* measure must be a single number expressible in the range  $[0,1]$ . *Goodness* is defined as follows:

$$g_i = \frac{O_i}{C_i} \quad (39.1)$$

where  $O_i$  is an estimate of the optimal cost of individual  $i$ , and  $C_i$  is the actual cost of  $i$  in its current location. Equation (39.1) assumes a minimization problem (maximization of goodness). Notice that, according to the previous definition, the  $O_i$ 's do not change from generation to generation, and, therefore, are computed only once during the initialization step. Hence, only the  $C_i$ 's have to be recomputed at each call to the *Evaluation* function. Empirical evidence [29] shows that the accuracy of the estimation of  $O_i$  is not very crucial to the successful application of SimE; however, the *goodness* measure must be strongly related to the target objective of the given problem.

<sup>1</sup> In SimE terminology, a population refers to a single solution. Individuals of the population are components of the solution; they are the movable elements.

FIGURE 39.81 Selection.

FIGURE 39.82 Allocation.

## Selection

The second step of the SimE algorithm is *Selection*. Selection takes as input the population  $P$  together with the estimated *goodness* of each individual and partitions  $P$  into two disjoint sets, a selection set  $P_s$  and a set  $P_r$  of the remaining members of the population (see Fig. 39.81). Each member of the population is considered separately from all other individuals. The decision whether to assign individual  $i$  to the set  $P_s$  or set  $P_r$  is based solely on its *goodness*  $g_i$ . The operator uses a selection function *Selection*, which takes as input  $g_i$  and a parameter  $B$ , which is a *selection bias*. Values of  $B$  are recommended to be in the range  $[-0.2, 0.2]$ . In many cases a value of  $B = 0$  would be a reasonable choice.

The *Selection* function returns *true* or *false*. The higher the *goodness* value of the element, the higher is its chance of staying in its current location, i.e., unaltered in the next generation. On the other hand, the lower the *goodness* value, the more likely the corresponding element will be selected for alteration (mutation) in the next generation (will be assigned to the selection set  $P_s$ ). An individual with a high *fitness* (*goodness* close to one) still has a nonzero probability of being assigned to the selected set  $P_s$ . It is this element of nondeterminism that gives SimE the capability of escaping local minima.

For most problems, it is always beneficial to alter the elements of the population according to a deterministic order that is correlated with the objective function being optimized. Hence, in SimE, prior to the *Allocation* step, the elements in the selection set  $P_s$  are sorted. The sorting criterion is problem specific. Usually there are several criteria to choose from [8].

## Allocation

*Allocation* is the SimE operator that has most impact on the quality of solution. *Allocation* takes as input the two sets  $P_s$  and  $P_r$  and generates a new population  $P'$  that contains all the members of the previous population  $P$ , with the elements of  $P_s$  mutated according to an *Allocation* function (see Fig. 39.82).

The choice of a suitable *Allocation* function is problem specific. The decision of the *Allocation* strategy usually requires more ingenuity on the part of the designer than the *Selection* scheme. The *Allocation* function may be a nondeterministic function, which involves a choice among a number of possible mutations (moves) for each element of  $P_s$ . Usually, a number of *trial-mutations* are performed and rated with respect to their *goodnesses*. Based on the resulting *goodnesses*, a final configuration of the population  $P'$  is decided. The goal of *Allocation* is to favor improvements over the previous generation, without being too greedy.

The *Allocation* operation is a complex form of genetic *mutation* that is one of the genetic operations thought to be responsible for the evolution of the various species in biological environments; however, there

is no need for a *crossover* operation as in GA since only one parent is maintained in all generations; however, because *mutation* is the only mechanism used by SimE for inheritance and evolution, it must be more sophisticated than the one used in GA.

*Allocation* alters (mutates) all the elements in the selected set  $P_s$ , one after the other in a predetermined order. For each individual  $e_i$  of the selected set  $P_s$ ,  $W$  distinct trial alterations are attempted. The trial that leads to the best configuration (population) with respect to the objective being optimized is accepted and made permanent. The *goodness* of each individual element is also tightly coupled with the target objective, so the superior alterations are supposed to gradually improve the individual *goodnesses* as well. Hence, *Allocation* allows the search to progressively evolve toward an optimal configuration where each individual is optimally located.

### Initialization Phase

This step precedes the iterative phase. In this step, the various parameters of the algorithm are set to their desired values, namely, the maximum number of iterations required to run the main loop, the selection bias  $B$ , and the number of trial alterations  $W$  per individual. Furthermore, similar to any iterative algorithm, SimE requires that an initial solution be given. The convergence aspects of SimE are not affected by the quality of the initial solution; however, starting from a randomly generated solution usually increases the number of iterations required to converge to a near-optimal solution.

### Convergence Aspects

One of the desirable properties that a stochastic iterative algorithm should possess is the convergence property, i.e., the guarantee of converging to one of the global optima if given enough time. The convergence aspects of the simulated annealing algorithm have been the subject of extensive studies. For a thorough discussion of simulated annealing convergence we refer the reader to [6,7,30].

For convergence properties of the GA heuristic based on Markovian analysis, the reader is referred to [31–37]. Fogel [38] provides a concise treatment of the main GA convergence results.

The tabu search algorithm as described in this article is known as *ordinary* or *deterministic tabu search*. Because of its deterministic nature, ordinary tabu search may never converge to a global optimum state. The incorporation of a nondeterministic element within tabu search allows the algorithm to lend itself to mathematical analysis similar to that developed for simulated annealing, making it possible to establish corresponding convergence properties. Tabu search with nondeterministic elements is called *probabilistic tabu search* [11,39]. Probabilistic tabu search has been shown to converge in the limit to a global optimum state. The proof is analogous to that of SA.

Proof of convergence of SimE can be found in [28,40]. For complete convergence analysis, the reader may refer to [8].

### Parallelization/Acceleration

Due to their iterative and blind nature, the heuristics discussed in this chapter section require large runtime, especially on large problems, and CPU-intensive cost functions. Substantial amount of work has been done to parallelize or design accelerators to run these time consuming heuristics. With respect to simulated annealing, which is inherently sequential, some ingenuity is required on the part of the designer to cleverly parallelize the annealing process. Several parallel implementations of SA have been reported in [6,41–47]. Hardware acceleration that consists of implementing time consuming parts in hardware is described in [48]. Parallel acceleration, where execution of the algorithm is partitioned on several concurrently running processors, is reported in [49–51]. Other approaches that have been applied to parallelize SA are found in [6,49,52,53]. The parallel accelerations follow two general strategies: (1) move acceleration, also called single-trial parallelism, and (2) parallel moves or multiple-trial parallelism.

The GA is highly parallel. The reported GA parallelization strategies fall into three general categories: the *island model* [54,55], the *stepping stone model* [56–59], and the *neighborhood model*, also called the cellular model [60,61].

Work on parallelization of the tabu search heuristic can be found in [8,62–66]. The heuristic has also been parallelized and executed on a network of workstations using PVM [67]. Techniques to accelerate the execution of SimE by implementing it on vector-processors [29] or on a network of workstations [68] are described in [8].

## Applications

The first applications of SA were on placement [2]. Furthermore, the largest number of applications of SA was on digital design automation problems [5]. A popular package that uses SA for VLSI standard-cell placement and routing is the TimberWolf3.2 package [46]. In addition to placement, SA has been applied successfully to several other problems. These include classical problems such as the TSP [2], graph partitioning, matching problem, Steiner problems [69], linear arrangement [1], clustering problem [70], quadratic assignment [71], various scheduling problems [72,73], graph coloring [74], etc. In the area of engineering SA has been applied extensively to solve various hard VLSI physical design automation problems [5]. In addition, it has been applied with success in other areas such as topology design of computer networks [75], image processing [76], test pattern generation, code design, etc. A comprehensive list of bibliography of some of the above applications and some details of their implementation such as cost function formulation, move set design, parameters, etc., is available in [6,8,77–79].

In addition to their application to classical optimization problems such as the knapsack problem [80], TSP [81,82], Steiner tree problem [83], set covering problem [84], N-queens problem [85], clustering problem [86], graph partitioning [87], etc., GAs have also been applied to several engineering problems. Some examples of these applications include job shop and multiprocessor scheduling [81,88,89], discovery of maximal distance codes for data communications [90], bin-packing [91], design of telecommunication (mesh) networks [92], test sequence generation for digital system testing [93], VLSI design (cell placement [5,94–96], floorplanning [97], routing [98]), pattern matching [99], technology mapping [100], PCB assembly planning [101], and high-level synthesis of digital systems [102,103]. The books by Goldberg (1989) [10], Davis (1991) [104], recent conference proceedings on evolutionary computation, and on applications of genetic algorithms discuss in detail the various applications of GAs in science and engineering. These range from optimization of pipeline systems and medical imaging to applications such as robot trajectory generation and parametric design of aircraft [10,104].

TS has also been applied to solve combinatorial optimization problems appearing in various fields of science, engineering, and business. Results reported indicate superior performance to other previous techniques. Examples of some hard problems to which tabu search has been applied with success include graph partitioning [105], clustering [106], TSP [107], maximum independent set problem [108], graph coloring [109,110], maximum clique problem [111], and quadratic assignment problem [62,112] to name a few. In the area of engineering, tabu search has been applied to machine sequencing [113], scheduling [22,114–118], fuzzy clustering [119], multiprocessor scheduling [120], vehicle routing [121–123], general fixed charge problem [17], bin-packing [124], bandwidth packing [24], VLSI placement [125], circuit partitioning [126], global routing [127], high-level synthesis of digital systems [128,129], etc. A good summary of most recent applications of tabu search can be found in [8,18,130].

The SimE algorithm has also been used to solve a wide range of combinatorial optimization problems. Kling and Banerjee published their results with respect to SimE in design automation conferences [25,27] and journals [26,28]. This explains the fact that most published work on SimE has been originated by researchers in the area of design automation of VLSI circuits [40,131–134]. The first problem on which SimE was first applied is standard cell placement [25,28]. A number of papers describe SimE-based heuristics as applied to the routing of VLSI circuits [131,135–140]. SimE was also successfully applied in high-level synthesis [141–143]. Other reported SimE applications are in micro-code compaction [144], automatic synthesis of gate matrix [134], and the synthesis of cellular architecture field programmable gate arrays (FPGAs) [145].

## Conclusion

This chapter section has introduced the reader to four effective heuristics that belong to the class of *general approximation iterative algorithms*, namely SA, GA, tabu search, and SimE. From the immense literature that is available it is evident that for a large variety of applications, in certain settings, these heuristics produce excellent results. All five algorithms are general iterative metaheuristics. A value of the objective function is used to compare results of consecutive iterations and a solution is selected based on its value.

All algorithms incorporate domain specific knowledge to dictate the search strategy. They also tolerate some element of nondeterminism that helps the search escape out of local minima. They all rely on the use of a suitable cost function, which provides feedback to the algorithm as the search progresses. The principle difference among these heuristics is how and where domain specific knowledge is used. For example, in SA such knowledge is mainly included in the cost function. Elements involved in a perturbation are selected randomly, and perturbations are accepted or rejected according to the *Metropolis* criterion, which is a function of the cost. The cooling schedule has also a major impact on the algorithm performance and must be carefully crafted to the problem domain as well as the particular problem instance.

For the two evolutionary algorithms discussed in the chapter, GA and SimE, domain specific knowledge is exploited in all phases. In the case of GA, the fitness of individual solutions incorporates domain specific knowledge. Selection for reproduction, the genetic operations, as well as generation of the new population also incorporate a great deal of heuristic knowledge about the problem domain. In SimE, each individual element of a solution is characterized by a goodness measure that is highly correlated with the objective function. The perturbation step (selection followed by allocation) affects mostly low goodness elements. Therefore, domain specific knowledge is included in every step of the SimE algorithm.

Tabu search is different from the above heuristics in that it has an explicit memory component. At each iteration the neighborhood of the current solution is partially explored, and a move is made to the best nontabu solution in that neighborhood. The neighborhood function as well as tabu list size and content are problem specific. The direction of the search is also influenced by the memory structures (whether intensification or diversification is used).

A classification of meta-heuristics proposed by Glover and Laguna [130] is based on three basic features: (1) the use of adaptive memory, where the letter *A* is used if the meta-heuristic employs adaptive memory, and the letter *M* is used if it is memoryless; (2) the kind of neighborhood exploration, where the letter *N* is used if the meta-heuristic performs a systematic neighborhood search, and the letter *S* is used if stochastic sampling is followed; and (3) the number of current solutions carried from one iteration to the next, where the digit 1 is used if the meta-heuristic maintains a single solution, and the letter *P* is used if a parallel search is performed with a population of solutions of cardinality *P*. For example, according to this classification, GA is *M/S/P*, tabu search is *A/N/1*, SA is *M/S/1*, and SimE is also *M/S/1*.

It is also possible to make hybrids of these algorithms. The basic idea of hybridization is to enhance the strengths and compensate for the weaknesses of two or more complementary approaches. For the details about the hybridization the readers are referred to [8].

In this chapter section, it has not been the authors' intention to demonstrate the superiority of one algorithm over the other. Actually it would be unwise to rank such algorithms. Each one of them has its own merits. Recently, an interesting theoretical study has been reported by Wolpert and Macready in which they proved a number of theorems stating that the average performance of any pair of iterative (deterministic or nondeterministic) algorithms across all problems is identical. That is, if an algorithm performs well on a certain class of problems then it necessarily pays for that with degraded performance on the remaining set of problems [146]; however, it should be noted that the reported theorems assume that the algorithms do not include domain specific knowledge of the problems being solved. Obviously, it would be expected that a well-engineered algorithm would exhibit superior performance to that of a poorly engineered one.

## Acknowledgment

The authors acknowledge King Fahd University of Petroleum and Minerals, Dhahran, Saudi Arabia, for all support. This work is carried out under university-funded project number COE/ITERATE/221. Special thanks to Junaid Asim Khan and Salman Khan for their tremendous assistance and help in the preparation of this manuscript.

### 40.1 Introduction

---

#### Computing Models for Internet-Based Architectures

The increasingly competitive global marketplace puts pressure on companies to create and deliver their products faster, with high quality and greater performance. To get the new products and technologies to consumers is through a new industry called application service providers (ASPs). Similar to Internet service providers, that linked businesses and consumers up to the Internet, ASPs lease software applications to businesses and consumers via the Internet. These applications range from word processing programs to payroll management software, document management systems, and many others. The major challenge is to develop an efficient Internet-based architecture, which will efficiently provide access to these software applications over the Internet.

Application architectures have traditionally followed software development architectures. The software development architectures can be classified into:

- traditional desktop computing model,
- client-server computing model,
- network computing model,
- server-based computing model.

*Traditional desktop computing model* assumes that the whole application is on the client and the application is executed locally. The client must be a “fat” client.

*Client-server computing model* assumes that clients are powerful and processing is centered around local execution on clients. Computer resources were split between a server and one or several clients.

This architecture allowed for larger, more scalable, applications to be brought to a larger number of clients; however, the key for this architecture was to successfully partition the complexity of overall application and determine correctly which part should reside on the server and which part should run on the client. As more and more functionality migrated to the client, it became harder for applications to be maintained and updated.

*Network computing model*, supported by Sun, Oracle, Netscape, IBM, and Apple, assumes that software applications are dynamically downloaded from the network into the client for execution by the client. This architecture requires that the clients are fat.

*Server-based computing model*, supported by Citrix, assumes that business applications reside on the servers and can be accessed by users without requiring them to be downloaded to the client. The client can be either “thin” or “fat.”

### Server-Based Computing Model

The fundamental three elements of the server-based (or host-based) computing model are [1]:

- multi-user operating system,
- efficient computing technology,
- centralized application and client management.

*Multi-user operating system* allows multiple concurrent users to run applications in separate, protected sessions on a single server.

*Efficient computing technology* separates the application from its user interface, so only simple user’s commands, received through keystrokes, mouse clicks, and screen updates, are sent via the network. As a result, application performance does not depend on network bandwidth.

*Centralized application and client management* allows efficient solution of application management, access, performance, and security.

A server-based computing model is very efficient for enterprise-wide application deployment, including cross-platform computing, Web computing, remote computing, thin-client device computing, and branch-office computing, as illustrated in Fig. 40.1 [1].

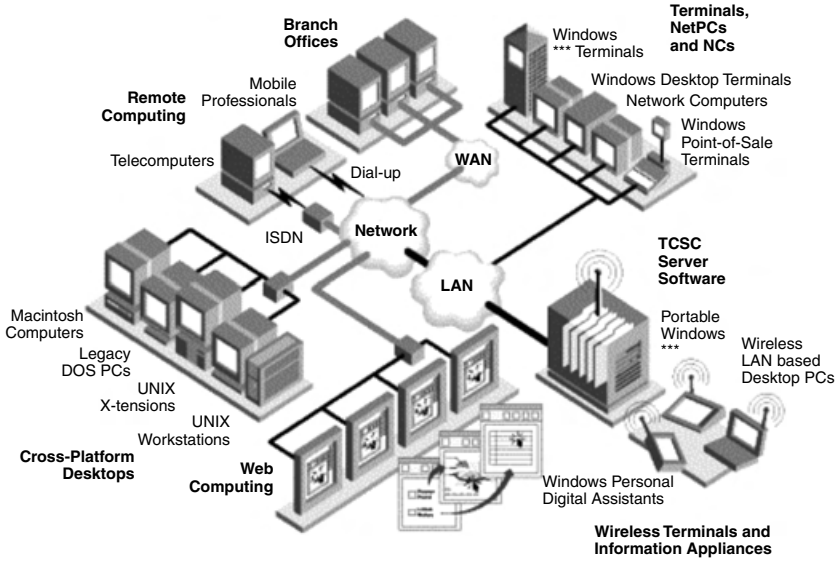

FIGURE 40.1 Server-based computing models can be used for enterprise-wide application deployment.

# 40.2 Evolution of Internet-Based Application Service Architectures

Similar to software development architectures, applications service architectures have emerged from the traditional client-server architectures to three-tier and multitier architectures.

The first generation of Internet-based application service architecture was based on delivery of information via public Web sites. This technology, sometimes referred to as the “first wave” Internet [2] employs the Web to present the information to the user and then allows the user to give some relevant information back. The primary focus of this architectural model is mass distribution of public information over the Internet. This architecture, which focuses on accessing information, consists of three levels (or three tiers)—presentation level, content level, and data and service level, as shown in Fig. 40.2 [2].

At the presentation level, there is the client system, which is used to view Web page information. The client contains both presentation and application logic components. At the content level, there is a Web server that provides interactive view of information from a relational database. Finally, at the data and service level, there is a relational database system, which provides data for the Web server. This architecture is also called three-tier architecture consisting of client tier, Web server tier, and database tier.

With the advancements of the Internet, the Web, and related technologies (such as Java and HTML), as well as acceptance of standard communication protocols (such as TCP/IP and HTTP), a new architecture has emerged. In this architecture, sometimes referred as to the “second wave” Internet [2] or network-based application architecture [3], focus is on highly targeted, private distribution of software services over Intranets and Extranets. In this architecture, the Web page is not only the agent for providing information but also offers a variety of application services to speed up business transactions and offer additional services. This architecture consists of *n*-tiers and offers maximum functionality and flexibility in a heterogeneous Web-based environment. An example of four-tier architecture is shown in Fig. 40.3.

At the presentation level, the client views Web pages for information as well as for a variety of application services. At the second, content level, the Web server provides an interactive view of information and supports client-initiated transactions. At the third, application level, there is an application server, which is used to find requested data and services, makes them available for viewing, and carries out transactions. At the fourth, data and service level, there is a variety of data and services accessible by the application server. This architecture, also called multitier architecture, consists of client tier, Web server tier, application server tier, and database tier.

Two-tier Internet architecture is typically limited for systems with a small number of users, a single database, and nonsecure network environments.

FIGURE 40.2 The three-tier architecture for application service providers (ASPs) is focused on accessing information.

FIGURE 40.3 The multitier Internet-based architecture for ASPs is focused on accessing application services.

## 40.3 Application Server

In the second generation of Internet architectures, the focus has shifted to access to business services rather than to information only. The main component of the system is an application server, which searches for services and data—this is done in the background without involving the user.

The main challenges in developing the first generation of Internet architectures and application services were related to user interfaces and cross-platform interoperability. In developing the second generation of Internet architectures, the main challenge for service developers is to deliver their services seamlessly via the Internet, which in turn requires innovations in many areas. The following challenges need to be addressed in developing the second generation of Internet architectures:

- **Standards.** Many standards are used for developing Web pages, which causes difficulties for developers.
- **Increased programming complexity.** The implementation of business services on the Internet is a very complex programming task.
- **Network performance.** Business applications over Intranets and Extranets require very reliable and high-performance networks.
- **Security.** Business applications on the Internet require a very high level of security.
- **Web access to legacy applications.** As mentioned earlier, the new Internet architectures are focused on accessing various business applications rather than just information.
- **Database connection support across Web-based requestors.** Users should be able to access a variety of databases connected to the application server.

The majority of these functions, sometimes called *middleware*, are implemented in application servers that provide support for developing and deploying business applications located on the server or partitioned across client and server.

Application server offers support for developing and deploying business logic that may be located on the server or, more often, partitioned across client and server. Running business applications on the server provides many benefits [4].

### Key Technologies for Application Servers

Key technologies for developing contemporary application servers include:

- Java programming language and environment,

- JavaBeans—the Java-based component technology, which allows the development of new applications more rapidly and economically,
- ActiveX—the competing technology to JavaBeans, which is Windows platform-dependent and language-independent,
- Java Database Connectivity (JDBC)—the Java SQL that provides cross-platform database access for Java programs,
- Java servlets—small Java routines that service HTTP requests and dynamically generate HTML, and
- Common object request broker architecture (CORBA)—provides a standard architecture for distributed computing and interoperability on the Internet.

Java application servers have recently emerged as an efficient solution, with many features, for the application server tier. A Java application server:

- Makes it easy to develop and deploy distributed Java applications.
- Provides scalability, so hundreds to thousands of cooperative servers can be accessed from ten of thousands clients. Therefore, Java must be fully multithreaded and have no architectural bottlenecks that prevent scaling.
- Provides an integrated management environment for comprehensive view of application resources (e.g., Java Beans, objects, events, etc.), network resources (databases), system resources (ACLs, threads, sockets, etc.), and diagnostic information.
- Provides transaction semantics to protect the integrity of corporate data even as it is accessed by distributed business components.
- Provides secure communications.

CORBA and JavaBeans are open standards for component software development and deployment that allow writing small code objects that can be reused in multiple applications and updated quickly. They also allow developers to expose legacy system data and functionality as services available over the Web, and therefore most application servers are based on these technologies.

For example, the CORBA architecture makes it possible to find and use services over the Internet. Similarly, Enterprise JavaBeans is a standard server component model for Java application servers that provides services to network-enable applications, so that they may be easily deployed on Intranets, Extranets, and the Internet [5].

CORBA provides universal connectivity in broadly distributed environments as well as cross-platform interoperation of both infrastructures and applications. The object Web model based on CORBA and other standards is shown in Fig. 40.4 [7].

**FIGURE 40.4** The object Web model based on CORBA and other standards provides universal connectivity in distributed environments.

**FIGURE 40.5** CORBA provides a standard for interoperability that includes many services required by object applications.

CORBA currently provides many services including naming, security, transactions, and persistence, as illustrated in Fig. 40.5 [7].

## 40.4 Implementations of Internet Architectures

In this section, four popular Internet architectures developed by Sun, Netscape, IBM, and Microsoft are presented.

### Sun's Architecture

Initially, Sun Microsystems defined, in Fall 1996, Java-based application development architecture, which consisted of three tiers: the client tier that provided user interface, the middle tier for business logic and database access, and the database tier, as illustrated in Fig. 40.6 [8].

Sun selected Java language for the client tier, which provided more sophisticated GUI capabilities than HTML implementation. Client applets did not perform significant business logic functions in order to keep clients as thin as possible. Java technology was also used for the middle tier and the middle tier servers were implemented as standalone Java applications.

Because both client and middle tiers are implemented using Java, client middle tier communication was performed using remote method invocation (RMI), where the middle tier servers created the necessary RMI objects and made them available to clients via the RMI object registry. The middle tier communicated with the database via the JDBC API. This architecture is based on client-server computing model, in which client resides on the user's desktop, and the middle and database tiers reside on one or more of five data centers around the company.

Recently, Sun has developed an enhanced multitier architecture, which includes an additional tier—the WebTop server tier, as shown in Fig. 40.7 [8].

In the three-tier architecture (Fig. 40.6), applets were dynamically downloaded at runtime to the users' locations from an application server. For remote locations and modem connections with constrained bandwidth, applet download time was a few minutes, which was unacceptable.

Another issue related to three-tier architecture was the access to network resources such as files and printers. Java prohibits applets from accessing any local or network resources. In addition, Java does not allow communications with any machine other than the one from which the applet was downloaded. As a result of these limitations, file access occurred at the middle tier. This meant that information might be sent from the client to the middle tier and then back to a file server near the client.

Introducing a new tier, WebTop server tier, has resolved the issues related to the three-tier architecture. The WebTop server runs the Java Web server and is located near the users it serves. This server is used as a cache for applets and static application data, so the first problem was resolved. The server also supports services that access network resources such as user files and printers, which are typically located near the users. Finally, the WebTop server is used to find the services that users need.

FIGURE 40.6 Sun's Java-based three-tier architecture for ASP.

FIGURE 40.7 Sun's Java-based multitier architecture for ASP.

In the architecture in Fig. 40.7 the client is thin and typically includes a graphical user interface written as an applet that runs from a Web browser. The application server tier provides access to data and implements business logic and data validation. The application server is responsible for all database transaction handling.

For the communication between the client and WebTop server tier and between the WebTop server and the application server tier, HTTP and RMI are used. Communication between application servers and databases is performed via JDBC.

One of the main benefits of the multitier architecture is that it increases application scalability and performance by enabling clients to be connected concurrently. In a client-server model clients are directly connected to databases, while in a multitier architecture only application servers connect directly to databases. In this way, the application server can process multiple requests from many clients through a pool of preallocated database connections, thus reducing the database server load. Load on the application server tier can be balanced by using multiple application servers.

Another benefit of the multitier architecture is that it supports thinner clients, because most of the logic runs in the application server and database tiers. Thus, broad range of client platforms can run the applications.

## Netscape's Architecture

Similar to Sun's architecture, Netscape recently developed multitier architecture for application development and distributed computing, which is based on the separation of presentation logic from application logic, as illustrated in Fig. 40.8 [2].

In Netscape's multitier architecture, the client tier is typically based on an open-standard browser such as Netscape Navigator. The presentation logic and GUI is built using HTML pages that include Java applets. At the content level, a Web server primarily uses HTTP. It provides base-level information and content services as well as simple database information access via Java, JavaScript, and other high-level CGI scripting languages such as Perl.

FIGURE 40.8 Netscape's multitier architecture for ASP.

The application server uses CORBA and JavaBeans components or objects. Transaction services enable access to relational databases and other legacy systems.

The first three levels in the multitier architecture in Fig. 40.8 are provided by Netscape technologies and products, while the last levels—back-end services and other legacy systems—are accessed through standard Internet interfaces.

## IBM's Architecture

IBM has developed the Component Broker, which is Internet middleware for distributed objects [7]. Component Broker is a software system that allows developers to build, run, and manage Web-enabled business objects, components, and applications. Component Broker consists of:

- tools for building distributed and business objects, and applications,
- a runtime that provides a distributed-object infrastructure on the middle tier, and
- a system management functions for the distributed object runtime and its resources.

Component Broker architecture, shown in Fig. 40.9, accepts inputs from any clients (Java or C++) transported via Internet InterORB Protocol, and ActiveX transported via a bridge. The object server consists of components that provide control, services, context, and connection resources.

The Component Broker receives client requests through the CORBA-compliant object request broker (ORB). Object services are supplied through the CORBA common object services (COS). These services provide object transaction services, database services, system services, and object management functions, as illustrated in Fig. 40.9.

Application adapters connect Component Broker object applications with existing software systems and applications.

## Microsoft's Architecture

Microsoft Internet architecture is a component-based architecture based on Windows DNA [14]. The heart of Windows DNA is the component object model (COM) that allows developers to build applications from binary software components at any tier of the application architecture. These components

FIGURE 40.9 Architecture of IBM's Component Broker at the middleware tier.

provide support for packaging, partitioning, and distributing application functionality [14]. Distributed COM (DCOM) enables communications between COM components that reside on different machines. DCOM is a competing model for distributed object computing to CORBA, described in section 40.3.

## 40.5 A Contemporary Architecture for Application Service Providers

In this section, ASP computing architecture using server-based computing model and the related ASP application architecture is presented.

### ASP Computing Architecture

Our computing architecture for application service providers is based on the server-based computing model, described in the subsection on "Computing Models for Internet-Based Architectures." As we indicated earlier, in server-based computing all applications and data are managed, supported, and executed on the server. This architecture provides the following benefits:

- Single-point management
- Predictable ownership costs
- High reliability
- Bandwidth-independent performance
- Universal application access
- Use of thousands of off-the-shelf applications
- Low-cost and fast application development
- Use of open standards
- Graphical and rich user interface
- Wide choice of client devices

The proposed server-based architecture uses two technologies developed by Citrix:

- Independent computing architecture (ICA)
- Windows-based terminal (WBT)

*Independent computing architecture* is a Windows presentation services protocol that turns any client device (thin or fat) into the thin client. The ICA consists of three components: server software, client software, and network protocol.

**FIGURE 40.10** The proposed architecture for ASP uses server-based model. All applications are executed at the server or cluster of servers.

On the server, ICA separates applications from the user interface, while on the client users see and work with applications' interface. The application logic executes on the server. The ICA protocol transports keystrokes, mouse clicks, and screen updates over standard protocols requiring less than 20 kbps of network bandwidth.

A *Windows-based terminal* is a thin-client hardware device that connects to Citrix server-based system software. The WBT does not require downloading of the operating system or applications and there is no local processing of applications at the client, as in the case of other thin clients such as network computers or NetPCs. A WBT has the following features:

- An embedded operating system such as DOS, Windows CE, or any real-time operating system
- ICA protocol to transport keystrokes, mouse clicks, and screen updates between the client and the server
- Absolute (100%) execution of application logic on the server
- No local execution of application at the client device

The proposed architecture also allows consumers and business to access software applications from their Internet browsers. This is provided using Citrix's software *Charlotte*. In addition, software component *Vertigo* allows more interactive applications on the Web. This software allows customized Web pages such as electronic trading accounts to be updated automatically without hitting the refresh button on the computer.

The proposed architecture for ASP using server-based model and Citrix technologies is shown in [Fig. 40.10](#).

The proposed architecture is platform independent and allows non-Windows and specialized ICA devices to run Windows applications residing and executing on application server farm. Application server farm is a group of application servers that are linked together as a single system to provide centralized administration and scalability.

The architecture in [Fig. 40.10](#) allows ASPs to rapidly develop and deploy applications across complex computing environments. It also provides application access to all users, regardless of their location, type of client device, or form of network connectivity. The architecture can be applied to any type of client hardware, and therefore requires no change in client hardware. The system significantly reduces requirements for network bandwidth compared to other architectures. Finally, the proposed architecture reduces the total cost of application, as analyzed in section 40.6.

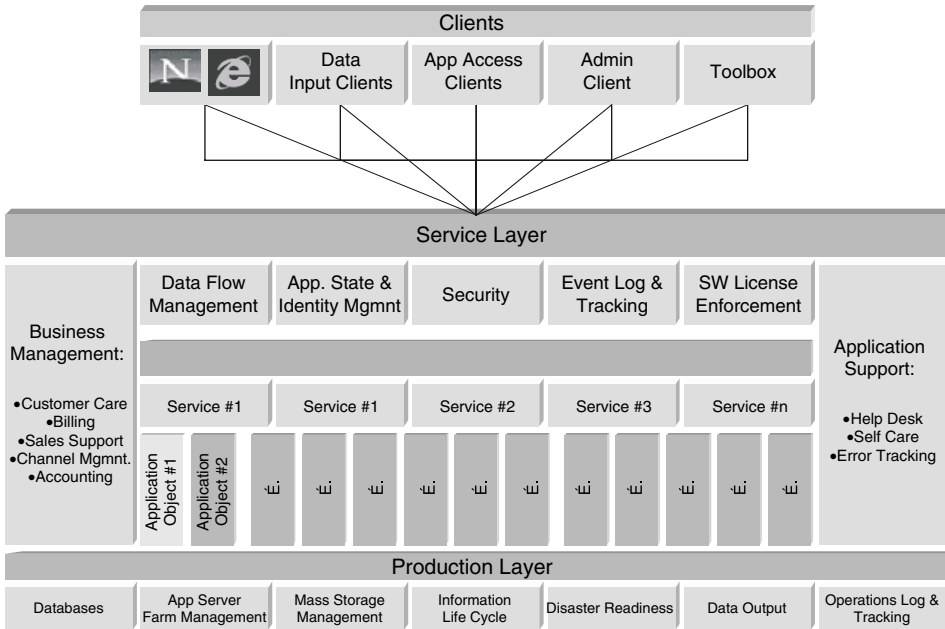

FIGURE 40.11 Architecture of an ASP application.

## ASP Application Architecture

To take maximum advantage of ASP computing architecture, a new breed of applications needs to be developed. The key drivers of new distributed application architecture is a need for wide spectrum of thin clients, bandwidth usage optimization, application multi-identity shared back-end computing, reliable data flow management, security, legacy application integration, and long list of service operation requirements. The diagram shown in Fig. 40.11 can depict a desired architecture of an ASP application.

### Client Software

ASP application client software is in general very different from types of client software provided as part of traditional client-server applications available on the market today. To support ASP business model, client software must be “thin,” i.e., requiring minimum computing power, installation and support effort, minimum communication bandwidth, and minimum version upgrade. Highly distributed nature of ASP service requires from client software ability to support versatile data inputs, highest level of user’s security, and ability to support multiple communication protocols.

### Data Input

ASP service architecture is in essence remote computing architecture, which requires capabilities to generate and import application data into the remote application. Data can be generated as part of specialized batch program or as by-product of third party software. Data input clients can be stand alone or integrated within other clients or legacy applications. Multistep data flow requires advanced information security, tracking, reporting, and above all ability to restore data in case that any stage system failure results in data loss. Data input clients may or may not be thin. The footprints of these clients are primarily defined by local functionality necessary to create the data at optimum cost.

### Application Access

Application access clients are characterized by limited local computation capability and remote command capability to the server side application concentrated at service back end. These clients are the ones that should be as generic and as thin as possible. The smaller and simpler the client, the lesser the operational

cost at the front end. The ideal application access client is plain Web browser. However, browser access is limited to very low level of functionality provided by HTML protocol. Function rich application computing requires specialized client software or plug-ins providing access to remote application at the back end.

### ***Toolbox***

To bridge the existing legacy applications with ASP service, an ASP application software requires a comprehensive set of APIs or application enabling tools providing the system integration capabilities and customizations.

### ***Administration***

This client should provide the end user with the ability to completely control its own application. Desired functions are: adding new users, setting up security profiles, managing application specific variables, usage tracking and reporting, and billing presentments and reporting.

### ***Security***

Client software security capability must include ability to authenticate users on the front end and to create virtual private channel of communication with the service back end.

### ***Service Layer***

Server side application is characterized by concentration of all computing and data intensive processes at back end, application multi-identity, sophisticated data flow management, and by its ability to integrate with business management, application support, and service production components. The ultimate goal of such application engineering is to create the fastest computing environment, economy of scale through all customers' sharing of common computing and data management infrastructure, and maximum operational readiness.

### ***Application Layer***

At the core of service layer is the application layer of software providing actual computing application packaged as specific service, for example: Service #1. This service application can be either stand alone application or user interface into integrated solution based on several other independent third-party applications.

### ***Data Flow Management***

Data generated through data input clients is managed by data flow management software. One can consider this software component as a data switch capable of accepting data input, decompressing and decoding data, identifying the owner of data and target data base, importing data in the target data base, caching and mirroring data at each stage for disaster readiness reasons, and creating logs for data input tracking and reporting.

### ***Application State and Identity Management***

An ASP provider will have many different applications for many different customers simultaneously. Also, each individual application will have many different users requiring different application setup and profile. Application state and identity management software acts as an application switch identifying individual users and applications and then assigning the appropriate user's profile. Therefore, ASP applications must support multiple identity capability. Ability to share the same computing and data management resources between many different users and applications is essential for reliable service delivery and economy of scale.

### ***Business Management***

The ASP application should also integrate into business management software enabling automatic account creation and usage data feed into billing solution.

### ***Application Support***

The ASP application should also integrate with application support solution that consists from customer self support site.

## 40.6 Evaluation of Various Architectures

Analysts and IT professionals have developed numerous models for estimating the total cost of IT services, sometimes called “total cost of ownership (TCO).” In the past, these models had the hardware-centric view because they analyzed the costs of owning and maintaining desktop computer hardware. In the age of the Internet, Web-based computing, and E-commerce, applications must be accessible across a wide variety of connectivity options, from low-speed, dial-up connections to wireless, WAN, and Internet connections. A contemporary cost analysis should consider the total cost of application ownership (TCA), rather than the total cost associated with specific computing devices. The Tolly Group has developed a model for comparing the TCA of different computing models, discussed earlier [9]. We present and discuss their results in this section.

In order to determine the cost of application deployment, four computing models introduced in section 40.1 can be analyzed from the following points of views:

- physical location of the application,
- execution location of the application,
- physical location of data,
- location of the user and means of connectivity.

The cost of complexity of deploying and managing an application strongly depends on physical location of the application. The cost of application distribution, installation, and managing of updates must be considered.

The choice of where an application is executed determines the hardware, network, and connectivity costs. An application can run on the server, on the client, or in a distributed server-client environment. In some cases, the application must be downloaded from a server to a client, which has an impact on performance and productivity.

The location of stored data determines the speed at which information is available. It also has an impact on the cost related to protecting and backing up critical corporate data.

The location of the user and the means of connectivity also have an impact on the cost and complexity of deploying an application.

Table 40.1 summarizes the application deployment characteristics for four computing models introduced in section 40.1 [9].

Tolly Group has analyzed and calculated the total cost of application ownership for a medium-size enterprise of 2500 users, with 175 mobile users working on the road. The calculated costs were divided into (a) Initial (first-year) cost (which includes hardware, software, network infrastructure, and user training) and (b) annual recurring costs (which includes technical support and application maintenance). The results of analysis are presented in Fig. 40.12.

Traditional desktop computing approach requires relatively high initial cost for hardware, software, network infrastructure, and training (\$14,000) as well as very high annual recurring costs for technical support and application maintenance (\$11,000 annually).

**TABLE 40.1** Computing Models and Application Deployment Characteristics

	Application Location	Application Execution	Data Location	User Access	Network Requirements
Traditional desktop	Client	Client	Client	Local	None
Client-server	Client and server	Client and server	Client and server	Lan, WAN, Internet	High bandwidth
Network-based	Server	Client and server	Server or client	LAN,WAN, Internet	High bandwidth
Server-based	Server	Server	Server	LAN,WAN, Internet	Low bandwidth

**FIGURE 40.12** Analysis of total cost of application (TCA) for various computing approaches [9].

Client-server and network computing approaches require slightly higher initial investment (\$16,000) in order to replace existing client hardware; however, annual recurring costs are reduced (\$9,500). This model becomes less expensive than the traditional desktop model from the third year forward.

The server-based approach gives the best TCA both in terms of initial costs and annual recurring costs (\$6,000 and \$2,600, respectively). The reason for it is that this model allows any type of client to access any application across any type of connection. This model also provides single point for the deployment and management of applications.

In summary, the server-based model, which was applied in our architecture, is the most efficient and cost-effective solution to application deployment and management.

## 40.7 Conclusions

This chapter presented and evaluated contemporary multitier Internet architectures, which are well suited for distributed applications on the Internet including ASPs. The chapter also evaluated several computing models for Internet-based architectures and proposed a server-based computing model, which has a number of advantages over the other models.

### 41.1 Introduction

---

The history of home entertainment consumer electronics begins in May 7, 1946, with the founding of Tokyo Tsushin Kogyo (Tokyo Telecommunication Engineering ) by Masaru Ibuka (36) and Akio Morita (25) in Tokyo, Japan. Had these two bright young men not met and combined their considerable resolve and talents, the home electronics business would not have accelerated so much as we see it today, and our semiconductor business efforts would have been aimed only for military purposes for a while.

In the Founding Prospectus, Ibuka eloquently stated his dreams for the company. Morita, together with the company's first directors headed by Kazuo Iwama, led employees to realize these goals. Throughout their work, the young force was inspired by the free and dynamic atmosphere of the "ideal" factory they were striving to create. From the onset, Ibuka, Morita, and Iwama endeavoured to develop unique and exciting products that fulfil their customers' dream.

Iwama was 35 when he visited Western Electric to study transistors in January 1954. Iwama was the first engineer in Japan who understood the concept of "electron fog" in the bipolar transistor device physics.

He worked as the leader of the bipolar transistor development project to realize the epoch-making portable bipolar transistor radio TR-55 introduced to the home entertainment electronics market in August 1955.

Seven years had passed since the invention of the bipolar transistor in Bell Lab in December 1947. I was only seven years old and had no idea about how a transistor works at that time.

I was a junior undergraduate at CalTech in Pasadena, California, in 1969 when I learned how the bipolar transistor and MOSFET work with the classical textbook by Grove. My class instructor was Prof. James McCaldin who was known as the co-inventor of basic planar passivation technology in modern MOS transistor fabrications.

In the summer of 1971, I visited Sony Atsugi plant right after I received a B.S. from CalTech and worked as a reliability engineer in Bipolar IC production line for Sony's Trinitron color TV sets.

In the fall of 1971, I returned to CalTech to pursue further my graduate work and learned how to design MOS LSIs from Professor Carver Mead. My Ph.D. thesis was about the buried channel CCD imagers, which can be applied to low light intensity solid state imagers. Prof. T.C. McGill was my Ph.D. thesis advisor.

After defending my Ph.D., in February 1975, I joined Sony at the Central Research Center in Yokohama, Japan, and engaged in further research on high-performance CCD imagers project headed by Iwama who was the pioneer engineer in the early bipolar technology development effort in Sony.

My first patent filed in Sony in November 1975 was about a simple pnp-substructure used as the light sensing device for imagers. The sensor structure is now called the HAD sensor in Sony’s current video cameras and digital still cameras.

Sony put most of its engineering sources in CCD imagers and camera systems in 1970s. We engineers had to design signal processing and camera control chips by ourselves. Those experiences were useful to apply to other MOS LSI design applications, which made possible the current home entertainment LSI chip sets such as digital cameras, home robots, and games.

In this chapter, some basic semiconductor device concepts are first reviewed briefly. They are about the concept of “electron fog,” the bipolar and MOSFET device model, the buried channel CCD imager structure, and the pnp-substructure which is used as the light sensing device, which is now universally adopted in most of high performance solid state imagers. Then, some general discussions on the product specifications and performance aspects of the home entertainment consumer LSI chip sets such as for digital cameras, home robotics, and games are presented in detail.

## 41.2 Basic Semiconductor Device Concepts

In this section, some introductory comments on the basic semiconductor device concepts are explained. They are strongly related to the microelectronics of the present home entertainment LSI chips.

### Concept of Electron Fog

Figure 41.1 shows the electron fog in metal and semiconductor. Electrons in metal are depicted in this picture as the moisture above the water surface in the container, while the electrons in the semiconductor are depicted as the moisture on the top of a floating box in water. If the box is heavy, the water surface is very close to the top of the box and there is a lot of moisture.

FIGURE 41.1 Electron fog model in metal and semiconductor.

FIGURE 41.2 Bipolar transistor action.

This corresponds to the n-type semiconductor band diagram. If the box is relatively light, only a small bottom portion of the box is submerged into the water and the top of the box can be quite dry, and there will a lot of bubbles (holes) under the bottom of the box. This corresponds to the p-type semiconductor.

Applying these p- and n-type semiconductor box models, a diode behavior model can be constructed and the diode rectifying characteristics can be explained.

### Bipolar Transistor Device Model

Figure 41.2 shows energetic boys (electron fog in the emitter region) trying to climb a hill (base region) to catch the girls on the hill (hole fog, which is the majority carrier in the base region). Some of the boys can luckily catch girls on the hill, recombine, become happy and disappear as light or heat energy. But the hill width is very short and most of the boys will not have enough time to catch girls and fall down the cliff (the base-collector depletion region). The poor boys are now collected deep down the cliff in the collector region.

In the time interval  $\Delta t$ ,  $I_E \Delta t$  boys are jumping to the hill to catch girls on the hill. Some boys are lucky enough to catch girls on the hill. The number of girls caught by the energetic boys in  $\Delta t$  is  $I_B \Delta t$ , which is proportional to the number of the average boys on the hill  $Q_n$ . The girls are supplied as the base current  $I_B$ . Other salient physical parameters normally used in the bipolar transistor device modeling are also given in the figure.

### MOSFET Model

Figure 41.3 shows a MOSFET structure. If you see how the electron fog moves from the left source n+ region to the right n+ region through the Si-SiO<sub>2</sub> surface under the MOS gate, one can see that it is also considered as an electron transportation along an npn-structure. In this case, however, the potential in the p-region is controlled by the gate voltage isolated by the thin oxide.

The figure shows the electron fog moving from the source to the region under the gate at the onset of strong inversion at the Si-SiO<sub>2</sub> surface. At this point the electron fog density at the channel is equal to the density of the majority “hole fog” in the p-type Si substrate, and the gate voltage at this point is defined to be the threshold voltage  $V_{th}$  of the MOSFET.

Figure 41.4 shows water flowing from the right source region to the left drain region through the water gate. The depth of the channel  $V_{ch}$  is given as  $(V_g - V_{th})$ , where  $V_g$  is the applied gate voltage which induces the channel depth  $V_{ch} = (V_g - V_{th})$ . The amount of the water flow  $I$  is proportional to the mobility  $\mu$ , the water amount  $Q$  under the gate and the electric field  $E$ , i.e.,  $I = \mu QE$  can be written in this rough approximation.

$$V_{th}(V_{BB}, V_S) = V_{FB} + \{B + V_S - V_{BB}\} + \gamma \sqrt{\{B + V_S - V_{BB}\}}$$

$$V_{FB} = V_{BB} - (kT/q) \ln\{N_c N_A/n_i^2\} - \{\chi_{Si} - \phi_m\}/q + Q_{SS}/C_{OX}$$

$$K = q \epsilon_{Si} N_A / C_{OX}^2$$

$$\gamma = \sqrt{2K}$$

$$B = 2(kT/q) \ln(N_A/n_i)$$

FIGURE 41.3 MOSFET at Onset  $V_G = V_{th}$ .

FIGURE 41.4 MOSFET I-V characteristics.

In the first approximation, take  $E = (V_d - V_s)/L$ , where  $V_d$ ,  $V_s$ , and  $L$  are the drain voltage, the source voltage, and the gate channel length. The total charge can be approximated as  $Q = WC_o \Delta V$ , where  $W$  and  $C_o$  are the channel width and the oxide capacitance of the actual corresponding MOSFET transistor, respectively. Now,  $\Delta V$  corresponds to the voltage difference between the average water surface  $(V_d + V_s)/2$  and the channel potential  $V_{ch} = (V_g - V_{th})$ .

That is,  $\Delta V = (V_d + V_s)/2 - V_{ch}$ . Hence, since  $Q = WC_o \Delta V$ , the equivalent amount  $Q$  of the water (or charge) under the gate is given as  $Q = WC_o [(V_d + V_s)/2 - V_{ch}]$ , where  $V_{ch} = (V_g - V_{th})$ ,  $E = (V_d - V_s)/L$ .

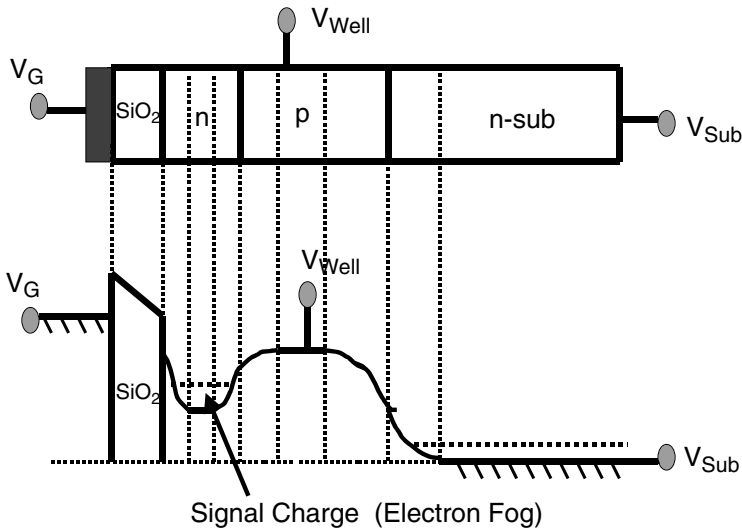

FIGURE 41.5 Buried channel CCD structure.

Now if these relationships are put into the original equation  $I = \mu QE$ , this leads, without going through the calculations normally done in the classical gradual channel approximation, finally to the classical MOS I-V equation:

$$\begin{aligned}
 I &= (W/L) \mu C_o [V_d + V_s - \phi_{ch}] (V_d - V_s) \\
 &= (W/2L) \mu C_o [V_d + V_s - 2(V_g - V_{th})] (V_d - V_s)
 \end{aligned}$$

## Buried Channel CCD Structure

Figure 41.5 shows the physical structure and the potential profile of a buried channel CCD. The signal charge is the electron fog in the lightly doped n-region at the surface. As you can see, these signal charges are isolated from the direct contact to the Si-SiO<sub>2</sub> interface and do not suffer the charge trapping. This structure gives a good CCD charge transfer efficiency of more than 99.9999% along the buried channel CCD shift register in the direction of this chapter. At very high light, excess charge can be drained into the substrate by lowering the well voltage  $V_{well}$  or making the substrate voltage very deep and inducing the punch-through mode in the n-p-n(sub) structure.

High-density and high-performance, solid-state imagers became available applying this structure as the scanning system. The surface n-layer is completely depleted when there is no signal charge. It is dynamically operated.

It is considered as one extended application of dynamic MOS device operations. The most well-known dynamic operation of a MOS device application is the DRAM data storage operation.

## HAD Sensor, a pnp-substructure

The floating diode structure for image sensing unit was well known in early 1970s. The author simply proposed to use a pnp-substructure instead for the imaging element. Figure 41.6 shows the proposed structure.

It is a simple pnp bipolar transistor structure itself with a very lightly doped base region, operated in the strong cut-off mode with the base majority charge completely depleted.

It is the first practical application of the bipolar transistor in dynamic operation mode, which turned out to be the best structure and way to convert photons to electrons for imaging including the current MOS imagers applications. The sensor structure is now called the HAD sensor in Sony's current video cameras and digital still cameras.

FIGURE 41.6 A typical PNP bip Tr structure in the early 1970s, and a proposed application as an image-sensing element in 1975.

### 41.3 LSI Chips for Home Entertainment

#### Digital Still Camera

The picture in the Fig. 41.7 shows a 2/3 in. 190 K pixel IT CCD imager, ICX016/XC-37, which the author designed when he was still a young CCD design engineer in early 1981. This model became the model of the world's first consumer CCD video camera for mass production in 1983.

The goal now is to become "Imaging Device No. 1!" Many applications of CCD and LCD are used, as seen in Fig. 41.8.

FIGURE 41.8 Applications of CCD and LCD.

## AIBO, a Home Entertainment Robot

This subsection reviews the most popular product, the entertainment robot AIBO shown in Fig. 41.9. When you buy a brand new AIBO, it is like a baby, so it does not have any knowledge. It has a certain intelligence level that is preprogrammed. You can play with the AIBO and gradually your AIBO will recognize your gestures and voices. AIBO will remember the wonderful time you spent together with it. Actually the experience and knowledge AIBO accumulates during these memorable moments are stored in a chewing gum size NVRAM called a memory stick shown in Fig. 41.9.

This memory stick can be also used in other products such as PCs, digital audios, and DSCs. Unfortunately it is not used in PS and PS2 for generation compatibility as of now. But in one form or another, there is a definite need NVRAMs in PS, DSC, digital audio, PC, and the future home entertainment robots.

The twenty-first century will become an era of autonomous robots, which are partners of human beings. Autonomous robot will help and support people in the future. AIBO is designed to be the first product model of robot entertainment systems. The main application of this robot is a pet-style robot, which must be lifelike in appearance.

Although AIBO is not a nursing robot, the development of AIBO is the first step of the era of autonomous robots in the twenty-first century.

The following are some works done in the Digital Creation Laboratory at Sony. Most of the works were actually done by the pioneering engineers, Mr. Fujita, Mr. Kageyama, Mr. Kitano, and Mr. Sabe.

The epoch-making debut of AIBO, model ERS-110 in 1999, had the following features:

First of all, it has a CCD color camera with 180 K pixels. Of course, it does not have a mechanical shutter. It does not have any eyelid. It has an audio sensor called microphones, a pair of them for stereo audio pick-up. It also has an acceleration sensor, gyrometer, and also a tactile sensor. So, if you pat it on the head gently, it will show some happy gesture. If you strike it on the head, it will interpret it as your sermon. The moving joints have 18 degrees-of-freedom in total.

FIGURE 41.9 AIBO model ERS-110.

AIBO 2nd Generation, ERS-210

Sony Dream Robot, SDR-3

FIGURE 41.10 New AIBO models: ERS-210 and SDR-3.

Before introducing this first AIBO model, ERS-110, the basic research period lasted about five years. Now we have the second generation AIBO model, ERS-210 and also another type of robot, Sony Dream Robot, SDR-3, as seen in [Fig. 41.10](#).

The second generation AIBO model, ERS-210, has the following features:

Joint DOF: neck: 3, mouth: 1, ear: 2, legs:  $3 \times 4$ , tail: 2, total: 20

Sensors: color CMOS image

sensor (1100 K pixel)  
 Microphone  $\times$  2  
 Infrared sensor  
 Acceleration sensor  $\times$  3  
 Tactile sensor  $\times$  7  
 CPU: 64 bit RISC processor (192 MHz)  
 Memory: 32 MB DRAM  
 OS, Architecture: Aperios, OPEN-R1.1  
 IF: PCMCIA, memory stick

The model SDR-3 has the following features:

Joint DOF: neck: 2, body: 2, arms:  $4 \times 2$ , legs:  $6 \times 2$ , total: 24  
 Sensors: color CCD camera  
 1800 K pixel, microphone  $\times$  2  
 Infrared sensor, acceleration sensor  $\times$  2 gyrometer  $\times$  2, tactile sensor  $\times$  8  
 CPU: 64 bit RISC processor  $\times$  2  
 Memory: 32 MB DRAM  $\times$  2  
 OS, Architecture: Aperios, OPEN-R

It weighs 5.0 kg and its size is  $500 \times 220 \times 140$  mm.

It has an OPEN-R architecture. It is made of configurable physical components (CPCs). The CPU in the head recognizes the robot configuration automatically. The components are built for plug & play or hot plug-in use. The relevant information in each segment is memorized in each CPC.

Each CPS may have a different function such as behavior planning, motion detection, color detection, walking, and camera module. Each CPS is also provided the corresponding object oriented programming and software component.

With this OPEN-R architecture, the body can be decomposed or assembled anyway for plug & play or hot plug-in use. The diagram in Fig. 41.11 shows the details of the logical hardware block diagrams, which contain DMAC : FBK: CDT: IPE and HUB

FIGURE 41.11 Logical hardware block diagram.

FIGURE 41.12 Topology of ERS-110.

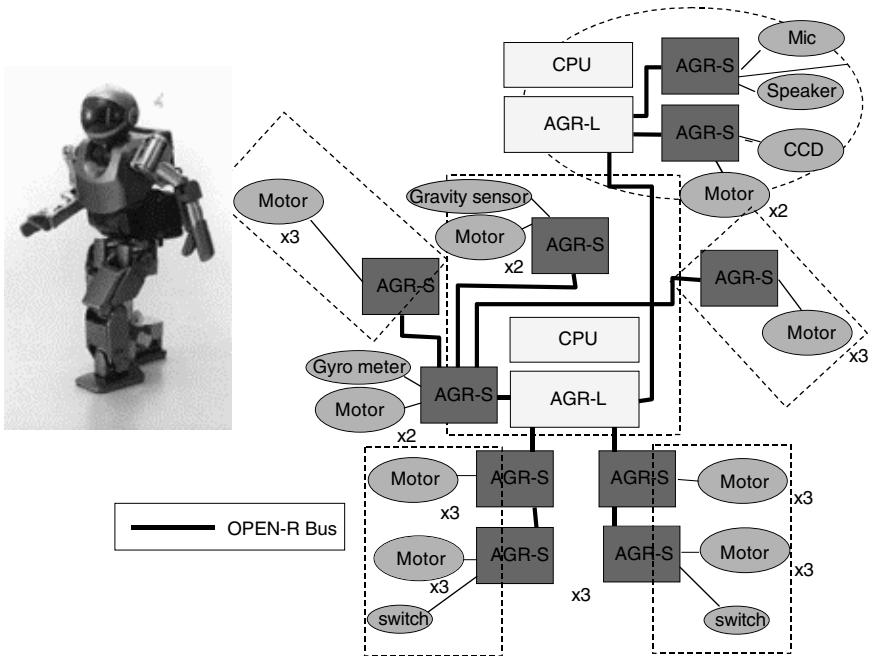

FIGURE 41.13 Topology of SDR-3x.

In the following two figures, Figs. 41.12 and 41.13, the topology of model ERS-110 and Model SDR-3x are shown, respectively.

At the same time, it is very important to have a powerful software platform that covers the top semantic layer to the deep bottom of the device driver objects codings. Careful design considerations are very important to make the middleware software components.

FIGURE 41.14 Form comparison.

FIGURE 41.15 Internal structure.

## Memory Stick

AIBO, VAIO PC, and other audio and video products now use memory sticks as digital data recording media.

In July 1997, Sony had a technical announcement. The following year, in January 1998, the VAIO center was inaugurated. On July 1998, Sony had a product announcement. The 4 Mbyte and 8 Mbyte memory sticks were on sale in September 1998. In February 1999, Sony announced Magic Gate, that is, memory sticks with copyright protection feature. Figure 41.14 shows the form comparison. The memory stick is unique in its chewing gum-like shape and it is much taller in length than other media. The difference in appearance of memory stick from other media is clear in size and features.

Figure 41.15 shows the internal structure. It is fool proof. It features a simple 10-pin connection and it is impossible to touch the terminals directly.

The shape was designed intentionally to make exchanging of media easy, without having to actually see them, and to guide the direction for easy and correct insertion. Much contrivance is made in the design.

In order to decrease the number of connector pins for ensuring reliability of the connectors, serial interface was adopted instead of parallel interface used in conventional memory cards. As a result, connector pins were reduced to 10. And as the structure is such that these pins do not touch the terminal directly, extremely high reliability is ensured. The length is same as AA size battery of 50 mm for further deployment to portable appliances. The width is 21.5 mm and the thickness is 2.8 mm.

The memory stick consists of Flash EEPROM and a controller, controlling multiple Flash EEPROM, flexible to their variations, and capable of correcting errors unique to different Flash EEPROMs used. The memory stick converts parallel to/from serial data with the controller designed in compliance with the serial interface protocol; any kind of existing or future Flash EEPROM can be used for the memory stick. The function load on the controller chip is not excessive, and its cost can be kept to a minimum.

It is light and the shape makes it easy to carry around and to handle. Also, the write-protection switch enables easy protection of variable data.

For still-image format, DCF standardized by JEIDA is applied. DCF stands for design rule for camera file system and JEIDA stands for Japan Electronic Industry Development Association. For voice format, ITU-T Recommendation G.726 ADPCM is adopted. The format is regulated for applications that convert voice data to text data by inserting a memory stick to a PC.

The memory stick can handle multiple applications such as still image, moving image, voice, and music on the same media. In order to do this, formats of respective application and directory management must be stipulated to realize compatibility among appliances. Thus, simply by specifying the “control information” format, one can have a new form of enjoyment through connecting AV appliances and the PC. This format, which links data handed in AV appliances, enables relating multiple AV applications. For example, voice recorded on IC recorder can be dubbed on to a still image file recorded by a digital still camera.

Presently, the music world is going from analog to digital, and the copyright protection issue is becoming serious along with the wide use of the Internet. The memory stick can provide a solution to this problem by introducing “Magic Gates (MG),” a new technology.

Open MG means (1) allowing music download through multiple electronic music distribution platforms, (2) enabling playback of music files and extracting CD on PCs (OpenMG Jukebox), (3) transferring contents securely from PCs to portable devices.

Figure 41.16 shows the stack technology applied to the memory stick with four stacked chips.

## PlayStation 2

PlayStation 2 was originally aimed at the fusion of graphics, audio/video, and PC. The chipset includes a 128-bit CPU called “Emotion Engine” with 300 MHz clock frequency with direct Rambus DRAM of 32 Mbyte main memory. The chipset also includes a graphic synthesizer chip with 150 MHz clock frequency. It has 4 MB video RAM as an embedded cache.

As SPUs, the chipset also has an I/O processor for X24 speed CR-ROM drive and X4 speed DVD-ROM. Figure 41.17 shows PlayStation 2 (SCPH-10000) system block diagram.

PlayStation 2, which Sony Computer Entertainment, Inc., released in March 2000, integrates games, music, and movies into a new dimension. It is designed to become the boarding gate for computer entertainment. PlayStation 2 uses an ultra-fast computer and 3-D graphics technology to allow the creation of video expressions that were not previously possible.

Although it supports DVD, the latest media, it also features backward compatibility with PlayStation CD-ROM so that users can enjoy the several thousand titles of PlayStation software. PlayStation 2 is designed as a new generation computer entertainment system that incorporates a wide range of future possibilities. The table shows the performance specifications of the graphic synthesizer chip, CXD2934.

FIGURE 41.18 4 MB EmDRAM for PSX2.

In addition to the 128-bit CPU Emotion Engine™ and I/O processor, Playstation 2 adopts several advanced technologies. The graphics synthesizer graphic engine, CXD2934GB, takes full advantage of embedded DRAM system LSI technology. The Fig. 41.18 shows the chip photograph of Sony's 0.25  $\mu\text{m}$  CMOS 4 MB embedded DRAM, which has 42.7 M Trs. The clock rate is 150 MHz, with 48 GB/s bandwidth. It can draw 75 M polygons per second. It has 384 pin in BGA. Its cross-sectional view is also shown here.

The semiconductor's optical integrated device technology contributes significantly to miniaturization and high reliability in the optical pickups, SLK3201PE, a two-wavelength laser coupler chip. Playstation 2 also adopts the optical disc system chip solution which has a solid track record, CXD2942R, a sound processor chip, and has earned the trust of the optical disc system market.

It also includes CXD1869 (CD/DVD signal processor LSI), CXP102064R (disk controller), CXA2605R (Cd/DVD RD matrix amplifier), and CXA3525R (analog video encoder).

The first commercial product for use in consumer products were the 0.5  $\mu\text{m}$  LSI chips for 8-mm camcorders in 1995. Then, Sony had 0.35  $\mu\text{m}$  LSI chips for MD products with low voltage operation of 2.0 V. Now, the 0.25  $\mu\text{m}$  Playstation 2 graphics synthesizer has eDRAM with 48 GB/s bandwidth. Figure 41.19 shows the EmDRAM history.

Sony Em-DRAM has a high-band performance of 76.8 GB/s. See Fig. 41.20. In the following three figures, Figs. 41.21, 41.22, and 41.23, the memory cell size trend, some details of our embedded DRAM history, and the vertical critical dimensions between 0.25 and 0.18  $\mu\text{m}$  EmDRAM process are shown, respectively.

Now, a few words on the feature and critical issues of 130 nm Emb-DRAM LSI process. The most advanced design rule to achieve high performance Tr –

- Enhance resolution, and
- refine OPC system (speed, accuracy)
- Large variation in duty cycles
- Reduce isolation—dense bias
- High global step-> Enlarge D.O.F
- High aspect hole process
- Enhance etching durability
- OPC = optical proximity correction
- DOF = depth of focus

FIGURE 41.19 Embedded DRAM history.

### High-Bandwidth DRAM Performance

FIGURE 41.20 Performance of embedded DRAM.

In the  $0.18\ \mu\text{m}$  EmDRAM process, the optical proximity correction (OPC) technology and the phase-shift mask technology (PSM) were very important. See Figs. 41.24 and 41.25. Many high-performance manufacturing and measurement automatic machines, such as those shown in Fig. 41.26, are necessary.

Figure 41.27 shows the cross-sectional view of  $0.18\ \mu\text{m}$  EmDRAM, which was realized by utilizing all these technologies and high-performance machines.

Now some comments on key factors: technology extension such as optical extension and full flat process technology. KrF lithography optical extension features high NA, ultra-resolution, thin photo resist, and the OPC technology. Wirings are fully planarized interlayers of Cu/Dual Damascene. The EmDRAM features a fully planarized capacitor with the global step-less DRAM/logic structure by self-align process.

## 41.4 Conclusion

Some introductory comments on the basic semiconductor device concepts were given. They are strongly related to the microelectronics of the present home entertainment LSI chips. The chapter covered in detail some product specifications and performance aspects of the home entertainment LSI chip sets, such as those used in digital cameras, home robotics, and games. Cost of EmDRAM and its solutions by using EmDRAM are strongly related with new market creation such as PSX2. The EmDRAM technology for PS2/computer and some other future home entertainment electronics gadgets has a potential to be the technology driver in the years to come.

## 42.1 Bluetooth—A Cable Replacement and More

---

*John F. Alexander and Raymond Barrett*

### What is Bluetooth?

Anyone who has spent the time and effort to connect a desktop computer to its peripheral devices, network connections, and power source knows the challenges involved, despite the use of color-coded connectors, idiot proof icon identification, clear illustrations, and step-by-step instructions. As computing becomes more and more portable, the problems are compounded in the laptop computer case, and the palmtop device case, let alone the cell phone case, where cabling solutions are next to impossible. The challenges associated with cabling a computer are tough enough for purposes of establishing the “correct” configuration, but are nearly unmanageable if the configuration must be dismantled each time a portable device is carried about in its portable mode.

Similar to a knight in shining armor, along comes Bluetooth; offering instant connectivity, intelligent service identification, software driven system configuration, and a myriad of other advantages associated with replacing cabling with an RF link. All of this good stuff is provided for a target price of \$5 per termination, a cost that is substantially lower than the cost of most cables with a single pair of terminations. This miracle of modern communication technology is achieved with a 2.4-GHz frequency hopping transceiver and a collection of communications protocols. At least, that is the promise. The participants who include such industrial giants as IBM, Motorola, Ericsson, Toshiba, Nokia, and over a thousand other consortium participants provide credibility for the promise.

There has been considerable interest in the press over the past few years in the evolution of the open Bluetooth® [1] specification for short-range wireless networking [2]. Bluetooth is one of many modern technological “open” specifications that are publicly available. The dream is to support Bluetooth short-range wireless communications (10–100 m) any where in the world. The 2.4 GHz frequency spectrum was selected for Bluetooth primarily because of its globally available free license. As we entered the twenty-first century there were already more than 1800 members of Bluetooth special interest group (SIG) [3]. Its reasonably high data rate (1 Mb/s gross data rate) and advanced error correction make it a serious consideration that is irresistible for hundreds of companies in a very diverse group of industries, all interested in ad hoc wireless data and voice linkages.

The Bluetooth specification utilizes a frequency hopping spread spectrum algorithm for the hardware and specifies rapid frequency hopping of 1600 times per second. As one might conclude 2.4 GHz digital radio transceivers that support this type of high frequency communication are quite complex, however, the hardware design and implementation is just the tip of the iceberg in understanding Bluetooth. The goal of this chapter is to provide the reader with a thorough overview of Bluetooth. An overview is detailed in the standard, but the Bluetooth specifications alone are thousands of pages.

Some of the proposed and existing Bluetooth usage models are the cordless computer, the ultimate headset, the three-in-one phone, the interactive conference (file transfer), the Internet bridge, the speaking laptop, the automatic synchronizer, the instant postcard, ad hoc networking, and hidden computing.

### Competing Infrared Technology

First, a brief digression will be taken into infrared wireless communication. With the advent of the personal digital assistant (PDA), it was obvious for the need of a low cost, low power means of wireless communication between user’s devices and peripherals. At an Apple Newton users group one could see hundreds of enthusiasts “beaming” business cards back and forth. As other vendors came out with PDA each had its own proprietary infrared communication scheme. Eventually one “standard” method of communication between users applications came about as an outgrowth of the work of the Infrared Data Association. This specification became known as IrDA [4]. An international organization creates and promotes interoperable, low cost infrared data interconnection standards that support a walk-up, point-to-point user model. The standards support a broad range of appliances, computing, and communications devices.

Several reasons exist for mentioning the IrDA. First, many of the companies involved in the Bluetooth effort are members of the IrDA and have many products, which support IrDA protocols. Thus, much of the learning time in developing and attempting to implement a workable open standard for ad hoc short range wireless communication is *in house*. Also the IrDA has been one of the many well thought out high technology products that never gained much user acceptance. Many of the members of the Bluetooth SIG were anxious not to make the same mistake but to gain a way to profit from all the hard work invested in IrDA.

The proposed solution seemed simple. Just include more or less the entire IrDA software protocol stack in Bluetooth. Thus, the many already developed but seldom-used “beaming” applications out there could readily use Bluetooth RF connectivity. Whether this was a good idea, only time can tell. But it is important in understanding the Bluetooth specification because it is so heavily influenced by millions of hours of corporate IrDA experience and frustrations.

## Secure Data Link

Providing a secure data link is a fundamental goal for the Bluetooth SIG. One could envision the horror of walking through an airport with your new proprietary proposal on your laptop and having the competition wirelessly link to your machine and steal a copy. Without good security Bluetooth could never gain wide acceptance in virtually all cell phones, laptops, PDAs, and automobiles that the drafters envisioned.

Secure and nonsecure modes of operation are designed into the Bluetooth specification. Simple security is provided via authentication, link keys, and PIN codes, similar to bank ATM machines. The relatively high frequency hopping at 1600 hops/sec adds significantly to the security of the wireless link. Several levels of encryption are available if desired. In some cases, this can be problematic in that the level of encryption allowed for data and voice varies between countries and within countries over time. The Bluetooth system provides a very secure environment, eavesdropping is difficult. Bluetooth probably will be shown to be more secure than landline data transmission [5].

## Master and Slave Roles

The Bluetooth system provides a simple network, called a piconet, nominally 10 m in radius. This is the 1-mW power mode (0 dbm). There is also a 10-mW mode allowed, which probably could reach a 100 m in ideal cases, but it may not become widely implemented. One should think of a Bluetooth piconet as a 10 m personal bubble providing a moderately fast and secure peer-to-peer network. The specification permits any Bluetooth device to be either a master or a slave. At the baseband level, once two devices establish connection, one has to be a master and the other a slave. The master is responsible for establishing and communicating the frequency-hopping pattern based on the Bluetooth device address and the phase for the sequence based on its clock [6].

Up to seven active slaves are allowed all of which must hop in unison with the master. The Bluetooth specification allows for the direct addressing of up to 255 total slave units, but all but seven of the slaves must be in a “parked” mode. The master–slave configuration is necessary at the low protocol levels to control the complex details of the frequency hopping, however, at higher levels, the communication protocol is a peer-to-peer and the connection established looks like point-to-point. The protocol supports several modes, which include active, sniff & hold, and park. Active uses the most power. While the master unit is in sniff mode, it conserves power by periodically becoming active. Additionally, the slave is in a hold mode but wakes up periodically based on timing from the master to “see” if any data is ready for it. While a slave is in park mode it consumes the least power, but the slave still maintains synchronization with the master.

A more complex Bluetooth communication topology is the scatternet. In one of the simpler scatternet schemes there are two masters with a common slave device active in two piconets. In another variation on the scatternet, one device is a slave in one piconet and the master in another. Using this scatternet idea some have speculated that an entire wireless network could be formed by having many piconets,

each with one common node. Theoretically, this would work, but the rest of the original Bluetooth specification is not designed for making Bluetooth a wireless LAN. It is likely the newer SIG work group on personal area networking will be interested in expanding the definition and capability of Bluetooth scatternet capability. Currently there is lots of interest in forming location aware ad hoc wireless networks [7]. NASA has already approached this author for ideas for use of Bluetooth for ad hoc small area networks in space missions. The appeal of a wireless link made up of five dollar, very small, low-power, self-configuring, parts capable of connecting various sensors is irresistible for complex space missions where power and payload weight is at a premium.

## **Bluetooth SIG Working Groups**

To understand the Bluetooth specification it is important to understand how the very large Bluetooth SIG is organized. The actual work in producing the various specifications is done by the various SIG working groups. Given that the Bluetooth specification is thousands of pages of detailed technical documentation, it is not practical to just sit down and read the specification sheet. Briefly, five major groups compose the SIG including the air interface group, the software group, the interoperability group, the legal group, and the marketing group [3].

The software group contains three working subgroups primarily responsible for the Bluetooth protocol stack. These are the lower Transport Protocol Group, the Middleware Protocol Group, and the Application Group. The protocol stack follows the international origination of standardization (ISO) seven-layer reference model for open system interconnection [8].

## **The Transport Protocol Group**

The Transport Protocol Group includes ISO layers one and two, which are the Bluetooth radio, the link controller baseband, the link manager, the logical link controller and application protocol (L2CAP) layer, and the host controller interface. Collectively this set of protocol groups form a virtual pipe to move voice and data from one Bluetooth device to another. Audio applications bypass all of the higher level layers to move voice from one user to another [6].

The L2CAP layer prevents higher level layers from having to deal with any of the complexity of the frequency hopping Bluetooth radio and its complex control or special packets used over the Bluetooth air radio interface. The responsibility of the L2CAP layer is to coordinate and maintain the desired level of service requested and coordinate new incoming traffic. The L2CAP layer's concern is with asynchronous information (ACL packet) transmission [6]. This layer does not know about the details of the Bluetooth air interface such as master, slave, polling, frequency hopping, and such. Its job is to support the higher layer protocol multiplexing so multiple applications can establish connectivity over the same Bluetooth link simultaneously [9].

Device authentication is based on an interactive transaction from the link manager. When an unknown Bluetooth device request connectivity, the device requested ask the requester to send back a 16 byte random number key, which is similar to the familiar bank ATM PIN code procedure. Once a device is authenticated it is necessary for the device to store the authentication codes so this process can be automatic in future connections. Link encryption up to 128 bytes is supported and is controlled by desirability and governing legal issues of the area. Encryption applies only to the data payload and is symmetric.

Power management of connected devices is also handled at this level. In sniff mode the slave must wake up and listen at the beginning of each even-numbered slot to see if the master intends to transmit [6]. In hold mode the slave is suspended for a specified time. The API for hold mode puts the master in charge but provisions are available to negotiate the time. In Park mode, the slave dissociates itself from the piconet while still maintaining synchronization of the hopping sequence. Before going in to park mode the master informs the slave of a low-bandwidth beacon channel the master can use to wake the parked slave if there not already seven active slaves.

Paging schemes allow for a more repaid reconnection of Bluetooth devices. For example, paging is used in the event a master and a slave need to switch rolls to solve some problem such as forming some

sort of local area network. Support for handling paging is optional in the Bluetooth specification. Another role of the link managers is to exchange information about each other to make passing data back and forth more efficient.

## **The Bluetooth Transceiver**

The Bluetooth systems operate in the industrial and scientific (ISM) 2.4 GHz band. This band is available license free on a global basis and is set aside for wireless data communications. In the United States the Federal Communication Commission (FCC) sets up rules for transmitters operating in the ISM band under section 15.247 of the Code of Federal Regulations. The frequency allocated is from 2,400 MHz to 2,483.5 MHz. The Bluetooth transceiver operates over 79 channels each of which is one megahertz wide. At least 75 of the 79 frequencies hoped to be pseudo-random. Bluetooth uses all 79 channels and hops at a rate of 1600 hops per second.

## **The Middleware Protocol Group**

The Middleware Protocol Group includes ISO layers three and six, which are made up of the RFCOMM protocol, the service discovery protocol (SDP), IrDA interoperability protocols, IrDA, and Bluetooth wireless protocol, and the audio and telephony control protocol. Fitting Bluetooth into the ISO model is really up to the developer. If you want to make it fit it makes sense, but there is lots of strange baggage imbedded protocols in Bluetooth that makes this difficult to see. First, we have already seen the voice communication connect down at the L2CAP layer. Now we are faced with how the toss in multiplexed serial port emulation, IrDA interoperability, and a bunch of protocols from telephony world. No wonder the standard goes on for thousands of pages and hundreds of companies around the world are struggling with comparability testing of various Bluetooth devices designed from this very complex specification.

## **The Application Protocol Group**

The Application Protocol Group includes ISO layer seven. This grouping contains the most extensive variety of special-purpose profiles all of which rely on the six lower levels for service. These include the generic profiles, the serial and object exchange profile, the telephony profiles, and the networking profiles.

The generic profiles includes the generic access profile and the service discovery application profile. The serial and object exchange profile contains the serial port profile, the generic object exchange profile, the object push profile, the file transfer profile, the synchronization profile, the networking profiles, the dial-up networking profile, the LAN access profile, the fax profile, the telephony profiles, the cordless telephony profile, the intercom profile, the headset profile, and the cordless telephony profile. Most of these applications profiles are self-explanatory and are only of detailed interest to the software developer when developing a specific application using the appropriate profile. This is not to say that they are not important, but they provide very detailed application programmer interfaces (API) [15].

The possible Bluetooth applications keep expanding. This stimulates interest in expanding the array of application profiles in the Bluetooth specification. Several of the newer application profiles are the car profile, a richer audio/video profile, and a local positioning profile.

## **Bluetooth Development Kits**

Given the obvious complexity of the Bluetooth hardware and software applications, having access to good development kits is essential to speed the implementation of the specification. The first inexpensive development kit to become widely available to universities was Ericsson's Bluetooth Application and Training Toolkit. This is a first generation Bluetooth kit that demonstrates important Bluetooth features and has a well defined, but extensive proprietary API in C++. Application development is possible, but is time-consuming and tedious requiring knowledge of C++ to learn a vast API. Newer kits, specifically for development, are more efficient.

Cambridge Silicon Radio (CSR) Bluetooth silicon radio has been very well publicized in the Bluetooth development and features “all CMOS” one chip solution. The CSR development kit includes software for CRR “BlueCore™” [11] IC with on-chip Bluetooth™ protocol and a PC development environment. Tools for embedded “1-chip” products are provided. Bluetooth BlueCore-to-host serial protocol and integrated Bluetooth protocol: BlueStack™. An innovative feature is that BlueCore devices enable users to configure the level of BlueStack that loads at boot time using software switches. SCR claims that running the full Bluetooth protocol locally on a BlueCore device significantly reduces the load on the host embedded processor, delivering major advantages to users of their Bluetooth system on a chip solution [12].

Many other development tools can be found currently at the [http://www.bluetooth.com/product/dev\\_tools/development.asp](http://www.bluetooth.com/product/dev_tools/development.asp). The above two are referenced because they have been around for a year or so and the authors have direct experience with them [2].

## Interoperability

There is a conflict with IEEE 802.11 Wireless Network Specification, which uses a direct sequence spread spectrum approach in the same frequency band. The direct sequence modulation is incompatible with the frequency hopping approach employed in Bluetooth. It is unlikely that an elegant interoperability solution can be found, without duplication of the entire hardware solutions for each; however, some early ad hoc reports in the trade press seem to point to the interoperability between 802.11 and Bluetooth to be minor [13,14].

Both operate in the 2.4 GHz ISM band, and both are a form of spread spectrum, but the 802.11 is direct sequence modulated spread spectrum and allows more power. Bluetooth is frequency hopping and low power.

## Bluetooth Hardware Implementation Issues

First, for Bluetooth to achieve the stated goals for widespread usage at low cost, there are severe hardware constraint issues to be addressed. Second, the environment into which Bluetooth is likely to be deployed is rapidly changing. Finally, the business models for adoption of Bluetooth technology are also impacted.

Broadly speaking, there are two classes of hardware implementation for Bluetooth, one employs discrete multiple chips to produce a solution, and a second in which Bluetooth becomes an embedded intellectual property (IP) block in a system-on-a-chip (SoC) product.

For the short run, the multiple chip strategy provides an effective implementation directed at prototype and assembly-level products. The strategy is effective during the initial period of development for Bluetooth, while the specification is still evolving and the product volumes are still low; however, a strong case can be made that the high volumes, low cost, and evolving environment make an IP block approach inevitable if Bluetooth is to enjoy wide acceptance.

In addressing the environmental issues, the most widely dispersed communications product today is the cell phone, with its service variants. The Internet connectivity of cell phones is soon to surpass the Internet connectivity of the desktop computer. The consequence of the cell phone driving the environment for all information processing connectivity under its constraints of low power, tight packaging, high volume, and low cost manufacturing forces examination of IP blocks for SoC solutions.

Bluetooth is highly attractive for cell phone products as a wire replacement, enabling many of the existing profiles from a cell phone, as well as providing expansion for future applications. The desktop computer embraces Bluetooth also as a wire replacement, but has a history of services supported by cabling. The cell phone cannot support many services with cabling, and in contrast to the desktop, service extensions for the raw communication capability of 3G and 4G cell phones must be addressed by wireless solutions.

Once Bluetooth IP block solutions exist, the market forces will drive high-volume products toward either embedded or single-chip Bluetooth implementations.

Technological hurdles must be overcome in the road toward Bluetooth IP block solutions. Presently, the RF front-end solutions for Bluetooth are nearly all implemented in bipolar IC technology, implying at least a BiCMOS IC, which is widely recognized as too high cost for high-volume SoC products. As the lithography becomes available for denser CMOS IC products, the deep submicron devices provide the density and speed increases to support SoC solutions in the digital arena, and also improve the frequency response of the analog circuitry, enabling the possibility of future all-CMOS implementation.

In addition, communications system problems must be solved in order to ensure the feasibility of an all-CMOS implementation. For example, one of the more popular architectures for a modern communications receiver is the zero-IF (ZIF) approach. Unfortunately, the ZIF approach usually converts the RF energy immediately to baseband without significant amplification, which places the very small signal in the range of  $1/f$  noise of the semiconductor devices employed. Typically, the only devices with substantially low enough noise are bipolar devices, which are to be avoided for system level considerations. Alternative architectures that are suitable include variants of super heterodyne architectures that usually require tuned amplifiers, which are also seldom suitable for integration. One approach that seems to meet all the requirements is one variant of the super heterodyne architecture known as low-IF, that places the energy high enough in the spectrum to avoid noise considerations, but low enough to be addressed by DSP processing to achieve the requisite filtering.

Regardless of the particular architecture chosen, the rapid channel switching involved in the frequency-hopping scheme necessitates frequency synthesis for local oscillator functions. There is considerable design challenge in developing a fully integrated voltage-controlled-oscillator (VCO) for use in a synthesizer that slews rapidly and still maintains low phase noise.

To compound the above issues, true IP block portability implies a level of process independence that is not currently enjoyed by any of the available architectures. Portability issues are likely to be addressed by intelligence in the CAD tools that are used to customize the IP blocks to the target process through process migration and shrink paths.

## 42.2 Signal Processing ASIC Requirements for High-Speed Wireless Data Communications

---

*Babak Daneshrad*

### Introduction

To date, the role of application specific integrated circuits (ASICs) in wireless communication systems has been rather limited. Almost all of the signal processing demands of second generation cellular systems such as GSM and IS-136 (US TDMA) can be met with the current generation of general purpose DSP chips (e.g., TI TMS320, Analog Device's ADSP 21xx, or Lucent's DSP16xx families). The use of ASICs in wireless data communications has been limited to wireless LAN systems such as Lucent's WaveLAN and the front end, chip-rate processing needs of DSSS-CDMA based systems such as IS-95 (US CDMA).

Several major factors are redirecting the industry's attention towards ASICs for the realization of highly complex and power efficient wireless communications equipment. First, the move toward third generation (3-G) cellular systems capable of delivering data rates of up to 384 kbps in outdoor macro-cellular environments (an order of magnitude higher than the present second generation systems) and 2 Mbps in indoor micro-cellular environments. Second, the emergence of high-speed wireless data communications, whether in the form of high-speed wireless LANs [1] or in the form of broadband fixed access networks [2]. A third, but somewhat more subtle factor is the increased appeal of software radios. Radios that can be programmed to transmit and receive different waveforms and thus enable multi-mode and multi-standard operation. Although ASICs are by nature not programmable, they are parameterizable. In other words, ASIC designers targeting wireless applications must develop their architectures in such a way as to provide the user with features such as variable symbol rates and carrier frequency, as well as the ability to shut off parts of the circuit that may be unused under benign channel conditions. For DSSS systems the ASICs should provide sufficient flexibility to accommodate programmability of the chip-rate, spreading factor, and the spreading code to be used.

The next subsection further explores these elements and identify key signal processing tasks that are suited for ASIC implementation. In the subsection on "VLSI Architectures for Signal Processing Blocks" will present signal processing algorithms and ASIC architectures for the realization of these blocks. The chapter section ends with "Conclusions."

### Emerging High-Speed Wireless Systems

#### Third Generation (3-G) Cellular Networks

Second generation cellular systems such as IS-136, GSM, and IS-95 have mainly focused on providing digital voice services and low-speed data traffic. With the growing popularity of the Internet and the need for multimedia networking, standardization bodies throughout the world are looking at the evolution of current systems to support high-speed data and multimedia services. The technology of choice for all such 3-G systems is wideband code division multiple access (W-CDMA) based on direct sequence spread spectrum (DSSS) techniques [3,4]. The targeted chipping rate for these systems is 3.84 Mcps for the European UTRA standardization work, and a multiple of 1.2288 Mcps for the CDMA-2000 proposal.

In addition to providing higher data rates, which come about in part due to the increased bandwidth utilization of 3-G systems, a second and equally important aim of these systems is to increase the capacity of a cell (number of simultaneous calls supported by a cell). To this end, all the current proposals call for the use of sophisticated receivers utilizing multi-user detection and possibly smart antenna technologies.

In order to better appreciate the signal processing requirements of these receiver units, consider the block diagrams presented in Fig. 42.1. Figure 42.1(a) depicts the transmitter of a DSSS system, along with a candidate successive interference canceller (SIC) shown in Fig. 42.1(b) [5]. The details of the rake receiver are shown in Fig. 42.1(c).

**FIGURE 42.1** Block diagram of (a) generic DSSS transmitter, (b) successive interference canceller for multiuser detection, and (c) rake receiver for a system with parallel pilot channel (i.e., IS-95).

The tremendous processing requirements of this architecture will become evident by considering a modest system operating at a chip rate of say, 4 Mcps using a 32-tap shaping filter, four rake fingers per user, four complex correlators per rake finger and 10 users in the cell, the number of operations (real multiply-adds) needed for a 5-stage SIC is upwards of 14 billion operations per second or giga-operations per second (GOPS). This amount of processing can easily overwhelm even the latest generation of general-purpose processors such as the TI TMS320C6x which delivers 1.6 giga-instructions per seconds (GIPS), but only 400 mega multiply-add operations per second [6]. At an anticipated power dissipation of 850 mW per processor, the overall power consumption of a SIC circuit based on such units will be quite large.

It is also worth noting that many operands in the SIC or other MUD receiver that require only a few number of bits (i.e., multiplication with a 1-bit PN code sequence). This fact can be exploited in a dedicated ASIC datapath architecture but not in a general-purpose software programmable architecture.

### Broadband Wireless Networks

Emerging broadband fixed wireless access systems provide high-speed connectivity between a cellular base station and a home or office building at data rates of a few Mbps to a few tens of Mbps. On the other hand, standardization activities that are currently targeting high-speed wireless micro-cellular (wireless LAN) systems are looking at delivering 10–20 Mbps over the air data rates in the near future, with higher rates projected in the long term.

It is generally accepted that in order to achieve such high data rates, beam switching or beamforming techniques must be integrated into the development of the nodes. In addition, single carrier systems must include adaptive equalization to overcome time varying channel impairments, while multicarrier systems based on OFDM will require a large number of subcarriers [7]. The signal processing requirements for such high data rate systems could easily mount into the tens of GOPS range, thus necessitating the development of ASICs.

**FIGURE 42.2** Block diagram of an all-digital receiver for a single carrier system (i.e., QAM) featuring digital IF sampling, beamforming, variable symbol rate, adaptive equalization, all digital timing, and carrier recovery loops.

Furthermore, the flexibility of digital implementation compared to an analog implementation of the down-conversion path makes a digital IF architecture more appealing. Figure 42.2 depicts the detailed block diagram of a single carrier high-speed wireless communication receiver complete with adaptive beamforming, adaptive equalization, and variable symbol rates. The flexibility offered by such an architecture can meet the demands of different systems requiring different levels of performance.

In this architecture, the direct digital frequency synthesizer (DDFS) serves three roles. First, it enables down-conversion of any carrier frequency up to half the sampling frequency of the analog-to-digital converter. Second, it can replace or complement a VCO for the purposes of carrier recovery, and third it can easily generate different phases needed by the beamforming circuit.

The variable rate decimator block is a key element in variable symbol rate systems where it is desired to maintain the same exact analog filtering, but yet accommodate user defined symbol rates. This is particularly important in wireless systems where a predefined data rate is difficult to guarantee due to statistical channel variations such as fading and shadowing. In such scenarios, the user can simply back-off on the symbol rate and provide connectivity albeit at a lower data rate.

The flexible decimation architecture depicted in Fig. 42.2 consists of two stages. The first is a course decimator block, which can decimate the signal by  $2^N$  for  $N = 0, 1, 2, \dots, M$ . This section is realized using a cascade of  $N$  decimate by two stages. The second part of the decimator is a variable rate interpolator block, which can change the sampling rate by any value in the range of 2–4. Not only can this block be used to change the sampling frequency of the signal, but it is the vital element in the realization of an all digital timing recovery loop.

The matched filter is typically a fixed coefficient fixed impulse response (FIR) filter. This block is followed by a decision feedback equalizer (DFE) that helps mitigate the effects of intersymbol interference (ISI) caused by the multipath nature of the channel. The DFE is made up of two adaptive FIR filters referred to as the feedforward filter (FFF) and the feedback filter (FBF).

The amount of processing (in terms of real multiply-adds per second) needed to realize these blocks can easily run into several GOPS. As an example, a baseband QAM receiver consisting of a 30-tap matched filter, a 10-tap FFF and a 5-tap FBF adapted using the least mean squares (LMS) algorithm, and running at 10 Mbaud requires close to 2.5 GOPS of processing. Once the processing needs of the DDFS, variable rate filters, and the beamforming network are also factored in, the processing requirements can easily reach 7–8 GOPS.

**FIGURE 42.3** Alternative FIR filter structures: (a) Direct form FIR structure, (b) Transposed form FIR structure, and (c) Hybrid FIR structure.

## VLSI Architectures for Signal Processing Blocks

### Fixed Coefficient Filters

The most intuitive means of implementing a FIR filter is to use the direct form implementation presented in Fig. 42.3(a) [12]. Applying the transposition theorem to this filter we get the transposed structure shown in Fig. 42.3(b). The two structures are identical in terms of I/O, however, the transposed form is ideal for high speed filtering operations since the critical path for an  $N$  tap filter is always one multiplier delay plus one adder delay. The critical path of the direct form, however, is one multiplier delay plus  $N-1$  adder delays. The fact is that the symbol rate for most wireless communication systems is a few tens of megahertz, whereas a typical multiplier in today's CMOS process technologies can easily reach speeds of 80–100 MHz. It is thus desirable to use the hybrid architecture shown in Fig. 42.3(c) where each multiplier accumulator is time-shared between several taps (three in this case) resulting in a more compact circuit for lower symbol rates.

The implementation of fixed coefficient FIR filters can be further simplified by moving away from the use of 2's complement number notation, and using a signed-digit number system in which each digit can take on one of three values  $\{-1, 0, 1\}$ . In general there are multiple signed-digit representations for the same number and a canonic signed-digit (CSD) representation can be defined for which no two nonzero digits are adjacent [8]. The added flexibility of signed-digit numbers allows us to realize the same coefficient using fewer nonzero coefficients than would be possible with a simple 2's complement representation. Using an optimization program, it is possible to design an FIR filter using CSD filters with as few as three or four nonzero digits for each coefficient. This could help significantly reduce the complexity of fixed coefficient multipliers since the number of partial products generated is directly proportional to the number of nonzero digits in the multiplier.

### Direct Digital Frequency Synthesizer (DDFS)

Given an input frequency word  $W$ , a DDFS will produce a frequency proportional to  $W$ . The most common techniques for realizing a DDFS consist of first accumulating the frequency word  $W$  in a phase accumulator and then producing the sine and cosine of the phase accumulator value using a table lookup or a

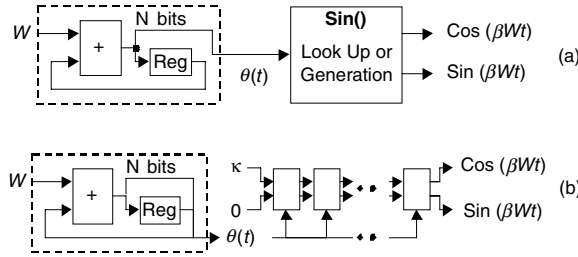

FIGURE 42.4 Two most common DDFS architectures: (a) Table lookup and (b) Coordinate rotation (CORDIC).

coordinate rotation (CORDIC) algorithm. These two approaches are depicted in Fig. 42.4. The two metrics for measuring the performance of a DDFS are the minimum frequency resolution  $\Delta f$  and the spurious free dynamic range (SFDR). The frequency resolution can be improved by increasing the wordlength used in the accumulator, while the SFDR is affected by the wordlengths in both the accumulator as well as the sine/cosine generation block.

One of the main challenges in the development of the table lookup DDFS has been to limit the size of the sine/cosine table. This has been accomplished through two steps [9]. First, by exploiting the symmetry of the sine and cosine functions it is only necessary to store  $\beta$  of the period of a sine wave and derive the remainder of the period through manipulation of the saved portion. Second, the number of bits per entry can be reduced by dividing the sine table between a coarse ROM and a fine ROM with the final result obtained after simple post-processing of the values. Combining these two techniques can result in the reduction of the sine tables by an order of magnitude or better.

In the CORDIC algorithm, Fig. 42.4, sine and cosine of the argument are calculated using a cascade of stages, each of which rotates its input complex vector by  $\delta/2^k$  ( $\delta = \pi/2$ ) if the  $k$ th bit of  $W$  is 0 and  $-\delta/2^k$  if the bit is a 1. Thus each stage performs the following matrix operation:

$$\begin{bmatrix} x_{\text{out}} \\ y_{\text{out}} \end{bmatrix} = \begin{bmatrix} \cos \theta & -\sin \theta \\ \sin \theta & \cos \theta \end{bmatrix} \begin{bmatrix} x_{\text{in}} \\ y_{\text{in}} \end{bmatrix} = \cos \theta \begin{bmatrix} 1 & -\tan \theta \\ \tan \theta & 1 \end{bmatrix} \begin{bmatrix} x_{\text{in}} \\ y_{\text{in}} \end{bmatrix}$$

In [10] a simplification of the CORDIC DDFS is presented in which for small  $\theta$ ,  $\tan(\theta)$  is simply approximated by  $\theta$ . In [11] a different modification to the CORDIC architecture is proposed that will facilitate low-power operation in cases where a sustained frequency is to be generated. This is achieved by calculating the necessary angle of rotation for each sampling clock period, and dedicating a single rotation stage in a feedback configuration to continually rotate the phasor through the desired angle.

### Decimate/Interpolate Filters

Variable rate interpolation and decimation filters play a very important role in the development of highly flexible and self contained all-digital receivers. As previously mentioned, they are the critical element of all digital timing recovery loops as well as systems capable of operating at a host of user defined symbol rates. Additionally, digital resampling allows the ASIC designer to ensure that the clock frequency at all portions of the circuit are the minimum that they need to be to properly represent the signals. This could have significant impact on the size and power consumption of the resulting ASIC since power scales with the clock frequency and the square of the supply voltage. Thus, for a given circuit with a critical path of say  $\tau$  seconds, if the data rate into the block is lowered by a factor  $K$ , then the frequency dependent portion of the dissipated power is also scaled by the same factor; however, additional power savings can be achieved by noting that the block now has  $K\tau$  seconds to complete its task. Because the speed of a digital circuit is proportional to the supply voltage, we can reduce the supply voltage and still ensure that the circuit meets the speed constraints.

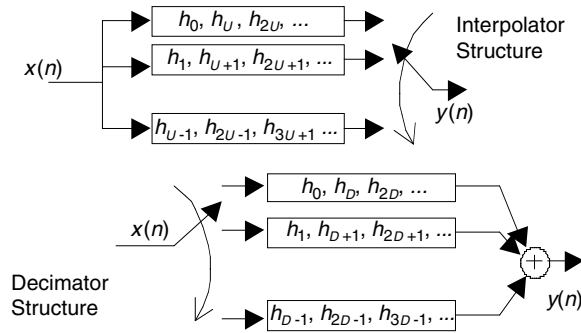

FIGURE 42.5 Polyphase filter structures for interpolation and decimation.

FIGURE 42.6 Variable rate interpolation.

Given the coefficients of an FIR decimation or interpolation filter, the structure of choice for the realization of a decimate by  $D$  or an interpolate by  $D$  filter is the polyphase structure [12] shown in Fig. 42.5. The attractiveness of this structure is in the fact that the filter is always operated at the lower sampling frequency.

In many cases it is desirable to resample the signal by a power of  $2^N$ . In which case  $N$  decimate (interpolate) by two stages can be cascaded one after the other. Each decimator will consist of a halfband filter followed by a decimator. The halfband filter could be realized using the polyphase structure to simplify its implementation. Moreover, these filters are typically very small consisting of anywhere from 7 to 15 taps depending on the specified stopband attenuation and the size of the transition band. Their implementation can be simplified by exploiting the fact that close to half of the coefficients are zero and the remainder are symmetric about the main tap due to the linear phase characteristics of the halfband filter. Finally, since these are fixed-coefficient filters, they can be realized using CSD coefficients [13].

It is interesting to note that for the special case of a decimate (interpolate) by  $2N$ , it is possible to reuse the same hardware element and simply recirculate the data through it. In this architecture, the filter is run at the highest data sampling rate. The first pass through the filter will use up  $1/2$  of its computational resources, the second pass will use up  $1/4$  of the resources, and so on [14]. Although conceptually attractive, the clock generation circuit for such an architecture is quite critical and complex and this approach loses its appeal for recirculating factors greater than 3 or 4.

In cases where the oversampling ratio is large (e.g., narrowband signal) an alternative approach using a cascaded integrator-comb (CIC) structure can be used to implement a multiplierless decimator. The interested reader is referred to [15] for a brief overview of a CIC ASIC.

The continuously variable decimator block shown in Fig. 42.2 can resample the input signal by any factor  $\alpha$  in the range of 2–4. The operation of this block is equivalent to that shown in Fig. 42.6, where the input data  $x(n)$ , originally sampled at  $1/T_s$  is resampled to produce an output sequence  $y(n)$  sampled at  $1/T_i$ . The entire operation is performed digitally.

To better understand the operation of this block, let us define the variable  $\mu_k$  to be the time difference between the output sample  $y(k)$  and the most recent input sample  $x_1$ . The job of the variable rate interpolator is to weight the adjacent input samples  $(\dots, x_0, x_1, \dots)$ , based on the ratio  $\mu_k/T_s$ , and add the weighted input samples to obtain the value of the output sample,  $y(k)$ . Mathematically, a number of interpolation schemes can perform the desired operation; however, many of them, such as sinc-based interpolation, require excessive computational resources for a practical hardware implementation. For real-time

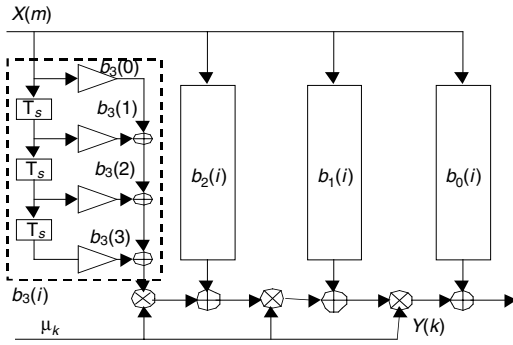

FIGURE 42.7 Farrow structure.

FIGURE 42.8 Frequency response of polynomial-based interpolator (from [18]).

calculation, Erup et al. [16] found polynomial-based interpolation to yield satisfactory results while minimizing the hardware complexity. In this approach, the weights of the input samples are given as polynomials in the variable  $\mu_k$  and can be easily implemented in hardware using the Farrow structure [17] shown in Fig. 42.7. In this structure, all the filter coefficients are fixed and polynomials in  $\mu_k$  are realized by nesting the multipliers as shown in Fig. 42.7.

The signal contained in the imageband will cause aliasing after resampling; however, proper choice of the coefficients in the Farrow structure can help optimize the frequency response of the interpolator for a particular application. An alternative method to determine the filter coefficients is outlined in (see Fig. 42.8) [18].

## Conclusions

Section 42.2 reviewed trends in the wireless communications industry towards high speed data communications in both the macrocellular and the microcellular environments. The implication of these trends on the underlying digital circuits will move designers towards dedicated circuits and ASICs to meet these demands. As such the paper outlined the major signal processing tasks that these ASICs will have to implement.

## 42.3 Communication System-on-a-Chip

---

*Samiha Mourad and Garret Okamoto*

### Introduction

Communication traffic worldwide is exploding: wired and wireless, data, voice, and video. This traffic is doubling every 100 days and it is anticipated that there will be a million people online by 2005. Today, more people are actually using mobile phones than are surfing the Internet. This unprecedented growth has been encouraged by the deployment of digital subscriber lines (DSL) and cable modems, which telephone companies have provided promptly and at a relatively low price. Virtual corporations have been created because of the availability and dependability of communication products such as laptops, mobile phones and pagers, which all support mobile employees. For example, vending machines may contact the suppliers when the merchandise level is low so that suppliers remotely vary the prices of the merchandise according to supply and demand.

With such proliferation in communication products and the need for a high volume, high speed transfer of data, new standards such as ATM and ITU-T are being developed. In addition, a vast body of knowledge, central to problems arising in the design and planning of communication systems, has been published; however, in fabricating products to meet these needs, the industry has continually attempted to use new design approaches that have not been fully researched or documented.

Communication devices need to be of small size and low power dissipation for portability and need to be operated at very high speed. Any of these devices, as other digital products, may consist of a single integrated circuit (IC) or more likely many ICs mounted on a printed circuit board (PCB). Although the new technology (small feature size) has resulted in higher speed ICs, the transfer of data from one IC to another still creates a bottleneck of information. The I/O pads, with their increasing inductance, cause supply surges that compromise signal integrity. As an alternative to PCB design, another design approach known as multichip module (MCM) consists of placing more than one chip in the same package. The connections between modules have a large capacitive load that slows down communication among all of the modules. In the late 1990s, a new paradigm design called system-on-a-chip (SoC) has been successfully used to integrate the components of an entire system on one chip. This is in contrast to the traditional design where the components are implemented in separate ICs and then assembled on a PCB.

Section 42.3 describes the new design paradigm of a SoC and its beneficial attributes are outlined. The remainder of the paper concentrates on communication devices and the subsection on “Need for Communication Systems” emphasizes the need for these systems. Descriptions of communication SoCs and projections on their characteristics are given in “Communication SoCs.” Latency, an important attribute, is the subject of “System Latency”; and “Communication MCMs” describes the integration of these systems with analog parts in MCM.

### System-on-a-Chip (SoC)

The shift toward very deep submicron technology has encouraged IC designers to increase the complexity of their designs to the extent that an entire system is now implemented on a single chip. To increase the design productivity and decrease time-to-market, reuse of previously designed modules is becoming common practice in SoC design; however, the reuse approach is not limited to in-house designs. It is extended to modules that have been designed by others as well. Such modules are referred to as *embedded cores*. This design approach has encouraged the founding of several companies that specialize in providing embedded cores to service multiple customers. It is predicted that in the near future, cores, of which 40% to 60% will be from external sources [Smith 1997], will populate 90% of a chip. Except for a very few, individual companies do not have the wide range of expertise that can match the spectrum of design types in demand today.

Core-based design, justified by the need to decrease time-to-market, has created a host of challenging problems for the design and testing community. First, there are legal issues for the core provider and the user, regarding the intellectual property (IP). Second, there are problems with integrating and verifying a mix of proprietary and external cores that are more involved than simply integrating ICs on a PCB.

A typical SoC configuration is shown in Fig. 42.9. It consists of several *cores* that are also referred to as *modules*, *blocks*, or *macros*. Often, these terms are used interchangeably. These cores may be DSP, RAM

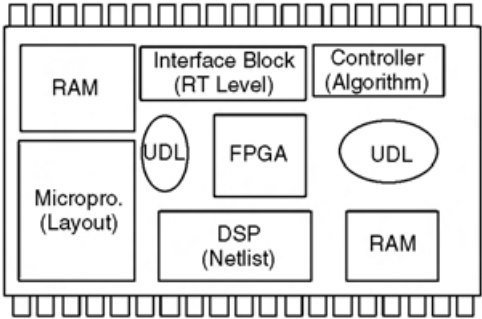

FIGURE 42.9 A system-on-a-chip (SoC).

**TABLE 42.1** Categorizing Reusable Cores [Hunt 1996]

Type	Flexibility	Design Flow	Representation	Libraries	Process Technology	Portability
Soft	Very flexible Unpredictable	System design	Behavioral	Not applicable	Independent	Unlimited
Firm	Flexible	RTL design Floor planning Placement	RTL RTL, blocks Netlist	Reference  Footprint, timing model	Generic	Library mapping
Hard	Inflexible Predictable	Routing Verification	Polygon data	Process specific library and design rules	Fixed	Process mapping

**FIGURE 42.10** Trade-offs among types of cores [Hunt 1996].

modules, or controllers. This same image of an SoC may be perceived as a PCB with the cores being the ICs mounted on it.

It also resembles standard cells laid on the floor of an IC. In the latter case, the blocks are of elementary gates of the same layout height. That is, they are all ICs in the PCB case or all standard cells in the IC case. For an SoC, they may consist of a several types, as described below. A UDL is a user defined logic that is basically equivalent to glue logic in microprocessors.

Cores are classified in three categories: hard, firm, and soft [Gupta 1997]. *Hard cores* are optimized for area and performance and they are mapped into a specific technology and possibly a specific foundry. They are provided as layout files that cannot be modified by the users. *Soft cores*, on the other hand, may be available as HDL technology-independent files. From a design point of view, the layout of a soft core is flexible, although some guidelines may be necessary for good performance. The flexibility allows optimization to the desired levels of performance or area. *Firm cores* are usually provided as technology-dependent netlists using library cells whose size, aspect ratio, and pin location can be changed to meet the customer needs. Table 42.1 summarizes the attributes of reusable cores. The table indicates a clear trade-off between design flexibility on one hand, and predictability and hence time-to-market performance complexity on the other. Soft cores are easily embedded in a design. The ASIC designers have complete control over the implementation of this core, but it is the designer's job to optimize it for area, test, or power performance.

Hard cores are very appropriate for time critical applications, whereas soft cores are candidates for frequent customization. The relationship between flexibility and predictability is illustrated in Fig. 42.10.

The cores can also be classified from a testing perspective. For example, there is typically no way to test a hard core unless the supplier provides a test set for this core, whereas a test set for the soft core needs to be created if not provided by the core provider. This makes hard cores more demanding when developing a test strategy for the chip. For example, it would be difficult to transport through hard cores a test for an adjacent block that may be another core or a UDL component. In some special cases, the problem may be alleviated if the core includes well described testability functions.

## Design and Test Flow

An integrated design and test process is highly recommended. This approach cannot be more appropriate than it is for core-based systems. Conceptually, the SoC paradigm is analogous to the integration of several ICs on a PCB, but there is a fundamental difference. Whereas in a PCB the different ICs have been designed, verified, fabricated, and tested independently from the board, fabrication and testing of an SoC are done only after integration of the different cores. This fact implies that even if the cores are accompanied by a test set, incorporation of the test sets is not that simple and must be considered while integrating the system. In other words, reuse of design does not translate to easy reuse of the test set. What makes this task even more difficult is that the system may include different cores that have different test strategies. Also, the cores may cover a wide range of functions as well as a diverse range of technologies, and they may be described using different HDL languages, such as Verilog, VHDL, and Hardware C to GDSII.

The basic design flow applies to SoC design in the sense that the entire system needs to be entered, debugged, modified for testability, validated, and mapped to a technology; but all of this has to be done in an *integrated framework*. Before starting the design process, an overall strategy needs to be chartered to facilitate the integration. In this respect, the specification phase is enlarged and a test strategy is included. This move toward more design on the system level and less time on the logic level.

The design must first be partitioned. Then decisions must be made on such questions as:

- Which partition can be instantiated by an existing core?
- Should a core be supplied by a vendor or done in-house?
- What type of core should be used?
- What is the integration process to facilitate verification and testing?

Because of the wide spectrum of core choices and the diversity of design approaches, SoC design requires a *meta-methodology*. That is, a methodology that can streamline the demands of all other methodologies used to design and test the reusable blocks as well as their integration with user defined logic. To optimize on the core-based design, an industry group deemed it necessary to establish a common set of specifications. This group, known as the virtual socket interface alliance (VSIA), was announced formally in September 1996. Its intent is to establish standards that facilitate communication between core creators and users, the SoC designers [IEEE 1999a].

An example of using multiple cores is the IBM-designed PowerPC product line, based on the PowerPC 40X chip series [Rincon 1997]. The PowerPC micro-controller consisted of a hard core and several soft cores. For timing critical components such as the CPU, a hard core was selected, while soft cores were used for peripheral functions such as the DMA controller, external bus interface unit (EBIU), timers, and serial port unit (SPU). The EBIU may be substituted by, say, a hard core from Rambus.

A change in the simulation and synthesis processes is required for embedded cores due primarily to the need to protect the intellectual property of the core provider. Firm cores may be encrypted in such a manner as to respond to the simulator without being readable by humans. For synthesis, the core is instantiated in the design. In the case of a soft core, sometimes the parameters are scaled to meet the design constraints. To preserve the core performance, the vendor may include an environment option to prevent the synthesis program from changing some parts of the design. This will protect the core during optimization, but the designer may remove such an option and make some changes in the design. A hard or a firm core is treated as a black box from the library and goes through the synthesis process untouched.

FIGURE 42.11 Internet growth.

FIGURE 42.12 Components of a communication SoC.

### Advantages of SoCs

The overall size of the end product is reduced because manufacturers can put the major system functions on a single chip, as opposed to putting them on several chips. This reduces the total number of chips needed for the end product. For the same reason, the power consumption is reduced.

SoC products provide faster chip speeds due to the integration of the components/functions into one chip. Many applications such as high-speed communication devices (VoIP, MoIP, wireless LAN, 3G cellular phones) require chip speeds that may be unattainable with separate IC products. This is primarily due to the physical limitations of moving data from one chip to another, through bonding pads, wires, buses, etc. Integrating chip components/functions into one chip eliminates the need to physically move data from one chip to another, thereby producing faster chip speeds. Another important advantage of SoCs is the reuse of previously designed circuits, thereby reducing the design process time. This consequently translates into shorter time-to-market. In addition to decreasing time-to-market, it is very important to decrease the cost of packaging and testing, which are constantly increasing with the finer technology features. Instead of testing several chips and the PCB on which they are assembled, testing time is reduced to only one IC. SoCs are, however, very complex and standards are now being developed to facilitate their testing [IEEE 1995b]. In the remainder of this paper, we focus on communication systems that we will refer to as comm. SoC or simply SoC.

### Need for Communication Systems

Public switched telephone networks (PSTN) are becoming congested due to increasing Internet traffic as shown in Fig. 42.11. This drives the development of broadband access technology and high-speed optical networks. Another important factor is the convergence of voice, data, and video. As a consequence, there is a need for low and uniform latency devices for real time traffic. In addition, Internet service

providers (ISP) and corporate Intranet are needed for voice and data IP gateways. Mobile users drive the development of wireless and satellite devices. In addition, there is an increasing demand for routers/switches, DSL modems, etc.

All needs mentioned above require smaller size and faster communication devices. Telephone calls that used to last an average of three minutes now exceed an hour or more when connected to the Internet. This has resulted in increasing the demand on DSL that transmit data over Internet protocols (IP) such as voice-over-IP (VoIP), mobile-over-IP (MoIP), and wireless requires speeds that may be unattainable with separate IC products. Examples of products:

1. 2G and 3G wireless devices (CDMA2000, WCDMA), etc.
2. DSL modems
3. Infrastructure, carrier, and enterprise circuit, packet switched and VoIP devices
4. Satellite modems
5. Cable modems and HFC routing devices
6. De/MUX for data stream on optical network
7. Web browsers (WAP) or short messaging systems (I-mode)
8. LAN telephony
9. ATM systems
10. Enterprise, edge network and media-over-IP switches and high-speed routers
11. Wireless LAN (IEEE 802.11 IEEE 802.11a, and IEEE 802.11b)
12. Bluetooth

Maybe the most important example of an emerging wireless communication standard is Bluetooth. This is a wireless personal area network (PAN) technology from the Bluetooth special interest group (SIG), founded in 1998 by Ericsson, IBM, Intel, Nokia, 3Com, Lucent, Microsoft, Motorola, and Toshiba. Bluetooth is an open standard for short-range transmission of digital voice and data between mobile devices (cellular phones, PDAs, laptops) and desktop devices. Bluetooth may provide a common standard to enable PDAs, laptop and desktop computers, cellular phones, thermostats, and virtually every other home and business electronic device to communicate with each other. Manufacturers will rely on SoC advances to help reach the target of \$5 added cost to a consumer appliance by 2001. A study by Merrill Lynch projected that Bluetooth semiconductor revenue will reach \$3.4 billion in 2005, with Bluetooth included in 1.7 billion devices that year, and the Bluetooth SIG estimated that the technology would be a standard feature in 100 million mobile phones by the end of 2001.

## Communication SoCs

The exponential growth of the Internet and the bandwidth shown in [Fig. 42.11](#), indicate that more communication products are geared towards this technology, which requires a communication mode different than that used in traditional switching telephony. For example, in a PSTN, circuit switching is used and requires a dedicated physical circuit through the network during the life of a telephone session. In Internet and ATM technology, however, packet switching is used. Packet switching is a connectionless technology, where a message is broken into several small packets to be sent to a destination. The packet header contains the destination and source address, plus a sequence number so that the message can be reassembled.

There is a paradigm shift in digital communication motivated by the evolution of Internet as mission critical service that demands migration from circuit switch to packet switch. The older paradigm supported the data traffic part of the telephone networks. Whereas the new paradigm support the convergence of voice, data, and video and require a new class of media-over-IP systems voice traffic as part of the data network, thus requiring communication SoC for VoIP.

Most communication SoC consists of few components that are clustered around a central processing unit (CPU), which controls some or all of the following: (1) Packet processing, (2) Programmable DSP for data and signaling algorithm/protocol implementation, (3) I/O for interface with voice and data network such as ATM, PCI, Ethernet, H100/110, (4) memory system for intermediate storage of voice and data

FIGURE 42.13 Software for VoIP SoC.

FIGURE 42.14 Communications SoCs: Density and memory size.

streams, (5) hardwired DSP or accelerators for Codec and multi level mod/demod to increase system throughput, and (6) MPEG cores for media-over-IP MoIP processing.

Communication SoCs are actually a mix of software and hardware. Some of the circuits contain hardwired algorithms for code processing, but the software can be stored on the chip for protocols that process data. Figure 42.13 shows the software for a typical VoIP. This include several layers of software and IP such as:

1. *Telephony signaling*: Network interface protocol, which contains address translation and parsing and protocols such as H-3xx, media gateway control protocol (MGCP), and real time conferencing protocol (RTCP).
2. *Voice processing*: includes voice-coding unit using G.xx protocol, voice activation detection (VAD), comfort noise generation (CNG), which is used in fax-to-fax communication.
3. *User interface*: provides system services to the user such as key pad and display drivers and user procedures.
4. *Network management*: software upload and handling Java applets.
5. *Network Interface Protocols*: such as transmission control protocol (TCP), user datagram protocol (UDP), which is a TCP/IP, and Ethernet driver.

Other software and protocol may also be included such as packet processing and network management protocols, call control/signaling protocols/fax and modem tone detection, echo canceller, VAD, CNG, read to order systems (RTOS), and other software components for MoIP systems. Communication SoCs that accomplish the above tasks are expected to grow in size as projected in Fig. 42.14. The number of

FIGURE 42.15 Communications SoCs processing power and memory bandwidth.

FIGURE 42.16 (a) Number of DSP processors per SoC. (b) Price per functional VoIP channel.

gates per chip will increase from one million in 1999 to 7 M in 2003. A major component in a communication SoC is the embedded memory banks, which is also expected to increase from 1 to 16 Mbit. The type of memory used will change from static RAMs (SRAM) to enhanced dynamic RAMs (EDRAM), which are much more compact.

The processing power of these SoCs is also expected to increase as illustrated in Fig. 42.15. The processing power is measured in million instructions per second (MIPs). It is predicted to grow from 100 to 1000 MIPs (dashed line) from 1999 to 2003. In same time period, the memory bandwidth (solid line) will increase from 100 to 1000 Mbits. The growth of the number of DSP processors by SoC is shown in Fig. 42.16(a). With all of this growth, it is interesting that the price of SoCs is estimated to decrease according to the trend shown in Fig. 42.16(b).

Several predictions were given to the bandwidth of communication chips. Two of these predictions are shown in Fig. 42.17. One assumes that the bandwidth will triple each year in the next 25 years as illustrated by the solid line [George Dilder-Telecosm]. The other shows that the growth will be at the rate of 8–16 times a year [SUN Microsystems]. In the 1990s, Bill Gates claimed that “we will have infinite bandwidth in a decade of time [Gates 1994].”

## System Latency

Latency is defined as the delay experienced a certain processing stage. The latency trends in Fig. 42.18 refer to the time taken to map the voice data into a packet to be transmitted. Three main types of latency are usually identified:

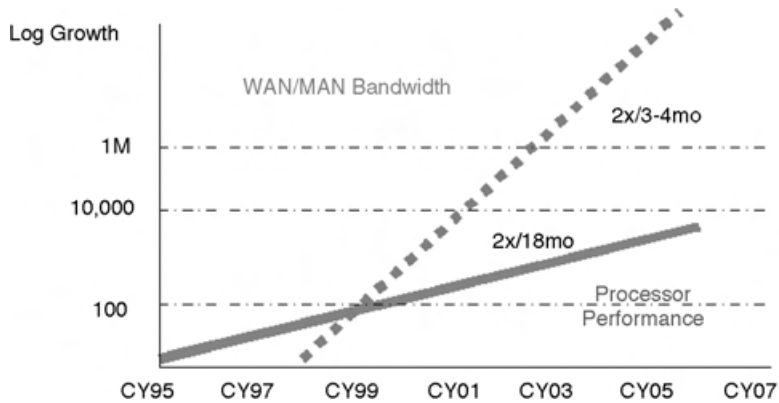

FIGURE 42.17 Bandwidth trends.

FIGURE 42.18 System latency.

- Frame/packetization Delay
- Media processing delay/complexity of the system
- Bridging delay, e.g., used for conferencing or multi SoC system

These delays may occur at different times in the life of the data in the communication system. A simplified communication system is shown in Fig. 42.18. It starts with the sender transmitting data through the network to a receiver at the other end. The total system latency is known as the end-to-end delay. It consists of the time taken to send the first bit of a packet to the time it takes to receive the last bit in the stream of data, i.e.,

- delay in processing the data at the sending end,
- transit delay within the network,
- delay in processing the data at the receiving end.

With the use of SoC, latency has been reduced and this reduction is projected to continue as the technology feature is getting finer. The trend is illustrated in Fig. 42.19. Several SoCs may themselves be integrated in one multichip module (MCM) as will be discussed next.

FIGURE 42.19 Latency for voice to packet in communication SoCs.

FIGURE 42.20 Communication MCMs.

## Communication MCMs

Digital communication SoCs are usually connected to external analog functions and I/O as depicted in Fig. 42.20. In order to optimize the interface between digital SoCs and analog functions, it is beneficial to integrate both designs in a MCM. The simplest definition for an MCM is a single electronic package containing more than one IC [Doanne 1993]. An MCM then combines high performance ICs with a custom-designed common substrate structure that provides mechanical support for the chips and multiple layers of conductors to interconnect them. Such an arrangement takes advantage of the performance of the ICs because the interconnect length is much shorter.

Multichip modules are not new, they preceded SoC. They have several advantages because they improve the maximum external memory bandwidth achieved, reduce size and weight of the product, increase the operating speed, and decrease power dissipation of the system; however, they are limited by wiring capacitance to frequencies below 150 MHz, e.g., Sony's HandyCam. Thus, they are limited by slower memory in comparison with the massive parallel processing power of an SoC with embedded memory.

MCM wide bus pin out is restricted by cost and yield in comparison with an SoC that provides high throughput data processing with wide 256–1024 bit on chip data bus. System configurability is harder to achieve in MCM than in SoC that are software configurable.

Analog and digital functions are separately optimized in MCM while in SoC many analog functions are optimized and their yield improved by using on chip integrated DSP algorithms. Multiple communication SoCs and analog functions can be packaged on a single MCM. The advantage of MCMs is even more pronounced when the package is enhanced. For example, flip-chips may be used or even more advanced package

The interconnections between the various SoCs and the memory chips are the major paths for crosstalk and other types of signal distortion. Reducing the routing length of the connection will help to increase the operation speed. This can be achieved with a chip-on-chip (CoC) module. The metal redistribution layers were fabricated on the top of the processor and the two memory chips, while the original bond pads still remained for the wire bonding to the substrate. The memory chips can be mounted on the top of the processor using flip-chip technology. Redistribution layers have been used to replace the bond wires and traces on the substrate to provide the interconnections between memory chip and processor. Since Know Good Die memory chips are usually used, testing only requires open/short test between the processor and memory chips. No burn-in and extensive memory tests are required, so the connection to the package ball can be removed as a new test program is implemented with the open/short test of the memory interface through other IO paths of the VGA processor.

## Summary

The broadband access, infrastructure, carrier, and enterprise Communication SoCs will demand higher MIPS, integration, and memory bandwidth. They will also demand lower latency, power dissipation, and cost/channel or function. Comm. SoC utilizes programmable DSP, hardwired DSP accelerators, and I/O to implement Comm. protocols and systems in a highly integrated form. Higher memory access frequency, DSP interface speeds, and specialized analog functions will demand the integration of Comm. SoCs on Comm. MCM

## 42.4 Communications and Computer Networks

---

*Mohammad Ilyas*

The field of communications and computer networks deals with efficient and reliable transfer of information from one point to another. The need to exchange information is not new but the techniques employed to achieve information exchange have been steadily improving. During the past few decades, these techniques have experienced an unprecedented and innovative growth. Several factors have been and continue to be responsible for this growth. The Internet is the most visible product of this growth and it has impacted the life of each and every one. Section 42.4 describes salient features and operational details of communications and computer networks.

The contents of section 42.4 is organized in several subsections. "A Brief History" describes a brief history of the field of communications. The "Introduction" deals with the introduction of communication and computer networks. "Computer Networks" describes operational details of computer networks. "Resource Allocation Techniques" discusses resource allocation mechanisms. "Challenges and Issues" briefly describes the challenges and issues in communication and computer networks that are still to be overcome. The "Summary and Conclusions" subsection summarizes the article.

### A Brief History

Exchange of information (communications) between two or more entities has been a necessity since the existence of human life. It started with some form and shape of human voice that one entity can create and other(s) can listen and interpret. Over a period of several centuries, these voices evolved into languages. As the population of the world grew, more and more languages were born. For a long time, languages were used for face-to-face communications. If there were ever a need to convey some information (a message) over a distance, someone would be briefed and sent to deliver the message to a distant site. Gradually, additional methods were developed to represent and exchange the information. These methods included symbols, shapes, and eventually alphabets. This development facilitated information recording and use of nonvocal means for exchanging information. Hence, preservation, dissemination, sharing, and communication of knowledge became easier.

Until about 150 years ago, all communication was via wireless means and included smoke signals, beating of drums, and use of reflective surfaces for reflecting light signals (optical wireless). Efficiency of these techniques was heavily influenced by the environmental conditions. For instance, smoke signals were not very effective in windy conditions. In any case, as we will note later, some of the techniques that were in use centuries ago for conveying information over a distance, were similar to the techniques that we currently use. The only difference is that the implementation of those techniques is exceedingly more sophisticated now than it was centuries ago.

As the technological progress continued and electronic devices started appearing on the surface, the field of communication also started making use of the innovative technologies. Alphabets were translated into their electronic representations so that information may be electronically transmitted. Morse code was developed for telegraphic exchange of information. Further developments led to the use of telephone. It is important to note that in earlier days of technological masterpieces, users would go to a common site where one could send a telegraphic message over a distance or could have a telephonic conversation with a person at a remote location. This was a classic example of resource sharing. Of course, human help was needed to establish a connection with remote sites.

**FIGURE 42.21** A typical communication system.

As the benefits of the advances in communication technologies were being harvested, the electronic computers were also emerging and making the news. The earlier computers were not only expensive and less reliable, they were also huge in size. For instance, the computers that used vacuum tubes, were of the size of a large room and used roughly about 10,000 vacuum tubes. These computers would stop working if a vacuum tube had burnt, and the tube would need to be replaced by using a ladder. On the average, those computers would function for a few minutes, before another vacuum tube's replacement was necessary. A few minutes of computer time was not enough to execute a large computer program. With the advent of transistors, computers not only became smaller in size, less expensive, but also more reliable. These aspects of computers resulted in their widespread applications. With the development of personal computers, there is hardly any side of our lives that has not been impacted by the use of computers. The field of communications is no exception and the use of computers has escalated our communication capabilities to new heights.

## Introduction

Communication of information from one point to another in an efficient and reliable manner has always been a necessity. A typical communication system consists of the following components as shown in Fig. 42.21:

- Source that generates or has the information to be transported
- Transmitter that prepares the information for transportation
- Transmission medium that carries the information from one end to the other
- Receiver that receives the information and prepares it for delivering to the receiver
- Destination that takes the information from receiver and utilizes it as necessary

The information can be generated in analog or in digital form. Analog information is represented as a continuous signal that varies smoothly in time. As one speaks in a microphone, an analog voice signal is generated. Digital information is represented by a signal that stays at some fixed level for some duration of time followed by a change to another fixed level. A computer works with digital information that has two levels (binary digital signals). Figure 42.22 shows an example of analog and digital signals. Transmission of information can also be in analog or in digital form. Therefore, we have the following four possibilities in a communication system [21]:

- Analog information transmitted as an analog signal
- Analog information transmitted as a digital signal
- Digital information transmitted as an analog signal
- Digital information transmitted as a digital signal

There may not be a choice regarding the form (analog or digital) of information being generated by a device. For instance, a voice signal as one speaks, a video signal as generated by a camera, a speed signal generated by a moving vehicle, and an altitude signal generated by the equipment in a plane will always be analog in nature; however, there is a choice regarding the form (analog or digital) of information being transmitted over a transmission medium. Transmitted information could be analog or digital in nature and information can be easily converted from one form to another.

**FIGURE 42.22** Typical analog and digital signals.

Each of these possibilities has its pros and cons. When a signal carrying information is transmitted, it loses its energy and strength and gathers some interference (noise) as it propagates away from the transmitter. If energy of signal is not boosted at some intermediate point, it may attenuate beyond recognition before it reaches its intended destination. That will certainly be a wasted effort. In order to boost energy and strength of a signal, it must be amplified (in case of analog signals) and rebuilt (in case of digital signals). When an analog signal is amplified, the noise also becomes amplified and that certainly lowers expectations about receiving the signal at its destination in its original (or close to it) form. On the other hand, digital signals can be processed and reconstructed at any intermediate point and, therefore, the noise can essentially be filtered out. Moreover, transmission of information in digital form has many other advantages including processing of information for error detection and correction, applying encryption and decryption techniques to sensitive information, and many more. Thus, digital information transmission technology has become the dominant technology in the field communications [9,18].

As indicated earlier, communication technology has experienced phenomenal growth over the past several decades. The following two factors have always played a critical role in shaping the future of communications [20]:

- Severity of user needs to exchange information
- State of the technology related to communications

Historically, inventions have always been triggered by the severity of needs. It has been very true for the field of communications as well. In addition, there is always an urge and curiosity to make things happen faster. When electricity was discovered and people (scattered around the globe) wanted to exchange information over longer distances and in less time, telegraph was invented. Morse code was developed with shorter sequences (of dots and dashes) for more frequent alphabets. That resulted in transmission of message in a shorter duration of time. Presence of electricity, and capability of wires to

carry information over longer distances, led to the development of devices that converted human voice into electrical signal, and thus led to the development of telephone systems. Behind this invention was also a need/desire to establish full-duplex (two-way simultaneous) communication in human voice. As the use of telephone became widespread, there was a need for a telephone user to be connected to any other user, and that led to the development of switching offices. In the early days, the switching offices were operated manually. As the state of the technology improved, the manual switching offices were replaced by automatic switching offices. Each telephone user was assigned a telephone number for identification purposes and a user able to dial the number for the purpose of establishing a connection with the called party. As the computer technology improved and the computers became easier to afford and smaller in size, they found countless uses including their use in communications. The computers not only replaced the automatic (electromechanical) switching offices, they were also employed in many other aspects of communication systems. Examples include conversion of information from analog to digital and vice versa, processing of information for error detection and/or correction, compression of information, and encryption/decryption of information, etc.

As computers became more powerful, there were many other applications that surfaced. The most visible application was the amount of information that users started sharing among themselves. The volume of information being exchanged among users has been growing exponentially over the last three decades. As users needed to exchange such a mammoth amount of information, new techniques were invented to facilitate the process. There was not only a need for users to exchange information with others in an asynchronous fashion, there was also need for computers to exchange information among themselves. The information being exchanged in this fashion has different characteristics than the information being exchanged through the telephone systems. This need led to the interconnection of computers with each other and that is what is called computer networks.

## Computer Networks

Computer networks is an interconnection of computers. The interconnection forms a facility that provides reliable and efficient means of communication among users and other devices. User communication in computer networks is assisted by computers, and the facility also provides communication among computers. Computer networks are also referred to as computer communication networks. Interconnection among computers may be via wired or wireless transmission medium [5,6,10,13,18].

There are two broad categories of computer networks:

- Wide area networks
- Local/metropolitan area networks

Wide area computer networks, as the name suggests, span a wider geographical area and essentially have a global scope. On the other hand, local/metropolitan area networks span a limited distance. Local area networks are generally confined to an industrial building or an academic institution. Metropolitan area networks also have limited geographical scope but it is relatively larger than that of the local area networks [19]. Typical wide and local/metropolitan area networks are shown in [Fig. 42.23](#).

Once a user is connected to a computer network, it can communicate with any other user that is also connected to the network at some point. It is not required that a user must be connected directly to another user for communicating. In fact, in wide area networks, two communicating users will rarely be directly connected with each other. This implies that the users will be sharing the transmission links for exchanging their information. This is one of the most important aspects of computer networks. Sharing of resources improves utilization of the resources and is, of course, cost-effective as well. In addition to sharing the transmission links, the users will also share the processing power of the computers at the switching nodes, buffering capacity to store the information at the switching nodes, and any other resources that are connected to the computer network. A user that is connected to a computer network at any switching node will have immediate access to all the resources (databases, research articles, surveys, and much more) that are connected to the network as well. Of course, access to specific information may be restricted and a user may require appropriate authorization to access the information.

**FIGURE 42.23** (a) A typical wide area computer communication network. (b) A typical local/metro area communication bus network. (c) A typical local/metro area communication ring network.

The information from one user to another may need to pass through several switching nodes and transmission links before reaching its destination. This implies that a user may have many options available to select one out of many sequences of transmission links and switching nodes to exchange its information. That adds to the reliability of information exchange process. If one path is not available, not feasible or is not functional, some other path may be used. In addition, for better and effective sharing of resources among several users, it is not appropriate to let any user exchange a large quantity of information at a time;

however, it is not uncommon that some users may have a large quantity of information to exchange. In that case, the information is broken into smaller units known as packets of information. Each packet is sent towards destination as a separate entity and all packets are assembled together at the destination side to re-create the original piece of information [2].

Due to resource sharing environment, users may not be able to exchange their information at any time they wish to because the resources (switching nodes, transmission links) may be busy serving other users. In that case, some users may have to wait for some time before they begin their communication. Designers of computer networks should design the network so that the total delay (including wait time) is as small as possible and that the total amount of information successfully exchanged (throughput) is as large as possible.

As can be noted, many aspects must be addressed for enabling networks to transport users' information from one point to another. The major aspects are listed below:

- Addressing mechanism to identify users
- Addressing mechanism for information packets to identify their source and destination
- Establishing a connection between sender and receiver and maintaining it
- Choosing a path or a route (sequence of switching nodes and transmission links) to carry the information from a sender to a receiver
- Implementing a selected route or path
- Checking information packets for errors and recovering from errors
- Encryption and decryption of information
- Controlling the flow of information so that shared resources are not over taxed
- Informing the sender that the information has been successfully delivered to the intended destination (acknowledgement)
- Billing for the use of resources
- Making sure that different computers that are running different applications and operating systems, can exchange information
- Preparing information appropriately for transmission over a given transmission medium.

This is not an exhaustive list of items that need to be addressed in computer networks. In any case, all such issues are addressed by very systematic and detailed procedures. The procedures are called communication protocols. The protocols are implemented at the switching nodes by a combination of hardware and software. It is not advisable to implement all these features in one module of hardware or software because that will become very difficult to manage. It is a standard practice that these features be divided in different smaller modules and then modules be interfaced together to collectively provide implementation of these features. International Standards Organization (ISO) has suggested dividing these features into seven distinct modules called layers. The proposed model is referred to as Open System Interconnection (OSI) reference model. The seven layers proposed in the OSI reference model are [2]:

- Application layer
- Presentation layer
- Session layer
- Transport layer
- Network layer
- Data link layer
- Physical layer

Physical layer deals with the transmission of information on the transmission medium. Data link layer handles the information on a single link. Network layer deals with the path or route of information from

the switching node where source is connected to the switching node where receiver is connected. It also monitors end-to-end information flow. The remaining four layers reside with the user equipment. Transport layer deals with the information exchange from source to the sender. Session layer handles establishment of session between source and the receiver and maintains it. Presentation layer deals with the form in which information is presented to the lower layer. Encryption/decryption of information can also be performed at this layer. Application layer deals with the application that generates the information at the source side and what happens to it when it is delivered at the receiver side.

As the information begins from the application layer at the sender side, it is processed at every layer according to the specific protocols implemented at that layer. Each layer processes the information and appends a header and/or a trailer with the information before passing it on to the next layer. The headers and trailers appended by various layers contribute to the overhead and are necessary for transportation of the information. Finally, at the physical layer, the bits of information packets are converted to an appropriate signal and transmitted over the transmission medium. At the destination side, the physical layer receives the information packets from the transmission medium and prepares them for passing these to the next higher layer. As a packet is processed by the protocol layers at the destination side, its headers and trailers are stripped off before it is passed to the next layer. By the time information reaches the application layer, it should be in the same form as it was transmitted by the source.

Once a user is ready to send information to another user, he or she has two options. He or she can establish a communication with the destination prior to exchanging information or he can just give the information to the network node and let the network deliver the information to its destination. If communication is established prior to exchanging the information, the process is referred to as connection-oriented service and is implemented by using virtual circuit connections. On the other hand, if no communication is established prior to sending the information, the process is called connectionless service. This is implemented by using datagram environment. In connection-oriented (virtual circuit) service, all packets between two users travel over the same path through a computer network and hence arrive at their destination in the same order as they were sent by the source. In connectionless service, however, each packet finds its own path through the network while traveling towards its destination. Each packet will therefore experience different delay and the packets may arrive at their destination out of sequence. In that case, destination will be required to put all the packets in proper sequence before assembling them [2,10,13].

As in all resource sharing systems, allocation of resources in computer networks requires a careful attention. The main idea is that the resources should be shared among users of a computer network as fairly as possible. At the same, it is desired to maintain the network performance as close to its optimal level as possible. The fairness definition, however, varies from one individual to another and depends upon how one is associated with a computer networks. Although fairness of resource sharing is being evaluated, two performance parameters—delay and throughput—for computer networks are considered. The delay is the duration of time from the moment information is submitted by a user for transmission to the moment it is successfully delivered to its destination. The throughput is amount of information successfully delivered to its intended destination per unit time. Due to the resource sharing environment in computer networks, these two performance parameters are contradictory. It is desired to have the delay as small as possible and the throughput as large as possible. For increasing throughput, a computer network must handle increased information traffic, but the increased level of information traffic also causes higher buffer occupancy at the switching nodes and hence, more waiting time for information packets. This results in an increase in delay. On the other hand, if information traffic is reduced to reduce the delay, that will adversely affect the throughput. A reasonable compromise between throughput and delay is necessary for a satisfactory operation of a computer network [10,11].

## Wide Area Computer Networks

A wide area network consists of switching nodes and transmission links as shown in Fig. 42.23(a). Layout of switching nodes and transmission links is based on the traffic patterns and expected volume of traffic flow from one site to another site. Switching nodes provide the users access to a computer network and implement communication protocols. When a user is ready to transmit its information, the switching

node, to which the user is connected to, will establish a connection if a connection-oriented service has been opted. Otherwise, the information will be transmitted in a connectionless environment. In either case, switching nodes play a key role in determining path of the information flow according to some well-established routing criteria. The criteria include performance (delay and throughput) objectives among other factors based on user needs. For keeping the network traffic within a reasonable range, some traffic flow control mechanisms are necessary. In late 1960s and early 1970s, when data rates of transmission media used in computer networks were low (a few thousands of bits per second), these mechanisms were fairly simple. A common method used for controlling traffic over a transmission link or a path was an understanding that sender will continue sending information until the receiver sends a request to stop. The information flow will resume as soon as the receiver sends another request to resume transmission. Basically the receiver side had the final say in controlling the flow of information over a link or a path. As the data rates of transmission media started increasing, this method was not deemed efficient. To control the flow of information in relatively faster transmission media, a sliding window scheme was used. According to this scheme, sender will continuously send information packet but no more than a certain limit. Once the limit has reached, the sender will stop sending the information packets and will wait for the acknowledgement of the packets that have been transmitted. As soon as an acknowledgement is received, the sender may send another packet. This method ensures that there are no more than a certain specific number of packets in transit from sender to receiver at any given time. Again the receiver has the control over the amount of information that sender can transmit. These techniques for controlling the information traffic are referred to as reactive or feedback based techniques because the decision to transmit or not to transmit is based on the current traffic conditions.

The reactive techniques are acceptable in low to moderate data rates of transmission media. As the data rates increase from kilobits per second to megabits and gigabits per second, the situation changes. Over the past several years, the data rates have increased manifold. Optical fibers provide enormously high data rates. Size of the computer networks has also experienced tremendous increase. The amount of traffic flowing through these networks has been increasing exponentially. Given that, the traffic control techniques used in earlier networks are not quite effective anymore [11,12,22]. One more factor that has added to the complexity of the situation is that users are now exchanging different types of information through the same network. Consider the example of Internet. The geographical scope of Internet is essentially global. Extensive use of optical fiber as transmission media provides very high data rates for exchanging information. In addition, users are using Internet for exchanging any type of information that they come across, including voice, video, data, etc. All these factors have essentially necessitated use of modified approach for traffic management in computer networks. The main factor leading to this change is that the information packets are moving so fast through the computer networks that any feedback-based (or reactive) control will be too slow to be of any use. Therefore, some preventive mechanisms have been developed to maintain the information traffic inside a computer network to a comfortable level. Such techniques are implemented at the sender side by ensuring that only as much information traffic is allowed to enter the network as can be comfortably handled by the networks [1,20,22]. Based on the users' needs and state of the technology, providing faster communications for different types of services (voice, video, data, and others) in the same computer network in an integrated and unified manner, has become a necessity. These computer networks are referred to as broadband integrated services digital networks (BISDNs). Broadband ISDNs provide end-to-end digital connectivity and users can access any type of communication service from a single point of access. Asynchronous transfer mode (ATM) is expected to be used as a transfer mechanism in broadband ISDNs. ATM is essentially a fast packet switching technique where information is transmitted in the form of small fixed-size packets called cells. Each cell is 53 bytes long and includes a header of 5 bytes. The information is primarily transported using connection-oriented (virtual circuit) environment [3,4,8,12,17].

Another aspect of wide area networks is the processing speed of switching nodes. As the data rates of transmission media increases, it is essential to have faster processing capability at the switching nodes. Otherwise, switching nodes become bottlenecks and faster transmission media cannot be fully utilized. When transmission media consists of optical fibers, the incoming information at a switching node is

converted from optical form to electronic form so that it may be processed and appropriately switched to an outgoing link. Before it is transmitted, the information is again converted from electronic form to optical form. This slows down the information transfer process and increases the delay. To remedy this situation, research is being conducted to develop large optical switches to be used as switching nodes. Optical switches will not require conversion of information from optical to electronic and vice versa at the switching nodes; however, these switches must also possess the capability of optical processing of information. When reasonable sized optical switches become available, use of optical fiber as transmission media together with optical switches will lead to all-optical computer and communication networks. Information packets will not need to be stored for processing at the switching nodes and that will certainly improve the delay performance. In addition, wavelength division multiplexing techniques are rendering use of optical transmission media to its fullest capacity [14].

### **Local and Metropolitan Area Networks**

A local area network has a limited geographical scope (no more than a few kilometers) and is generally limited to a building or an organization. It uses a single transmission medium and all users are connected to the same medium at various points. The transmission medium may be open-ended (bus) as shown in Fig. 42.23(b) or it may be in the form of a loop (ring) as shown in Fig. 42.23(c). Metropolitan area networks also have a single transmission medium that is shared by all the users connected to the network, but the medium spans a relatively larger geographical area, upto 150 km. They also use a transmission medium with relatively higher data rates. Local and metropolitan area networks also use a layered implementation of communication protocols as needed in wide area networks; however, these protocols are relatively simpler because of simple topology, no switching nodes, and limited distance between the senders and the receivers. All users share the same transmission medium to exchange their information. Obviously, if two or more users transmit their information at the same time, the information from different users will interfere with each other and will cause a collision. In such cases, the information of all users involved in a collision will be destroyed and will need to be retransmitted. Therefore, there must be some well-defined procedures so that all users may share the same transmission medium in a civilized manner and have successful exchange of information. These procedures are called medium access control (MAC) protocols.

There are two broad categories of MAC protocols:

- Controlled access protocols
- Contention-based access protocols

In controlled access MAC protocols, users take turns in transmitting their information and only one user is allowed to transmit information at a time. When one user has finished its transmission, the next user begins transmission. The control could be centralized or distributed. No information collisions occur and, hence, no information is lost due to two or more users transmitting their information at the same time. Example of controlled access MAC protocols include token-passing bus and token-passing ring local area networks. In both of these examples, a token (a small control packet) circulates among the stations. A station that has the token is allowed to transmit information, and other stations wait until they receive the token [19].

In contention-based MAC protocols, users do not take turns in transmitting their information. When a user becomes ready, it makes its own decision to transmit and also faces a risk of becoming involved in a collision with another stations who also decides to transmit at about the same time. If no collision occurs, the information may be successfully delivered to its destination. On the other hand, if a collision occurs, the information from all users involved in a collision will need to be retransmitted. An example of contention-based MAC protocols is carrier sense multiple access with collision detection (CSMA/CD) which is used in Ethernet. In CSMA/CD, a user senses the shared transmission medium prior to transmitting its information. If the medium is sensed as busy (someone is already transmitting the information), the user will refrain from transmitting its information; however, if the medium is sensed as free, the user transmits

its information. Intuitively, this MAC protocol should be able to avoid collisions, but collisions still do take place. The reason is that transmissions travel along the transmission medium at a finite speed. If one user senses the medium at one point and finds it free, it does not mean that another user located at another point of the medium has not already begun its transmission. This is referred to as the effect of the finite propagation delay of electromagnetic signal along the transmission medium. This is the single most important parameter that causes deterioration of performance in contention-based local area networks [11,19].

Design of local area networks has also been significantly impacted by the availability of transmission media with higher data rates. As the data rate of a transmission medium increases, the effects of propagation delay becomes even more visible. In higher speed local area networks such as Gigabit Ethernet, and 100-BASE-FX, the medium access protocols are designed such that to reduce the effects of propagation delay. If special attention is not given to the effects of propagation delay, the performance of high-speed local area networks becomes very poor [15,19].

Metropolitan area networks essentially deal with the same issues as local area networks. These networks are generally used as backbones for interconnecting different local area networks together. These are high-speed networks and span a relatively larger geographical area. MAC protocols for sharing the same transmission media are based on controlled access. Two most common examples of metropolitan area networks are fiber distributed data interface (FDDI) and distributed queue dual bus (DQDB). In FDDI, the transmission medium is in the form of two rings, whereas DQDB uses two buses. FDDI rings carry information in one but opposite directions and this arrangement improves reliability of communication. In DQDB, two buses also carry information in one but opposite directions. The MAC protocol for FDDI is based on token passing and supports voice and data communication among its users. DQDB uses a reservation-based access mechanism and also supports voice and data communication among its users [19].

## **Wireless and Mobile Communication Networks**

Communication without being physically tied-up to wires has always been of interest and mobile and wireless communication networks promises that. The last few years have witnessed unprecedented growth in wireless communication networks. Significant advancements have been made in the technologies that support wireless communication environment and there is much more to come in the future. The devices used for wireless communication require certain features that wired communication devices may not necessarily need. These features include low power consumption, light weight, and worldwide communication ability.

In wireless and mobile communication networks, the access to a communication network is wireless so that the end users remain free to move. The rest of the communication path could be wired, wireless, or combination of those. In general, a mobile user, while communicating, has a wireless connection with a fixed communication facility and rest of the communication path remains wired. The range of wireless communication is always limited and therefore range of user mobility is also limited. To overcome this limitation, cellular communication environment has been devised. In a cellular communication environment, geographical region is divided into smaller regions called cells, thus the name cellular. Each cell has a fixed communication device that serves all mobile devices within that cell. However, as a mobile device, while in active communication, moves out of one cell and into another cell, service of that connection is transferred from one cell to another. This is called handoff process [7,16].

The cellular arrangement has many attractive features. As the cell size is small, the mobile devices do not need very high transmitting power to communicate. This leads to smaller devices that consume less power. In addition, it is well known that the frequency spectrum that can be used for wireless communication is limited and can therefore only support a small number of wireless communication connections at a time. Dividing communication region into cells allows use of the same frequency in different cells as long as they are sufficiently apart to avoid interference. This increases the number of mobile devices that can be supported. Advances in digital signal processing algorithms and faster electronics have led to very powerful, smaller, elegant, and versatile mobile communication devices. These devices have tremendous mobile communication abilities including wireless Internet access, wireless e-mail and news items, and

wireless video (through limited) communication on handheld devices. Wireless telephones are already available and operate in different communication environments across the continents. The day is not far when a single communication number will be assigned to every newborn and will stay with that person irrespective of his/her location.

Another field that is emerging rapidly is the field of ad hoc wireless communication networks. These networks are of a temporary nature and are established for a certain need and for a certain duration. There is no elaborate setup needed to establish these networks. As a few mobile communication devices come in one another's proximity, they can establish a communication network among themselves. Typical situations where ad hoc wireless networks can be used are classroom environment, corporate meetings, conferences, disaster recovery situations, etc. Once the need for networking is satisfied, the ad hoc networking setup disappears.

## Resource Allocation Techniques

As discussed earlier, computer networks are resource sharing systems. Users share the common resources as transmission media, processing power and buffering capacity at the switching nodes, and other resources that are part of the networks. A key to successful operation of computer networks is a fair and efficient allocation of resources among its users. Historically, there have been two approaches to allocation of resources to users in computer networks:

- Static allocation of resources
- Dynamic allocation of resources

Static allocation of resources means that a desired quantity of resources is allocated to each user and they may use it whenever they need. If they do not use their allocated resources, no one else can. On the other hand, dynamic allocation of resources means that a desired quantity of resources is allocated to users on the basis of their demands and for the duration of their need. Once the need is satisfied, the allocation is retrieved. In that case, someone else can use these resources if needed. Static allocation results in wastage of resources, but does not incur the overhead associated with dynamic allocation. Which technique should be used in a given a situation is subject to the famous concept of supply and demand. If resources are abundant and demand is not too high, it may be better to have static allocation of resources; however, when the resources are scarce and demand is high, dynamic allocation is almost a necessity to avoid the wastage of resources.

Historically, communication and computer networks have dealt with both the situations. Earlier communication environments used dynamic allocation of resources when users will walk to public call office to make a telephone call or send a telegraphic message. After a few years, static allocation of resources was adopted, when users were allocated their own dedicated communication channels and these were not shared among others. In late 1960s, the era of computer networks dawned with dynamic allocation of resources and all communication and computer networks have continued with this tradition to date. With the advent of optical fiber, it was felt that the transmission resources are abundant and can satisfy any demand at any time. Many researchers and manufacturers held the opinion in favor of going back to the static allocation of resources, but a decision to continue with dynamic resource allocation approach was made and that is here to stay for many years to come [10].

## Challenges and Issues

Many challenges and issues are related to communications and computer networks that are still to be overcome. Only the most important ones will be described in this subsection.

High data rates provided by optical fibers and high-speed processing available at the switching nodes has resulted in lower delay for transferring information from one point to another. However, the propagation delay (the time for a signal to propagate from one end to another) has essentially remained unchanged. This delay depends only on the distance and not on the data rate or the type of the transmission medium.

This issue is referred to as latency versus delay issue [11]. In this situation traditional feedback-based reactive traffic management techniques become ineffective. New preventive techniques for effective traffic management and control are essential for achieving the full potential of these communication and computer networks [22].

Integration of different services in the same networks has also posed new challenges. Each type of service has its own requirements for achieving a desired level of quality of service (QoS). Within the networks any attempt to satisfy QoS for a particular service will jeopardize the QoS requirements for other service. Therefore, any attempt to achieve a desired level of quality of service must be uniformly applied to the traffic inside a communication and computer network and should not be intended for any specific service or user. That is another challenge that needs to be carefully addressed and its solutions achieved [13].

Maintaining security and integrity of information is another continuing challenge. The threat of sensitive information passively or actively falling into unauthorized hands is very real. In addition, proactive and unauthorized attempts to gain access to secure databases are also very real. These issues need to be resolved to gain the confidence of consumers so that they may use the innovations in communications and computer networking technologies to their fullest [13].

## Summary and Conclusions

Section 42.4 discussed the fundamentals of communications and computer networks and the latest developments related to these fields. Communications and computer networks have witnessed tremendous growth and sophisticated improvements over the last several decades.

Computer networks are essentially resource sharing systems in which users share the transmission media and the switching nodes. These are used for exchanging information among users that are not necessarily connected directly. Transmission rates of transmission media have increased manifold and the processing power of the switching nodes (which are essentially computers) has also been multiplied. The emerging computer networks are supporting communication of different types of services in an integrated fashion. All types of information, irrespective of its type and source, is being transported in the form of packets (e.g., ATM cells). Resources are being allocated to users on a dynamic basis for better utilization. Wireless communication networks are emerging to provide worldwide connectivity and exchange of information at any time.

These developments have also posed some challenges. Effective traffic management techniques, meeting QoS requirements, and information security are the major challenges that need to be surmounted in order to win the confidence of users.

## 42.5 Video over Mobile Networks

---

*Abdul H. Sadka*

### Introduction

Due to the growing need for the use of digital video information in multimedia communications especially in mobile environments, research efforts have been focusing on developing standard algorithms for the compression and transport of video signals over these networking platforms. Digital video signals, by nature, require a huge amount of bandwidth for storage and transmission. A 6-second monochrome video clip of QCIF ( $176 \times 144$ ) resolution and a frame rate of 30 Hz requires over 742 kbytes of raw video data for its digital representation where each pixel has an 8-bit luminance (intensity) value. When this digital signal is intended for storage or remote transmission, the occupied bandwidth becomes too large to be accommodated and thus compression becomes necessary for the efficient processing of the video content. Therefore, in order to transmit video data over communication channels of limited bandwidth, some kind of compression must be applied before transmission.

Video compression technology has witnessed a noticeable evolution over the last decade as research efforts have revolved around the development of efficient techniques for the compression of still images and discrete raw video sequences. This evolution has then progressed into improved coding algorithms that are capable of handling both errors and varying bandwidth availability of contemporary communication media. The contemporary standard video coding algorithms provide both optimal coding efficiency and error resilience potential. Current research activity is focused on the technologies associated with the provision of video services over the future mobile networks at user-acceptable quality and with minimal cost requirements. Section 42.5 discusses the basic techniques employed by video coding technology, and the associated most prominent error resilience mechanisms used to ensure an optimal trade-off between the coding efficiency and quality of service of standard video coding algorithms. The chapter section also sheds the light on the algorithmic concepts underlying these technologies and provides a thorough presentation of the capabilities of contemporary mobile access networks, such as general packet radio service (GPRS), to accommodate the transmission of compressed video streams at various network conditions and application scenarios.

## Evolution of Standard Image/Video Compression Algorithms

The expanding interest in mobile multimedia communications and the concurrently expanding growth of data traffic requirements have led to a tremendous amount of research work during a period of over 15 years for developing efficient image and video compression algorithms. Both International Telecommunications Union (ITU) and International Organization for Standardization (ISO) have released a number of standards for still image and video coding algorithms that employ the discrete cosine transforms (DCT) and the Macroblock (MB) structure of an image to suppress the temporal and spatial redundancies incorporated in a sequence of images. These standardized algorithms aimed at establishing an optimal trade-off between the coding efficiency and the perceptual quality of the reconstructed signal. After the release of the first still-image coding standard, namely JPEG [1], CCITT recommended the standardisation of the first video compression algorithm for low-bit rate communications at  $p \times 64$  kbit/s over ISDN, namely ITU-T H.261 [2] in 1990. In post 1990s, intensive work has been carried out to develop improved versions of the aforementioned ITU standard, and this has culminated in a number of video coding standards, namely MPEG-1 [3] for audiovisual data storage (1.5-2 Mbit/s) on CD-ROM, MPEG-2 [4] (or ITU-T H.262) for HDTV applications (4–9 Mbit/s), ITU-T H.263 [5] for very low bit rate (<64 kbit/s) communications over PSTN networks, and then the first content-based, object-oriented audiovisual compression algorithm, namely MPEG-4 [6], for multimedia communications over mobile networks in 1998. Recent standardization work resulted in recommending annexes to ITU-T H.263 standard, namely H.263+ [7] and H.263++ [8] for improved coding efficiency, bit rate scalability, and error resilience performance. ITU-T is currently considering the standardization of H.26L, a new video compression algorithm expected to outperform H.263 at very low bit rate applications. Despite this remarkable evolution of digital video coding technology, the common feature for all the released standards so far is that they all employ the same algorithmic concepts and build on them for further improvement in both quality and coding efficiency. In this chapter section, the fundamental techniques that constitute the core of today's video coders are presented.

### Digital Representation of Raw Video Data

A video signal is a sequence of still images. When played at a high enough rate, the sequence of images (mostly referred to as video frames) gives the impression of an animated video scene. Video frames are captured by a camcorder at a certain sampling rate and processed as a sequence of still pictures correlated by motion dependencies. When adjacent frames are strongly correlated, smaller redundancy is found in the video signal if only the difference between successive frames is encoded. The process of exploiting temporal redundancies between adjacent frames by subtracting the prediction image (sometimes referred to as the motion compensated image) from the original input image and then coding the resulting residual is called INTER frame coding. If no motion prediction was employed in encoding a video frame and only spatial redundancies were exploited to compress a video frame, then the frame is said to be INTRA coded.

Each video frame is a two-dimensional matrix of pixels, each of which is represented by a luminance (intensity) component and two chrominance (color) components  $Y$ ,  $U$ , and  $V$ , respectively. In block-based video coders, each frame is divided into groups of blocks (GOB). Each GOB is divided into a number of MBs (macroblock). A MB relates to 16 pixels by 16 lines of luminance  $Y$  and the spatially corresponding 8 pixels by 8 lines of chrominance  $U$  and  $V$ . A MB consists of four  $Y$ -blocks and two spatially corresponding color difference blocks. [Figure 42.24](#) depicts the hierarchical layering structure of a video frame of Quadrature Common Intermediate Format (QCIF) resolution, i.e., 176 pixels by 144 lines.

### Basic Concepts of Block-Based Video Coding Algorithms

Despite their differences, the video coding standards have the same core structure. They all adopt the MB structure as described in the previous section and consist of the same major building blocks. The standard video coding algorithms employ one of the two coding modes, INTRA or INTER. A typical block diagram of a block-based transform video coder is depicted in [Fig. 42.25](#).

FIGURE 42.24 Hierarchical layering structure for a QCIF frame in block-based video coders.

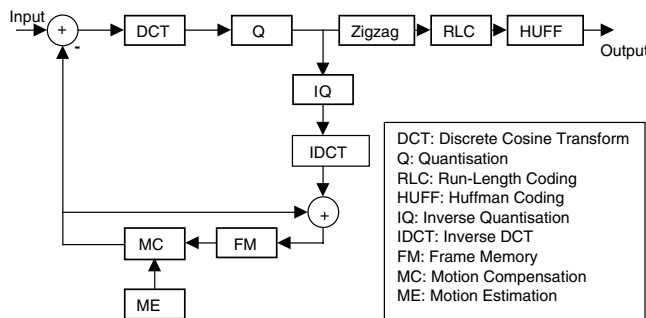

FIGURE 42.25 Block diagram of a block-based video coder.

### Discrete Cosine Transforms (DCT)

The 64 coefficients of an  $8 \times 8$  block of data are passed through a DCT transformer. DCT extracts the spatial redundancies of the video block by gathering the biggest portion of its energy in the low frequency components that are located in the top left corner of the block. The transfer function of a two-dimensional DCT transformer employed in a block-based video coder is given in Eq. (42.1) below:

$$F(u, v) = \frac{1}{4}C(u)C(v) \sum_{x=0}^7 \sum_{y=0}^7 f(x, y) \cos \left[ \pi(2x + 1) \frac{u}{16} \right] \cos \left[ \pi(2y + 1) \frac{v}{16} \right] \quad (42.1)$$

with  $u, v, x, y = 0, 1, 2, \dots, 7$ , where  $x$  and  $y$  are the spatial coordinates in the pixel domain,  $u$  and  $v$  are the coordinates in the transform domain

$$C(u) = \frac{1}{\sqrt{2}} \quad \text{for } u = 0; 1 \text{ otherwise}$$

$$C(v) = \frac{1}{\sqrt{2}} \quad \text{for } v = 0; 1 \text{ otherwise}$$

FIGURE 42.26 Sequence of zigzag-coding coefficients of a quantised  $8 \times 8$  block.

### Quantization

Quantization is a process that maps the symbols representing the DCT transformed coefficients from one set of levels to a narrower one in order to minimise the number of bits required to transmit the symbols. Quantization in block-based coders is a lossy process and thus it has a negative impact on the perceptual quality of the reconstructed video sequence. The quantization parameter ( $Q_p$ ) is a user-defined parameter that determines the level of distortion that affects the video quality due to quantization. The higher the quantization level,  $Q_p$ , the coarser the quantization process. Quantization uses different techniques based on the coding mode employed (INTRA or INTER), the position of the coefficient in a video block (DC or AC coefficients), and the coding algorithm under consideration.

### Raster Scan Coding

It is also known as zigzag pattern coding. The aim of zigzag coding the  $8 \times 8$  matrix of quantised DCT coefficients is to convert the two-dimensional array into a stream of indices with a high occurrence of successive 0 coefficients. The long runs of zeros will then be efficiently coded as will be shown in the next subsection. The order of a zigzag pattern encoder is depicted in Fig. 42.26.

### Run-Length Coding

The run-length encoder takes the one-dimensional array of quantised coefficients as input and generates coded runs as output. Instead of coding each coefficient separately, the run-length coder searches for runs of similar consecutive coefficients (normally zeros after the DCT and quantisation stages) and codes the length of the run and the preceding nonzero level. A 1-bit flag (LAST) is sent after each run to indicate whether or not the corresponding run is the last one in the current block. Run-lengths and levels are then fed to the Huffman coder to be assigned variable length codewords before transmission on the video channel.

### Huffman Coding

Huffman coding, traditionally referred to as entropy coding, is a variable length coding algorithm that assigns codes to source-generated bit patterns based on their frequency of occurrence within the generated bit stream. The higher the likelihood of a symbol, the smaller the length of the codeword assigned to it and vice versa. Therefore, Entropy coding results in the optimum average codeword size for a given set of runs and levels.

### Motion Estimation and Prediction

For each MB in a currently processed video frame, a sum of absolute differences (SAD) is calculated between its pixels and those of each  $16 \times 16$  matrix of pixels that lie inside a window (in the previous frame) of a user-defined size called the search window. The  $16 \times 16$  matrix, which results in the least

FIGURE 42.27 Motion estimation process in a block-based video coder.

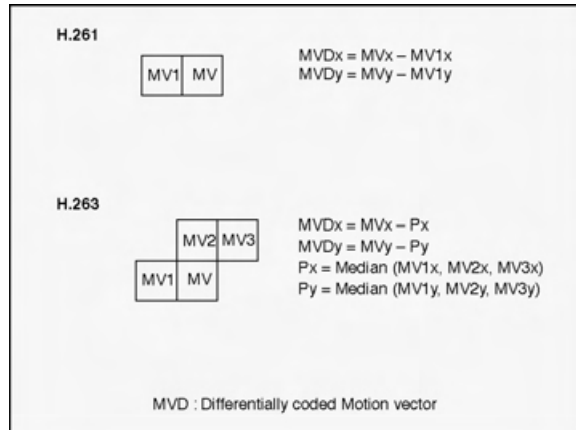

FIGURE 42.28 Motion prediction in 2 ITU-T video coding standards.

SAD, is considered to most resemble the current MB and referred to as the “best match.” The displacement vector between the currently coded MB and the matrix that spatially corresponds to its best match in the previous frame is called the motion vector (MV) and the relative SAD is called the MB residual matrix. If the smallest SAD is less than a certain threshold then the MB is INTER coded by sending the MV and the DCT coefficients of the residual matrix, otherwise the MB is INTRA coded. The coordinates of the MV are transmitted differentially using the coordinates of one or more MVs corresponding to neighboring MBs (left MB in ITU-T H.261 or left, top, and top right MBs in ITU-T H.263 and ISO MPEG-4) within the same video frame. Figures 42.27 and 42.28 illustrate the motion estimation and prediction processes of contemporary video coding algorithms.

### Subjective and Objective Evaluation of Perceptual Quality

The performance of a video coding algorithm can be simply subjectively evaluated by visually comparing the reconstructed video sequence to the original one. Two major types of subjective methods are used to assess the quality of perceptual video quality. In the first, an overall quality rating is assigned to the image (usually last decoded frame of a sequence). In the second, quality impairment is induced on a standard type image until it is completely similar to the reference image or vice versa.

**FIGURE 42.29** 150th Frame of original: (a) “Suzie” sequence and its compressed version at 64 kbit/s using, (b) H.261, (c) baseline H.263, and (d) Full-option H.263.

**FIGURE 42.30** PSNR values for Suzie sequence compressed at 64 kbit/s (a) baseline H.263 (b) Full-option H.263 (c) H.261.

Objectively, the video quality is measured by using some mathematical criteria, the most common of which is the peak-to-peak signal-to-noise ratio (PSNR) defined in Eq. (42.2).

$$\text{PSNR} = 10 \log_{10} \frac{255^2}{\frac{1}{M \times N} \sum_{i=0}^{M-1} \sum_{j=0}^{N-1} (x(i, j) - \hat{x}(i, j))^2} \quad (42.2)$$

For a fair comparison of perceptual quality between two video coding algorithms, the objective and subjective results must be evaluated at the same target bit rates. Because the bit rate in kbit/s is directly proportional to the number of frames coded per unit of time, the frame rate ( $f/s$ ) has also to be mentioned in the evaluation process.

Figures 42.29 and 42.30 show the subjective and objective results, respectively, for coding 150 frames of the sequence “Suzie” at a bit rate of 64 kbit/s and a frame rate of 25  $f/s$ .

## Error Resilience for Mobile Video

Mobile channels are characterised by a high level of hostility resulting from high bit error ratios (BER) and information loss. Because of the bit rate variability and the spatial and temporal predictions, coded video streams are highly sensitive to transmission errors. This error sensitivity can be the reason for an ungraceful degradation of video quality, and hence the total failure of the video communication service. A single bit error could lead to a disastrous damage to perceptual quality. The most damaging effect of errors is that which leads to a loss of synchronisation at the decoder. In this case, the decoder is unable to determine the size of the affected variable-length video parameter and, therefore, drops the stream bits following the position of error until it resynchronises at the next synch word. Consequently, it is vital to employ an error resilience mechanism for the success of the underlying video communication service.

A popular technique used to mitigate the effects of errors is called error concealment [9]. It is a decoder-based zero-redundancy error control scheme whereby the decoder makes use of previously received error-free video data for the reconstruction of the incorrectly decoded video segment. A commonly used approach conceals the effect of errors on a damaged MB by relying on the content of the spatially corresponding MB in the previous frame. In the case where motion data is corrupted, the damaged motion vector can be predicted from the motion vectors of spatially neighboring MBs in the same picture. On the other hand, transform coefficients could also be interpolated from pixels in neighboring blocks.

However, error concealment schemes cannot provide satisfactory results for networks with high BERs and long error bursts. In this case, error concealment must be used in conjunction with error resilience schemes that make the coded streams more robust to transmission errors and video packet loss. In the literature, there are a large number of error resilience techniques specified in the standard ISO MPEG-4 [10] and the annexes to ITU-T H.263 defined in recommendations H.263+ [11] and H.263++ [12]. One of the most effective ways of preventing the propagation of errors in encoded video sequences is the regular insertion of INTRA-coded frames, which do not make use of any information from previously transmitted frames; however, this method has the disadvantage of making the traffic characteristics of a video sequence extremely bursty since a much larger number of bits are required to obtain the same quality levels as for INTER (predictively coded) frames. A more efficient improvement to INTRA-frame refresh consists of regular coding of INTRA MBs per frame, referred to as Adaptive INTRA Refresh (AIR), where the INTRA coded MBs are identified as part of the most active region in the video scene. The insertion of a fixed number of INTRA coded MBs per frame can smooth out the bit rate fluctuations caused by coding the whole frame in INTRA mode. In the following subsections, we present two major standard-compliant error resilience algorithms specified in the MPEG-4 video coding standard, namely data partitioning and two-way decoding with reversible codewords.

### Video Data Partitioning

The non error-resilient syntax of video coding standards suggests that video data is transmitted on a MB basis. In other words, the order of transmission is established such as all the parameters pertaining to a particular MB are sent before any parameter of the following MB is transmitted. This implies that a bit error detected in the texture data of an early MB in the video frame leads to the loss of all forthcoming MBs in the frame. Data partitioning changes the order of transmission of video data from a MB basis to a frame basis or a Visual Object Plane (VOP) basis in MPEG-4 terminology. Each video packet that corresponds to a VOP consists of two different partitions separated by specific bit patterns called markers (DC marker for INTRA coded VOPs and motion marker for INTER coded VOPs). The first partition contains the shape information, motion data, and some administrative parameters such as COD for INTRA frames and MCBPC of all the MBs in the VOP, while the second partition contains the texture data (i.e., the transform coefficients TCOEFF) of all the MBs inside the VOP and other control parameters such as CBPY. Using this partitioning structure as illustrated in Fig. 42.31, the errors that hit the data bits of the second partition do not lead to the loss of the whole frame since the error-sensitive motion data would have been correctly decoded upfront.

FIGURE 42.31 Data partitioning for error resilient video communication.

FIGURE 42.32 One-way decoding of variable-length codes.

FIGURE 42.33 Two-way decoding of variable-length codes.

### Two-Way Decoding and Reversible Variable-Length Codewords

Two-way decoding is used with reversible VLC words in order to reduce the size of the damaged area in a video bit stream. This error resilience technique enables the video decoder to reconstruct a part of the stream that would have been skipped in the ordinary one-way decoding due to loss of synchronisation. This is achieved by allowing the decoding of the variable-length codewords of the video bit stream in the reverse direction. The reversible codewords are symbols that could be decoded in both the forward and reverse directions. An example of reversible VLCs is a set of codewords where each one of them consists of the same number of the starting symbol, either 1 or 0. For instance, the set of variable-length codewords that is defined by 0100, 11001, 10101, 01010, 10011, 0010, consists of codewords that contain three 1s or 0s each, where the 1 or 0 is the starting symbol, respectively.

In conventional one-way decoding, the decoder loses synchronisation upon detection of a bit error. This is mainly due to the variable rate nature of compressed video streams and the variable-length Huffman codes assigned to various symbols that represent the video parameters. In order to restore its synchronisation, the decoder skips all the data bits following the position of errors until it falls on the first error-free synch word in the stream. The skipped bits are then discarded, regardless of their correctness, resulting in an effective error ratio that is larger than the channel BER by orders of magnitude. The response of the one-way video decoder to a bit error is depicted in Fig. 42.32.

With two-way decoding, a part of the skipped segment of bits can be recovered by enabling decoding in the reverse direction as shown in Fig. 42.33. Upon detection of a bit error, the decoder stops its operation searching for the next synch word in the bit stream. Upon gaining synchronization at the synch word, the decoder resumes its operation in the backward direction thereby rescuing the part of the bit stream, which has been discarded in the forward direction. If no error is detected in the reverse direction then the damaged area is confined to the MB where the bit error has been detected in the forward direction. If an error has also been flagged up in the backward direction, then the segment of bits between the positions of error in both the forward and backward directions is discarded as the error damaged area as shown in Fig. 42.33.

In many cases, a combination of error resilience techniques is used to further enhance the error robustness of compressed video streams to transmission errors of mobile environments. For instance,

both data partitioning and two-way decoding can be jointly employed to protect the error-sensitive motion data of the first video partition. The motion vectors and the administrative parameters contained in the first partition are all coded with reversible VLC words. The detection of a bit error in the forward direction triggers the decoder to stop its operation, regain synchronisation at the motion marker separating the two partitions in the corresponding VOP, and then decode backwards to salvage some of the correctly received bits that were initially skipped in the forward direction.

## **New Generation Mobile Networks**

Packet-switched mobile access networks such as GPRS [13] and EGPRS [14] are intended to give subscribers access to a variety of mobile multimedia services that run on different networking platforms, let it be the core mobile network, i.e., UMTS, ATM, or even Internet. The packet-switched mobile access networks have a basic common feature in that they are all IP-based and allow time multi-slotting on a given radio interface. The multi-slotting capabilities enable the underlying networking platform to accommodate higher bit rates by providing the end-user with a larger physical layer capacity.

The real-time interactive and conversational services are very much delay-critical, so the provision of these services over mobile networks can only be achieved by using a service class capable of guaranteeing the delay constraints with one-delays in the order of 200 msec being required. In order to achieve such delay requirements, it is necessary to avoid using any retransmissions or repeat-requests scenarios by operating the RLC layer of the GPRS protocol stack in the unacknowledged mode of operations. Similarly, the transport layer protocol that must be employed is the user datagram protocol (UDP), which operates over IP and does not make use of any repeat-request system.

IP networks do not guarantee the delivery of packets and neither do they provide any mechanism to guarantee the orderly arrival of packets. This implies that not only does the inter-packet arrival time vary but it is also likely that packets may arrive out of order. Therefore, in order to transmit real-time video information, some transport-layer functionality must be overlaid on the network layer to provide timing information from which streaming video may be reconstructed. To offer this end-to-end network transport functionality, the IETF real-time transport protocol (RTP) [15] is used. RTP fulfills functions such as payload type identification, sequence numbering, timestamping, and delivery monitoring, and operates on top of IP and UDP for the provision of real-time services and video applications over the IP-based mobile networks.

On the other hand, the mobile access networks employ channel protection schemes that provide error control capabilities against multipath fading and channel interferers. For instance, GPRS employs four channel protection schemes (CS-1 to CS-4), offering flexibility in the degree of protection and data traffic capacity available to the user. Varying the channel coding scheme allows for an optimization of the throughput across the radio interface as the channel quality varies. The data rates provided by GPRS with the channel coding schemes enabled are 8 kbit/s for CS-1, 12.35 kbit/s for CS-2, 14.55 kbit/s for CS-3, and 20.35 kbit/s for CS-4; however, almost 15% of the bits in the payload of a radio block are used up by header information belonging to the overlying protocols. Therefore, the rates presented to the video source for each one of the channel coding schemes per time slot are 6.8 kbit/s for CS-1, 10.5 kbit/s for CS-2, 12.2 kbit/s for CS-3, and 17.2 kbit/s for CS-4. It is, however, envisaged that the CS-1 and CS-2 schemes will be used for video applications. Obviously, the available throughput to a single terminal will be multiples of the given rates per slot, depending upon the multi-slotting capabilities of the terminal. Conversely, EGPRS provides 9 channel coding schemes of different protection rates and capabilities and the choice of a suitable scheme is again a trade-off between the throughput and the error protection potential.

## **Provision of Video Services over Mobile Networks**

Taking into perspective the traffic characteristics of a coded video source employing a fixed quantiser, we observe that the output bit rate is highly variable with high peaks taking place each time an INTRA-coded frame is transmitted. INTRA frames require roughly three times on average the bandwidth required

for transmitting a predictively coded frame. Therefore, if the frequency of INTRA frames is increased for error control purposes as discussed in the subsection on “Error Resilience for Mobile Video,” the encoder will have to discard a number of frames following each INTRA coded frame until some bandwidth becomes available. Despite the fact that a fixed quantiser leads to a constant spatial quality, yet the frequent insertion of INTRA frames in the video sequence has a degrading effect on the temporal quality of the entire video sequence. In order to preventively cure this situation, it is advisable that a rate control mechanism be employed at the video encoder before the coded video bit stream is sent over the mobile channel. One method is to vary the used quantiser value in order to truncate the high-frequency DCT coefficients in accordance with the target bit rate of the video coder and the number of bits available to code a particular frame, VOP or MB. Coding an INTRA frame with a coarse quantiser results in a poor spatial quality but helps improve the temporal quality of the video sequence by maintaining the original frame rate and reducing the jittering effect caused by the disparity in size between INTRA and INTER coded frames.

The video delivery over mobile channels can take the form of real-time delay-sensitive conversational services, delay-critical (on-demand or live) streaming services, or delay-insensitive multimedia messaging applications. The latter requires guarantee on the error-free delivery of intended messages without placing any stipulation on the duration of transmission and therefore allows retransmissions of erroneous messages to take place. The former two categories of video services, however, are rather more delay-critical and necessitate the use of both application and transport layer end-to-end error control schemes for the robust transmission of compressed video in mobile environments.

The analysis of the GPRS protocol efficiency shows that a reduction of 15% in the data rate per time slot, as seen by the video encoder, is enough to compensate for all the protocol overheads. The video quality that can be achieved in video communications over the new generation mobile networks, is a function of the time slot/coding-scheme combination and the channel conditions during the time of video packet transmission. It is observed that in error-free conditions, CS-1 yields a sub-optimal quality due to the large overhead it places on the available bandwidth of each time slot; however, in error-prone conditions and for C/I ratios lower than 15 dB, CS-1 presents the best error protection capabilities and offers the best video quality as compared to other channel coding schemes. When eight time slots are used with CS-1, GPRS can offer a video payload data rate of 54.4 kbit/s. At this rate, it has been demonstrated that QCIF-resolution conversational MPEG-4 video services can be offered over GPRS for a frame rate of 10 f/s with fairly good perceptual quality, especially when frequency hopping is used; however, for highly detailed scenes involving a high amount of motion, the error-free video quality at high C/I ratios suffers both spatially and temporally because of the coarse quantiser used and the jitter resulting from the large number of discarded frames respectively. The error protection schemes of the GPRS protocol are used in conjunction with the application-layer error resilience techniques specified by the MPEG-4 video compression standard. Figure 42.34 shows the subjective video quality achieved

**FIGURE 42.34** One frame of Suzie sequence encoded with MPEG-4 at 18 kbit/s and transmitted over a GPRS channel with C/I = 15 dB, with CS-1 and 4 time-slots used: (a) no error resilience and (b) AIR.

by transmitting an MPEG-4 coded video sequence (at 18 kbit/s) over a GPRS channel with and without error resilience (AIR) when CS-1 and four time slots are used.

On the other hand, video services on EGPRS are less likely to encounter the same problems posed by the lack of bandwidth in the GPRS networks. When EGPRS employs the channel coding scheme MCS-9, the terminal can be offered a data rate of 402.4 kbit/s when 8 time slots are employed. Obviously, at this data rate, there exists a much higher flexibility in selecting the operating picture resolution and the video content intended for transmission over the mobile network.

## Conclusions

The provision of video services over the new generation mobile networks is made possible through the enabling technologies supported by the error protection schemes and the multi-slotting capabilities of the radio interface. Conversational video applications are delay-sensitive and thus do not support re-transmissions of corrupted video data. To provide a user-acceptable video quality, the video application must employ an error resilience mechanism in conjunction with the physical layer channel coding schemes. A wide range of error resilience techniques have been developed in recent video compression algorithms and their annexed versions. The use of error resilience techniques for supporting the provision of video services over mobile networks helps enhance the perceptual quality, especially at times where the mobile channel is suffering from low C/I ratios resulting from high BERs and radio block loss ratios.

## 42.6 Pen-Based User Interfaces—An Applications Overview

---

*Giovanni Seni and Jayashree Subrahmonia*

### Introduction

A critical feature of any computer system is its interface with the user. This has led to the development of user interface technologies such as mouse, touch-screen, and pen-based input devices. They all offer significant flexibility and options for computer input; however, touch-screens and mice cannot take full advantage of human fine motor control, and their use is mostly restricted to data “selection,” i.e., as pointing devices. On the other hand, pen-based interfaces allow, in addition to the pointing capabilities, for other forms of input such as handwriting, gestures, and drawings. Because handwriting is one of the most familiar communication media, pen-based interfaces appear to offer a very easy and natural input method.

A pen-based interface consists of a transducer device and a fine-tipped stylus so that the movement of the stylus is captured; such information is usually given as a time ordered sequence of  $x$ - $y$  coordinates (*digital ink*) and an indication of “inking,” i.e., whether the pen is up or down. Digital ink can be passed on to recognition software that will convert the pen input into appropriate computer actions. Alternatively, the handwritten input can be organized into ink documents, notes, or messages that can be stored for later retrieval or exchanged through telecommunications means. Such ink documents are appealing because they capture information as the user composed it, including text in any mix of languages and drawings such as equations and graphs.

Pen-based interfaces are desirable in mobile computing (e.g., Personal Information Appliances—PIAs) because they are scalable. Only small reductions in size can be made to keyboards before they become awkward to use; however, if they are not shrunk in size, they lose their portability. This is even more problematic as mobile devices develop into multimedia terminals with numerous functions ranging from agenda and address book to wireless web browser. Voice-based interfaces may appear to be a solution, but they entail all the problems that mobile phones already have introduced in terms of disturbing bystanders and loss of privacy. Furthermore, using voice commands to control applications such as a web browser can be difficult and tedious; by contrast, clicking on a link with a pen, or entering a short text by writing, is very natural and takes place in silence.

Recent hardware advances in alternative ink capture devices based on ultrasonic and optical tracking technologies have also contributed to the renewed interest in pen-based systems. These technologies avoid the need for pad electronics, thus reducing the cost and weight of a pen-enabled system. Furthermore, they can sometimes be retrofitted to existing writing surfaces such as whiteboards [4] or used with plain paper [5].

Section 42.6 reviews a number of applications, old and new, where the pen can be used as a very convenient and natural form of input. Our emphasis will be on the user experience, highlighting limitations of existing solutions and suggesting ways of improving them. We start with a short review of currently available pen input hardware in the subsection on “Pen Input Hardware.” We then, in “Handwriting Recognition,” discuss handwriting recognition user interfaces for mobile devices and the need for making applications aware of the handwriting recognition process. In “Ink and the Internet” we present Internet related applications such as ink messaging. In “Extension of Pen-and-Paper Metaphor” we discuss functionality that extends the traditional pen and paper metaphor. Finally, in “Pen Input and Multimodal Systems,” we present examples of synergistic interfaces that are being developed combining the pen with other input modalities.

### Pen Input Hardware

The function of the pen input hardware is to convert pen tip position over time into  $X,Y$  coordinates at a sufficient temporal and spatial resolution for handwriting recognition and visual presentation [25].

A pen input system consists of a combination of pen, pad, and in some cases, paper. Not all pen systems have a paper interface for capturing the position of the pen-tip. Examples of these include PIAs

and some electronic tablets. Some of these have a glass surface on the pad that is the interface to capture and display ink. Others (like the electronic tablets) have an input device that is separate from the display. Although these are usable for small quantities of input and for navigating through applications using touch-selection, they are extremely difficult from a usability standpoint for entering large quantities of digital ink. Paper-based systems provide the best user interface for inputting digital ink and hence are the best user interface for large note-taking applications. They are also the highest resolution displays for ink available today and do not suffer from issues like tolerance to glare that glass surfaces do.

In systems that use paper, an additional challenge that needs to be addressed comes from the fact that pen tip contact with paper also needs to be sensed to establish when ink is deposited on paper.

Pen hardware platforms available today use one of the following four kinds of technologies:

**Magnetic Tracking** Here, sequentially energized coils embedded in the pad couple a magnetic field into a pen tank circuit (coil and capacitor). Neighboring coils pick up the magnetic field from the pen, and their relative strength determines pen location [22]. The magnetic field can also be generated in the pen, requiring a battery that increases pen weight and thickness [23].

**Electric Tracking** Here, the conductive properties of a hand and normal pen can be used for tracking [24]. A transmitter electrode in the pad couples a small displacement current through the paper to the hand, down through the pen, and back through the paper to an array of receiver electrodes. Pen location is calculated as the “center of mass” of the received signal strengths.

**Ultrasonic Tracking** Ultrasonic tracking is based on the relatively slow speed of sound in air (330 m/sec). A pen generates a burst of acoustic energy. Electronics in the pad measure the time of arrival to two stationary ultrasonic receivers [4,5]. The ultrasonic transmission is either synchronized to the pad, typically with an infrared signal, or a third ultrasonic receiver is used [26].

**Optical Tracking Technology** Optical tracking systems can either provide relative tracking (like a mouse) or absolute position tracking (like a touch screen) [28,29].

Bar codes printed over an entire page can provide absolute position using a tiny camera mounted in a pen [30,31]. The bar codes can also encode page number, eliminating overwrites when a person forgets to tell the digitizer they have changed pages (a challenge that pen hardware systems with paper interfaces have to address). Another approach captures a sequence of small images of handwriting and assembles them to reconstruct the entire page [32].

## Discussion of Input Hardware

Magnetic tracking is the widest deployed system due to high spatial resolution (>1000 dpi), acceptable temporal resolution (>100 Hz), reliability, and modest cost [33].

Magnetic and electric tracking require pad electronics and shielding, making them thicker and heavier than a conventional clipboard. Electric tracking uses a normal pen but has no direct way to measure pen tip contact, and must rely on less reliable pen trajectory analysis [34].

Ultrasonic tracking does not require pad electronics, making it lower cost and weight. Relative tracking can reach 256 dpi, but absolute spatial resolution is limited to about 50 dpi due to air currents that cause Doppler shifts.

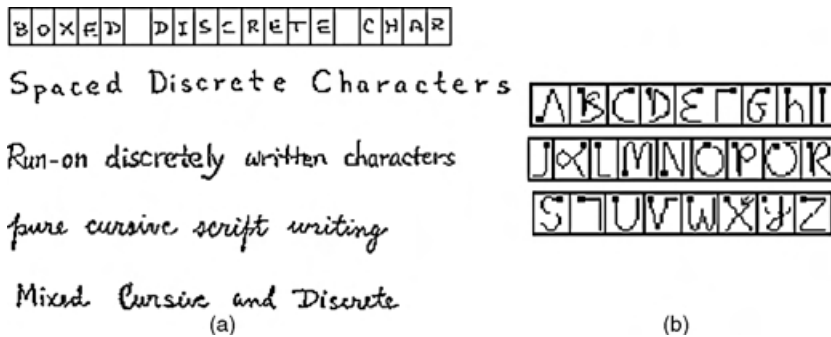

Optical tracking offers the highest spatial (>2000 dpi) and temporal (>200 Hz) resolution, and can utilize a self-contained pen that remembers everything written. Special bar code paper provides absolute position and page tracking. Optical methods based on CMOS technology lend themselves to low-power, low-cost, and highly integrated designs. These features suggest that optical tracking will play a significant role in future pen systems.

## Handwriting Recognition

Handwriting is a very well-developed skill that humans have used for over 5,000 years as means of communicating and recording information. With the widespread acceptance of computers, the future role of handwriting in our culture might seem questionable. However, as we discussed in introduction

**FIGURE 42.35** The handwriting recognition problem. The image of a handwritten character, word, or phrase is classified as one of the symbols, or symbol strings, from a known list. Some systems use knowledge about the language in the form of dictionaries (or Lexicons) and frequency information (i.e., Language Models) to aid the recognition process. Typically, a score is associated with each recognition result.

**FIGURE 42.36** Different handwriting styles. In (a), Latin characters are used, from top to bottom, according to the presumed difficulty in recognition (adapted from Tappert,1984). In (b), the *Graffiti*<sup>TM</sup> unistroke (i.e., written with a single pen trace) alphabet which restricts characters to a unique pre-specified way that simplifies automatic recognition, the square dot indicates starting position of the pen.

section, a number of applications exist where the pen can be more convenient than a keyboard. This is particularly so in the mobile computing space where keyboards are not ergonomically feasible.

Handwriting recognition is fundamentally a pattern classification task; the objective is to take an input graphical mark, the handwritten signal collected via a digitizing device, and classify it as one of a pre-specified set of symbols. These symbols correspond to the characters or words in a given language encoded in a computerized representation such as ASCII (see Fig. 42.35). In this field, the term *online* has been used to refer to systems devised for the recognition of patterns captured with digitizing devices that preserve the pen trajectory; the term *offline* refers to techniques, which instead take as input a static two-dimensional image representation, usually acquired by means of a scanner.

Handwriting recognition systems can be further grouped according to the constraints they impose on the user with respect to writing style (see Fig. 42.36(a)). The more restricted the allowed handwritten input is, the easier the recognition task and the lower the required computational resources. At the highest restricted end of the spectrum, *boxed-discrete* style, users write one character at a time within predefined areas; this removes one difficult step, segmentation, from the recognition process. Very high levels of recognition accuracy can be achieved by requiring users to adhere to rules that restrict character shapes so as to minimize letter similarity (see Fig. 42.36(b)). Of course, such techniques require users to learn a “new” alphabet. At the least restricted end of the spectrum, *mixed* style, users are allowed to write words or phrases the same way they do on paper—in their own personal style—whether they print, write in cursive, or use a mixture of the two.

Recognition of mixed-style handwriting is a difficult task due to ambiguity in segmentation (partitioning the word into letters), and large variation at the letter level. Segmentation is complex because it is often possible to wrongly break up letters into parts that are in turn meaningful (e.g., the cursive letter “d” can be subdivided into letters “c” and “l”). Variability in letter shape is mostly due to *co-articulation*

(the influence of one letter on another), and the presence of ligatures, which frequently give rise to unintended (“spurious”) letters being detected in the script.

In addition to the writing style constraints, the complexity of the recognition task is also determined by *dictionary-size* and *writer-adaptation* requirements. The size of dictionary can vary from very small (for tasks such as state name recognition) to open (for tasks like proper name recognition). In open vocabulary recognition, any sequence of letters is a plausible recognition result and this is the most difficult scenario for a recognizer. In the writer-adaptation dimension, systems capable of out-of-the box recognition are called writer-independent, i.e., they can recognize the writing of many writers; this gives a good average performance across different writing styles; however, there is considerable improvement in recognition accuracy that can be obtained by customizing the letter models of the system to a writer’s specific writing style. Recognition in this case is called writer-dependent.

Despite these challenges, significant progress has been made in the building of writer-independent systems capable of handling unconstrained text and using dictionary sizes of over 20,000 words [1,2,3]. Some of these systems are now commercially available. For a comprehensive survey of the basic concepts behind written language recognition algorithms see [14,21,37].

### User Interfaces on Mobile Devices

In Fig. 42.37, examples of user interfaces for handwritten text input are presented that are representative of those found on today’s mobile devices. Because of the limited CPU and memory resources available on these platforms, handwritten input is restricted to the boxed-discrete style.

Additional highlights of the user interface on these text input methods are:

**Special Input Area.** Users are not allowed the freedom of writing anywhere on the screen. Instead, there is an area of the screen specially designated for the handwriting user interface, whether for text input or control. This design choice offers the following advantages:

FIGURE 42.37 Character-based text input method on today’s mobile devices. In (a), user interface for English character input on a cellular phone. In (b), user interface for Chinese character input on a 2-way pager.

- *No toggling between edit/control and ink mode.* Pen input inside the input method area is treated as ink to be recognized by the recognizer; pen input outside this area is treated as mouse events, e.g., selection, etc. Without this separation, special provisions, sometimes unnatural, have to be taken to distinguish among the two pen modes.
- *Better user control.* Within the specially designated writing window it is possible to have additional GUI elements that help the user with the input task. For instance, there might be buttons for common edit keys such as backspace, newline, and delete. Similarly, a list of recognition alternates can be easily displayed and selected from. This is particularly important because *top-n* recognition accuracy—a measure of how often the correct answer is among the highest ranked *n* results, is generally much higher than *top-1* accuracy.
- *Consistent UI metaphor.* Despite its ergonomic limitations, an on-screen keyboard is generally available as one of the text input methods on the device. Using a special input area for handwriting makes the user interface of alternative text entry methods similar.

**Modal Input.** The possibilities of the user’s input are selectively limited in order to increase recognition accuracy. Common modes include “digits,” “symbols,” “upper-case letters,” and “lower-case letters” in English, or “traditional” versus “simplified” in Chinese. By limiting the number of characters against which a given input ink is matched, the opportunities for confusion and mis-recognition are decreased, and recognition accuracy is improved. Writing modes represent another tradeoff between making life simpler for the system or simpler for the user.

**Natural Character Set.** It is possible to use any character writing style commonly used in the given language, no need to learn a special alphabet. Characters can be *multi-stroke*, i.e., written with more than one pen trace.

**Multi-boxed Input.** When multi-stroke input is allowed, end of writing is generally detected by use of a timer that is set after each stroke is completed; the input is deemed concluded if a set amount of time elapses before any more input is received in the writing area. This “timeout” scheme is sometimes confusing to users. Multiple boxes give better performance because a character in one box can be concluded if input is received in another, removing the need to wait for the timer to finish.

Of all the restrictions imposed on users by these character-based input methods, modality is the one where user feedback has been strongest: people want *modeless* input. The challenge lies in that distinguishing between letters which have very similar forms across modes is virtually impossible without additional information. In English orthography, for instance, there are letters for which the lower case version of the character is merely a smaller version of the upper case version; examples include “Cc,” “Kk,” “Mm,” “Oo,” “Ss,” “Uu,” “Ww,” etc. Simple attempts at building modeless character recognizers can result in a disconcerting user experience because upper case letters, or digits, might appear inserted into the middle of lower case words. Such m1Xed CaSe w0rdS (mixed case words) look to users to be gibberish.

In usability studies, the authors have further found that as the text data entry needs on wireless PIA devices shifts from short address book or calendar items to longer notes or e-mail messages, users deem writing one letter at a time to be inconvenient and unnatural.

## More Natural User Interfaces

One known way of dealing with the character confusion difficulties described in section “User Interfaces on Mobile Devices” is to use contextual information in the recognition process. At the simplest level this means recognizing characters in the context of their surrounding characters and taking advantage of visual clues derived from word shape. At a higher level, contextual knowledge can be in the form of lexical constraints, e.g., a dictionary of known words in the language is used to restrict interpretations of the input ink. These ideas naturally lead to the notion of a *word-based* text input method. By “word” we mean a string of characters which, if printed in text using normal conventions, would be surrounded by white-space characters (see Fig. 42.38(a)).

**FIGURE 42.38** Word-based text input method for mobile devices. In (a), a user interface prototype. In (b), an image of the mixed-case word “Wow,” where relative size information can be used for distinguishing among the letters in the “Ww” pair. In (c), an image of the digit string “90187” where ambiguity in the identity of the first three letters can be resolved after identifying the last two letters as digits.

Consider the notion of a *mixed-case* word recognition context where the size and position of a character, relative to other characters in the word, is taken into account during letter identification (see Fig. 42.38(b)). Such additional information would allow us to disambiguate between the lower case and upper case version of letters that otherwise are very much alike. Similarly, Fig. 42.38(b) illustrates that relative position within the word would enable us to correctly identify trailing punctuation marks such as periods and commas. A different kind of contextual information can be used to enforce some notion of “consistency” among the characters within a word. For instance, we could have a *digit-string* recognition context that favors word hypotheses where all the characters can be viewed as digits; in the image example of Fig. 42.38(c), the recognizer would thus rank string “90187” higher than string “gol87.”

In addition to the modeless input enabled by a word-based input method, there is a writing throughput advantage over character-based ones. In Fig. 42.39 we show the results of a timing experiment where eight users were asked to transcribe a 42-word paragraph using our implementation of both kinds of input methods on a keyboardless PIA device. The paragraph was derived from a newspaper story and contained mixed-case words and a few digits, symbols, and punctuation marks. The length of the text was assumed to be representative of a long message that users might want to compose on such devices. For comparison purposes, users were also timed with a standard on-screen (software) keyboard. Each timing experiment was repeated three times. The median times were 158, 185, and 220 s for the keyboard, word-based, and character-based input methods, respectively. Thus, entering text with the word-based input method was, on average, faster than using the character-based method.

Our current implementation of the word-based input method does not have, on average, a time advantage over the soft keyboard; however, the user who was fastest with the word-based input method (presumably someone for whom the recognition accuracy was very high and thus had few corrections to do) was able to complete the task in 141 s, which is below the median soft keyboard time.

**FIGURE 42.39** Boxplots of time to enter a 42-word message using three different text input methods on a PIA device: an on-screen QWERTY keyboard, a word-based handwriting recognizer and a character-based handwriting recognizer. Median writing throughput were 15.9, 13.6, and 11.4 words-per-minute respectively.

**FIGURE 42.40** Write-anywhere text input method for mobile devices. Example of an Address Book application with the *Company* field appearing with focus. Hand written input is not restricted to a delimited area of the screen but rather can occur anywhere. The company name “Data Warehouse” has been written.

Furthermore, the authors believe that the time gap between these two input methods will be reduced in the case of European languages that have accents, since they require additional key presses in the case of the soft keyboard.

As one can expect, the modelless and time advantage of a word-based input method over a character-based one comes at the expense of additional computational resources. Currently, the word-based recognition engine requires a 10× increment in MIPS and memory resources compared to the character-based engine. One should also say that, as evidenced by the range of the timing data shown in the above plots, there isn’t a single input method that works best for every user. It is thus important to offer users a variety of input methods to experiment with and choose from.

### ***Write-Anywhere Interfaces***

In the same way that writing words, as opposed to writing one letter at a time, constitutes an improvement in terms of “naturalness” of the user experience, we must explore recognition systems capable of handling continuous handwriting such as phrases. For the kind of mobile devices we’ve been considering, with very limited screen real estate, this idea leads to the notion of a “write-anywhere” interface where the user is allowed to write anywhere on the screen, i.e., on top of any application and system element on the screen (see Fig. 42.40).

**FIGURE 42.41** Inherent ambiguity in continuous handwriting recognition. In (a), a sample image of a handwritten word. In (b), possible recognition results, strings not in the English lexicon are in italics.

A write-anywhere text input method is also appealing because there is no special inking area covering up part of the application in the foreground; however, a special mechanism is needed to distinguish pen movement events intended to manipulate user interface elements such as buttons, scrollbars, and menus (i.e., edit/control mode) and pen events corresponding to longhand (i.e., ink mode). The solution typically involves a “tap and hold” scheme wherein the pen has to be maintained down without dragging it for a certain amount of time in order to get the stylus to act temporarily as a mouse.

An additional user interface issue with a write-anywhere text input paradigm is that there are usually no input method control elements visible anywhere on the screen. For instance, access to recognition alternates might require a special pen gesture. As such, a write-anywhere interface will generally have more appeal to advanced users. Furthermore, recognition in the write-anywhere case is more difficult because there is no implicit information on the word separation, orientation, or size of the text.

### Recognition-Aware Applications

Earlier in this section, the authors discussed how factors such as segmentation ambiguity, letter co-articulation, and ligatures make exact recognition of continuous handwritten input a very difficult task. To illustrate this point consider the image shown in Fig. 42.41 and the set of plausible interpretations given for it. Can we choose with certainty one of these recognition results as the “correct” one? Clearly, additional information, not contained within the image, is required to make such a selection. One such source of information that we have already mentioned is the dictionary, or lexicon, for constraining the letter strings generated by the recognizer. At a higher-level, information from the surrounding words can be used to decide, for example, among a verb and a noun word possibility. It is safe to say that the more constraints that are explicitly available during the recognition process the more ambiguity in the input that can be automatically resolved. Less ambiguity results in higher recognition accuracy and thus, improved user experience.

For many common applications in PIA devices, e.g., contacts, agenda, and web browser, it is possible to specify the words and patterns of words that can be entered in certain data fields. Examples of structured data fields are telephone numbers, zip codes, city names, dates, times, URLs, etc. In order for recognition-based input methods to take advantage of this kind of contextual information, the existing text input framework on PIA devices needs to be modified. Currently, no differentiation is made between text input made by tapping the “keyboard” and that of using handwriting recognition; i.e., applications are, for the most part, not aware of the recognition process. A possible improvement over the current state of the art for UI implementation would be for applications to make an encoding of the contextual constraints associated with a given field available to the recognition engine.

One typically uses a *grammar* to define the permitted strings in a language, e.g., the language of valid telephone numbers. A grammar consists of a set of rules or productions specifying the sequences of characters or lexical items forming allowable strings in the defined language. Two common classes of grammars are BNF grammar or context-free grammar and regular grammar (see [6] for a formal treatment). Grammars are widely used in the field of speech recognition and recently the W3C Voice

    <token></token>
  </count>
  <ruleref uri="#suffix"/>
</rule>

```

**FIGURE 42.42** Example of an XML grammar defining telephone numbers and written as per the W3C Voice Working Group Specification. There are four “private” rule definitions that are combined to make the main rule called *phone-num*.

Browser Working Group has suggested an XML-based syntax for representing BNF-like grammars [7]. In Fig. 42.42 we show a fragment of a possible grammar for defining telephone number strings. In the extended text input framework that we are advocating, this grammar, together with the handwritten ink, should be passed along to the recognition engine when an application knows that the user is expected to enter a telephone number.

Information about how the ink was collected, such as resolution and sampling rate of the capture device, whether writing guidelines or other writing size hints were used, spatial relationships to nearby objects in the application interface, etc., should also be made available to the recognition engine for improved recognition accuracy.

## Ink and the Internet

Digital ink does not always need to be recognized in order for it to be useful. Two daily life applications where users take full advantage of the range of graphical representations that are possible with a pen are *messaging*, as when we leave someone a post-it note with a handwritten message, and *annotation*, as when we circle some text in a printed paragraph or make a mark in an image inside of a document. This subsection discusses Internet-related applications that will enable similar functionality. Both applications draw attention to the need for a standard representation of digital ink that is appropriate in terms of efficiency, robustness, and quality.

### Ink Messaging

Two-way transmission of digital ink, possibly wireless, offers PIA users a compelling new way to communicate. Users can draw or write with a stylus on the PIA’s screen to compose a note in their own handwriting. Such an ink note can then be addressed and delivered to other PIA users, e-mail users, or fax machines. The recipient views the message as the sender composed it, including text in any mix of languages and drawings (see Fig. 42.43).

In the context of mobile-data communications it is important for the size of such ink messages to be small. There are two distinct modes for coding digital ink: raster scanning and curve tracing [8,9]. Facsimile coding algorithms belong to the first mode, and exploit the correlations within consecutive scan lines. Chain Coding (CC), belonging to the second mode, represents the pen trajectory as a sequence of transitions between successive points in a regular lattice. It is known that curve tracing algorithms result in a higher coding efficiency if the total trace length is not too long. Furthermore, use of a raster-base technique implies the loss of all time-dependent information.

**FIGURE 42.43** Example of ink messaging application for mobile devices. Users can draw or write with a stylus on the device screen to compose an e-mail in their own handwriting; no automatic recognition is necessarily involved.

Message sizes of about 500 bytes have been recently reported for messages composed in a typical PIA screen size, using a CC-based algorithm known as multi-ring differential chain coding (MRDCC) [10]. MRDCC is attractive for transmission of ink messages in terms of data syntax, decoding simplicity, and transmission error control; however, MRDCC is lossy, i.e., the original pen trajectory cannot be fully recovered. If exact reconstructability is important, a lossless compression technique is required. This might be the case when the message recipient might need to run verification or recognition algorithms on the received ink, e.g., if the ink in the message corresponds to a signature that is to be used for computer authentication. One example of a lossless curve tracing algorithm proposed by the ITU is *zone coding* [11]. Our internal evaluation of zone coding, however, reveals there is ample room for improvement.

Additional requirements for an ink messaging application include support for embedded ASCII text, support for embedded basic shapes (such as rectangles, circles, and lines), and support for different pen-trace attributes (such as color and thickness).

### Ink and SMIL

SMIL, pronounced smile, stands for synchronized multimedia integration language. It is a W3C recommendation ([12]) defining an XML compliant language that allows a spatially and temporally synchronized description of multimedia presentations. In other words, it enables authors to choreograph multimedia presentations where audio, video, text, and graphics are combined in real-time. A SMIL document can also interact with a standard HTML page. SMIL documents might become very common on the web thanks to streaming technologies.

The basic elements in a SMIL presentation are (for a complete introduction see [13]): a **root-layout**, which defines things like the size and color of the background of the document; a **region**, which defines where and how a media element such as an image can be rendered, e.g., location, size, overlay order, scaling method; one or more media elements such as **text**, **img**, **audio**, and **video**; means for specifying a timeline of events, i.e., **seq** and **par** indicate a block of media elements that will all be shown sequentially or in parallel, respectively, **dur** gives an explicit duration, **begin** delays the start of an element relative to when the document began or the end of other elements; means for skipping some part of an audio or a video (**clip-begin** and **clip-end**); means for adapting the behavior of the presentation to the end-user system capabilities (**switch**); means for freezing a media element after its end (**fill**); and a mean for hyperlinking (**a**).

Digital ink is not currently supported as a SMIL native media type. One option would be to convert the ink into a static image, say in GIF format, and render it as an **img** element; however, this would preclude the possibility of displaying the ink as a continuous media (like an animation). Another option

```

<smil>
<head>
<meta name="title" content="Ink and SMIL" />
<root-layout width="300" height="200"
background-color="white" />
</head>
<body>
<par>

<ref src="car.uni" region="onmain"
type="ink/unipen" fill="freeze"/>
<audio src="car.wav" />
</par>
</body>
</smil>

```

(b)

**FIGURE 42.44** Example of the role of digital ink in SMIL documents. In (a), a diagram or photo taken with a digital camera can be annotated with a pen; the digital ink can be coordinated with a spoken commentary. In (b), a corresponding short SMIL document fragment assuming the existence of an appropriate MIME content-type called “ink” and a subtype called “unipen” for representing the ink.

is using the SMIL generic media reference **ref** (see Fig. 42.44); this option requires the existence of an appropriate MIME content-type/subtype.

In the near future, it is expected that a standard will be designed to allow SMIL documents to use animated or static digital ink content as a media component.

## Extension of Pen-and-Paper Metaphor

Use of the pen-and-paper paradigm dates back to almost 3000 BC. Paper, as we know of today, dates back to around 200 AD. Hence, the notion of writing with a pen on paper is a extremely natural way of entering handwritten information.

Archival and retrieval are two primary actions performed on handwritten information captured using traditional pen and paper. The problem, however, with regular pen and paper is that the process of retrieving information can be extremely inefficient. Retrieving information typically involves visually scanning the documents, which can be inefficient when the size of handwritten information becomes large. One way to make the process efficient is to tag the information in a useful way. For example, a yellow sticker on pages that relate to a certain topic, or entering information about different topics into different notebooks, can make the process of looking for information on a topic efficient, when using normal paper notebooks. The goal here is to extend the same functionality to electronic pen-and-paper systems.

Extending the pen-and-paper metaphor, one of the main applications for digital ink capture systems, aims to provide users with efficient ink archival/retrieval capabilities by providing users the tools to tag information captured on the devices in a useful way.

The need for efficient ink archival/retrieval is accentuated by devices like the IBM ThinkPad TransNote [27] and Anoto [30], which provide users the capability of using normal or special paper for capturing handwritten information. With paper, users of such devices tend to capture more handwritten information, which in turn increases the need for efficient ink archival/retrieval capabilities.

## Ink Archival and Retrieval

An example of a digital ink capture system that provides users the ability to efficiently archive/retrieve handwritten information is the ThinkPad TransNote system from IBM. The system combines a regular notebook PC with a digital notepad. Slider controls provided on the digital notepad allow users to assign handwritten notes to a particular page and to a specific topic. In addition, controls are provided on the digital notepad to mark blocks of handwritten ink as a keyword. Functions of the sliders and controls can be modified depending on the needs of the application.

**FIGURE 42.45** Ink retrieval using keywords. Example of an application that uses the ASCII tags associated with handwritten ink to retrieve information from handwritten documents.

**FIGURE 42.46** Ink searching example. Users can search for an ink pattern inside a longer ink document, or collection of documents.

Ink management software on the notebook PC allows users to archive handwritten notes and retrieve them, using either the time of creation of the handwritten notes or the tags associated with keywords. The tags are typically text strings created using a handwriting recognition system. Figure 42.45 shows an example of a piece of the ink management software that displays blocks of ink marked as keywords in the middle column and their tags in the left column. Users can retrieve handwritten documents by clicking on the keywords or typing a word in the search text box in the upper righthand-top corner of the application.

In the application shown in Fig. 42.45, all the tags are text strings; however, one can easily extend the retrieval paradigm to use graphical queries and retrieve documents containing graphics, using features extracted from the graphical query. An example of this is shown in Fig. 42.46.

### Gesture Recognition

A gesture is a set of handwritten ink that implies a certain action. In many cases, a gesture can be used to represent an action much more efficiently compared to enumerating the action through a set of keyboard events. An example is the task of moving a portion of text from one position to another. Using a keyboard would involve selecting the portion of ink to be moved, copying it into a clipboard, deleting the selection, moving the cursor to the place in the document where the user would like to place the ink, and finally pasting the ink. Using a pen would allow users to indicate the same action by drawing a selection area around the ink to be moved and an arrow indicating the position to move the selection to. An example of this is shown in Fig. 42.47.

FIGURE 42.47 Example of pen-and-paper-like editing. Users can perform erasing by scribbling directly on the unwanted text, moving text by circling and dragging, and transposing text by common gesturing.

### Tower of Hanoi

This is an ancient chinese puzzle. You have three poles and a set of 'n' disks is stacked on one of them in the decreasing order of size. The problem is to transfer the stack to another pole subject to the following conditions:

1. You can move only one disk at a time.
2. You should not place a disk over a smaller one.

The minimal sequence of moves for transferring a set of 3 disks from pole 1 to pole 2 is given below.

Move No.	Disk	From	To
1	1	1	2
2	2	1	3
3	1	2	3
4	3	1	2
5	1	3	1
6	2	3	2
7	1	1	2

The moves may be considered as transitions from one state to another in a state space. Hence the problem may be treated as a search in a solution space:

The table below shows the number of moves for different numbers of disks:

1	1
3	7
5	31
10	1023
20	$2^{20}-1$

### Tower of Hanoi

This is an ancient chinese puzzle. You have three poles and a set of 'n' disks is stacked on one of them in the decreasing order of size. The problem is to transfer the stack to another pole subject to the following conditions:

1. You can move only one disk at a time.
2. You should not place a disk over a smaller one.

The minimal sequence of moves for transferring a set of 3 disks from pole 1 to pole 2 is given below

Move	Disk	From	To
1	1	1	2
2	2	1	3
3	1	2	3
4	3	1	2
5	1	3	1
6	2	3	2
7	1	1	2

The moves may be considered as transitions from one state to another in a state space. Hence the problem can be treated as a search in a solution space.

The table below shows the number of moves for different numbers of disks:

1	1

5	31
10	1023
20	$2^{20}-1$

FIGURE 42.48 Segmentation and recognition of on-line documents. Example of a typical handwritten page with text, tables and drawings; and the desired segmentation interpretation.

### Smart Ink

One can extend the gesture recognition system to allow users to associate more complex actions with groups of pen strokes as shown in Fig. 42.48. The handwritten document on the left side is a typical handwritten page with text, tables and drawings, and the one of the right side is a version of the same document after being automatically interpreted by a smart ink recognition scheme. This association allows users to work with handwritten documents in more efficient ways, which turn an electronic pen into a more effective way of entering information than a keyboard and mouse.

A successful implementation of these ideas led to the development of a tool, called SILK [35], which allows graphic designers to quickly sketch a user-interface with a electronic pen and stylus. The tool addresses the needs of designers who prefer to sketch early interface ideas on paper or whiteboard and concentrate on behavior. Existing interactive user interface construction tools make it

hard for a user-interface designer to illustrate the behavior of an interface; these tools focus on specifying widgets and making it easy to manipulate details such as colors, alignment, and fonts, i.e., they can show what the interface will look like, but make it hard to show what it will do.

## Pen Input and Multimodal Systems

A multimodal interface is one that integrates multiple kinds of input simultaneously to achieve a desired result. With the increased availability of significant computing power on mobile devices and of efficient wireless connectivity enabling distributed systems, development of pen-based multimodal interfaces is becoming more and more feasible. The motivation is simple: create more robust, flexible, and user-friendly interfaces by integrating the pen with other input modalities such as speech. Higher robustness is achievable because cross-modal redundancy can be used to compensate for imperfect recognition on each individual mode. Higher flexibility is possible because users can choose from among various modes of achieving a task, or issuing commands, the mode that is most appropriate at the time. Higher user-friendliness will result from having computer interfaces that better resemble the multi-modality naturally present in human communication. In this section we review some successful multimodal systems that take advantage of the pen to produce very synergistic interfaces, highlighting their common features.

Cohen et al. [15] combined speech and pen gestures to interact with a 2D representation, like a map, of the entities in a 3D scene such as the one generated with a battlefield simulator. An interactive map is displayed on a handheld device where the user can draw or speak to control the system. For example, while holding the pen at some location in the map, the user may say “XXXX platoon”; this command will result in the creation of a platoon simulation element labelled “XXXX” at the desired location. The user can then assign a task to the new platoon by uttering a command like “XXXX platoon follow this route” while drawing a line on the map.

Heyer et al. [16] combined speech, pen gestures, and handwriting recognition in a travel planning application. Users interact with the map of a city, possibly displayed on a PIA device, to find out information about hotels, restaurants, and tourist sites. This information is accessed from a public database through the Internet. Pen and voice may be used by speaking a query such as “what is the distance from here to Fisherman’s Wharf” while making a mark on the map. Pen-only gestures can also be used for control actions, such as moving the viewing area. Similarly, voice-only commands are allowed as in “show me all hotels with a pool.”

Tue Vo et al. [17] prototyped a multimodal calendar application called Jeanie. This is a very common application on PIA devices and one having several tasks that can be simplified by the multimodal method of pointing to or circling objects on the screen in addition to speaking commands. For example, a command combining spoken and handwritten input is “reschedule this on Tuesday,” uttered while holding the pen on a meeting entry in the appointment list. An example of a pen-only command is drawing an X on a meeting entry to cancel it.

Suhm et al. [18] have explored the benefits of multimodal interaction in the context of error correction. Specifically, they have integrated handwriting recognition in an automatic dictation system. Users can switch from continuous speech to pen-based input to correct errors. This work capitalizes on the fact that words that might be confused in one modality (e.g., sound similar) are not necessarily so in another one (e.g., with similar handwritten shape). Their study concluded that multimodal error correction is more accurate and faster than unimodal correction by re-speaking.

Multimodal applications such as these ones are generally built using a distributed “agent” framework. The speech recognizer, the handwriting recognizer, the gesture recognizer, the natural language understanding module, the database access module, etc., might each be a different agent; a computing process that provides a specific service and which runs either locally on the PIA device or remotely. These agents cooperate and communicate in order to accomplish tasks for the user. One publicly available software environment offering facilitated agent communication is the open agent architecture (OAA) from SRI [19].

A special agent is needed for integrating information from all input sources to arrive at a correct understanding of complete multimodal commands. Such a unification agent is sometimes implemented using *semantic frames*, a knowledge representation scheme from the early A.I. days [36], consisting of

slots specifying pieces of information about the command. Recognition results from each modality agent are parsed into partially filled frames, which are then merged together to produce a combined interpretation. In the merging process information from different input modes is weighted, meaningless command hypotheses are filtered out, and additional feedback from the user might be requested.

## Summary

As more electronic devices with pen interfaces have and continue to become available for entering and manipulating information, applications need to be more effective at leveraging this method of input. Pen is a mode of input that is very familiar for most users since everyone learns to write in school. Hence, users will tend to use this as a mode of input and control when available. Providing enhanced user-interfaces that will make it easier for users to use the pen interface in effective ways will make it easier for them to work with such devices.

Section 42.6 has given an overview of the pen input devices available today along with some of the applications that use the electronic pen either in isolation or in conjunction with other modes of input such as speech and the keyboard. The community has made great strides in addressing a number of the user-interface issues for capturing and manipulating information from electronic pens. A number of challenges still need to be addressed before such devices truly meet the needs of a user to a higher level of satisfaction.

## To Probe Further

**Pen Computing.** <http://hwr.nici.kun.nl/pen-computing>. A Web site hosted at the Nijmegen University with links related to practical issues in pen and mobile computing.

**Handhelds.** <http://handhelds.org>. A Compaq-hosted Web site created to encourage and facilitate the creation of open source software for use on handheld and wearable computers.

## Acknowledgment

The authors thank Thomas G Zimmerman, Research Staff Member with the Human/Machine Interface Gadgets at IBM Research, for his input on the subsection on “Pen Input Hardware,” and Carlos McEvilly, Research Staff Member with the Motorola Human Interface Labs, for proofreading this manuscript.

## 42.7 What Makes a Programmable DSP Processor Special?

---

*Ingrid Verbauwhede*

### Introduction

A programmable DSP processor is a processor “tuned” towards its application domain. Its architecture is very different from a general-purpose von Neumann architecture to accommodate the demands of real-time signal processing. When first developed in the beginning of the 1980s, the main application was filtering. Since then, the architectures have evolved together with the applications. Currently, the

most stringent demands for low-power embedded DSP processors come from wireless communication applications: second, 2.5, and third generation (2G, 2.5G, and 3G) cellular standards. The demand for higher throughput and higher quality of source and channel coding keeps growing while power consumption has to be kept as low as possible to increase the lifetime of the batteries.

In this chapter section, first the application domain and its historical evolution will be described in the subsection on “DSP Application Domain.” Then, in “DSP Architecture,” the overall architecture will be described. In “DSP Data Paths,” the specifics of the DSP data paths will be given. In “DSP Memory and Address Calculation Units,” the memory architecture and its associated address generation units are described. In “DSP Pipeline,” the specifics of the DSP pipeline will be explained. Finally, in “Conclusions and Future Trends,” the conclusions will be given followed by some future trends.

## DSP Application Domain

DSP processors were originally developed to implement traditional signal processing functions, mainly filters, such as FIRs and IIRs [5]. These applications decided the main properties of the programmable DSP architecture: the inclusion of a multiply-accumulate unit (MAC) as separate data path unit and a Harvard or modified Harvard memory architecture instead of a von Neumann architecture.

### Original Motivation: FIR Filtering

The fundamental properties of these applications were (and still are):

- *Throughput driven calculations and real-time operation.* Signal processing applications, such as speech and video, can be represented as an “infinite stream” of data samples that need to be processed at a rate determined by the application [20]. The *sample rate* is a fundamental property of the application. It determines at what rate the consecutive samples arrive for processing. For speech processing, this is the rate of speech samples (kHz range), for video processing this might be the frame rate or the pixel rate (MHz range) [3]. The DSP has to process these samples at this given rate. Therefore, a DSP operates under worst-case conditions. This is fundamentally different from general-purpose processing on a micro processor, which operates on an average case base, but which has an unpredictable worst-case behavior.
- *Large amounts of computations, few amounts of control flow operations.* DSP processors were developed to process large amounts of data in a very repetitive mode. For instance, speech filtering, speech coding, pixel processing, etc., require similar operations on consecutive samples, pixels, frames, etc. The DSP processor has adapted to this, by providing means of implementing these algorithms in a very efficient way. It includes zero-overhead looping, very compact instruction code, efficient parallel memory banks, and associated address generation units.
- *Large amount of data,* usually organized in a regular or almost regular pattern. Because of the real-time processing and the associated “infinite” amount of data that is processed, DSP processors usually have several parallel memory banks; each bank has its own address generation unit and parallel reads and writes are supported by the DSP.
- *Embedded applications.* DSP processors are developed for embedded applications, ranging from cellular phones, disk drives, cable modems, etc. The result is that all the program codes have to reside on the processor (no external memory, no cache hierarchy). Thus, the code size has to be minimized, as a result of which, till today there is a lot of assembly code written. Secondly, the power consumption has to be minimized since many of these applications run from batteries or have tight cooling requirements such as the usage of cheap plastic packages or enclosed boxes.

### Modern Applications: Digital Wireless Communications

New applications drive the design of new DSP processors. State-of-the-art DSP processors will have more than one MAC, acceleration for Viterbi decoding, specialized instructions for Turbo decoding, and so on. Indeed, DSP processors have become the main workhorse for wireless communications for both the handsets and the base station infrastructure [22].

FIGURE 42.49 Fundamental building blocks in a communication system.

FIGURE 42.50 Relationship between speech signal and the transmitted signal.

Second generation (2G) cellular standards required the introduction of optimized instructions for speech processing and for communication algorithms used in the channel coding and modulation/demodulation. The fundamental components of a wireless system are shown on Fig. 42.49.

### Speech Coding

The source coder/decoder in 2G cellular standards (GSM, IS-136, IS-95 CDMA, Japanese PDC) is mainly a speech coder/decoder. The main function of a speech coder is to remove the redundancy and compress the speech signal and hence, reduce the bandwidth requirements for storage or transmission over the air. The required reduction in bit rate is illustrated in Fig. 42.50 for the Japanese PDC standard.

At point A, a “toll quality” digital speech signal requires the sampling of the analog speech waveform at 8 kHz. Each sample requires 8 bits of storage ( $\mu$ -law compressed) thus resulting in a bit rate of 64 kbits/s or 2560 bits for one 40 ms TDMA frame. This speech signal needs to be compressed to increase the capacity of the channel. One TDMA frame, which has a basic time period of 40 ms, is shared by six users. The bit rate at point B is 42 kbits/s. Thus, one user slot gets only 7 kbits/s. The 2560 bits have to be reduced to 138 bits, to which 86 bits are added for forward error correction (FEC), resulting in a total of 5.6 kbits/s.

The higher the compression ratio and the higher the quality of the speech coder, the more calculations, usually expressed in MIPS, are required. This is illustrated in Fig. 42.51. The first generation GSM digital cellular standard employs the Regular Pulse Excitation-Long Term Prediction (RPE-LTP) algorithm and requires a few thousand MIPS to implement it on a current generation DSP processor. For instance, it requires 2000 MIPS on the lode processor [21]. The Japanese half-rate coder Pitch Synchronous Innovation-Code Excited Linear Prediction (PSI-CELP) requires at least ten times more MIPS.

### Viterbi Decoding

The function of the channel codec is to add controlled redundancy to the bit stream on the encoder side and to decode, detect, and correct transmission errors on the receiver side. Thus, channel encoding and decoding is a form of error control coding. The most common decoding method for convolutional codes

FIGURE 42.51 MIPS requirement of several speech coders.

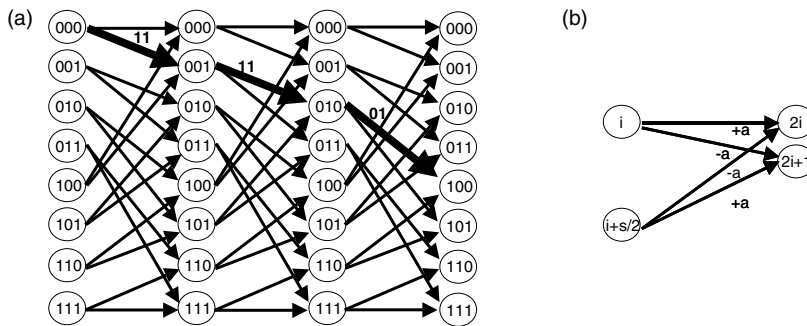

FIGURE 42.52 Viterbi trellis diagram and one butterfly.

is the Viterbi algorithm [4]. It is a dynamic programming technique as it tries to emulate the encoder’s behavior in creating the transmitted bit sequence. By comparing to the received bit sequence, the algorithm determines the difference between each possible path through the encoder and the received bit sequence. The decoder outputs the bit sequence that has the smallest deviation, called the minimum distance, compared to the received bit sequence.

Most practical convolutional encoders are rate  $1/n$ , meaning that one input bit generates  $n$  coded output bits. A convolutional encoder of constraint length  $K$  can be represented by a finite state machine (FSM) with  $K - 1$  memory bits. The FSM has  $2^{K-1}$  possible states, also called trellis states. If the input is binary, two next states are possible starting from the current state and the input bit. The task of the Viterbi algorithm is to reconstruct the most likely sequence of state transitions based on the received bit sequence. This approach is called the “most likelihood sequence estimation.” These state transitions are represented by a trellis diagram. The kernel of the trellis diagram is the Viterbi butterfly as shown in Fig. 42.52(b).

### Next Generation Applications

Current generation DSP processors are shaped by 2G cellular standards, the main purpose of which is voice communication. 3G cellular standards will introduce new features: increased focus on data communication, e-mail, web browsing, banking, navigation, and so on.

2G standards can support short messages, such as the popular SMS messages in the GSM standard, but are limited to about 10 to 15 kbits/s. In the 2.5G cellular standards, provisions are made to support higher data rates. By combining GSM time slots, generalized packet radio services (GPRS) can support up to 115 kbits/s. But the 3G standards are being developed specifically for data services. Wideband CDMA (WCDMA) will support up to 2 Mbits/s in office environments, lowered to 144 kbits/s for high mobile situations [6,13].

The increased focus on data services has large consequences for the channel codec design. The traditional Viterbi decoder does not provide a low enough bit error rate to support data services. Therefore, turbo

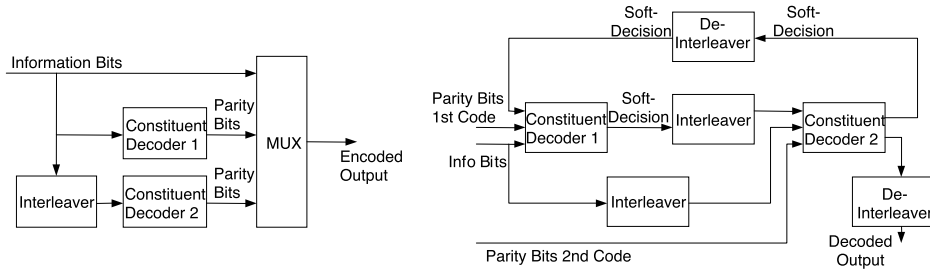

FIGURE 42.53 Turbo encoder and decoder.

codes are considered [2]. Turbo decoding (shown in Fig. 42.53) is a collaborative structure of soft-input/soft-output (SISO) decoders with the inclusion of interleaver memories between decoders to scatter burst errors [2]. Either soft-output viterbi algorithm (SOVA) [7] or maximum a posteriori (MAP) [1] can be used as SISO decoders. Within a turbo decoder, the two decoders can operate on the same or different codes. Turbo codes have been shown to provide coding performance to within 0.7 dB of the Shannon limit (after a number of iterations).

The log MAP algorithm can be implemented in a manner very similar to the standard Viterbi algorithm. The most important difference between the algorithms is the use of a correction factor on the “new path metric” value (the alpha, beta, and log-likelihood ratio values in Log MAP). This correction factor depends on the difference between the values being compared in the add-compare-select butterfly (as shown in Fig. 42.52). This means that the Viterbi acceleration units, that implement this add-compare-select operation, need to be modified. Turbo coding is one member of a large class of iterative decoding algorithms. Recently low density parity check codes (LDPC) that have gained renewed attention as another important class, which are potentially more easily translated to efficient implementations.

Other trends seem to place an even larger burden on the DSP processor. The Japanese i-Mode system includes e-mail, web browsing, banking, location finding in combination with the car navigation system, etc. Next generation phones will need to support video and image processing, and so on. Applications and upgrades will be downloadable from the Internet.

But at the same time, consumers are used to longer talk times (a couple of hours) and very long standby times (days or weeks). Thus, they will not accept a reduction of talk time nor standby time in exchange for more features. This means that these increased services have to be delivered with the same power budget because the battery size is not expected to grow nor is the battery technology expected to improve substantially.

## DSP Architecture

The fundamental property of a DSP processor is that it uses a Harvard or modified Harvard architecture instead of a von Neumann architecture. This difference is illustrated in Fig. 42.54.

A von Neumann architecture has one unified address space, i.e., data and program, are assigned to the same memory space. In a Harvard architecture, the data memory map is split from the program memory map. This means that the address busses and data busses are doubled. Together with specialized address calculation units, this will increase the memory bandwidth available for signal processing applications. This concept will be illustrated by the implementation of a simple FIR filter. The basic equation for an  $N$  tap FIR equation is the following:

$$y(n) = \sum_{i=0}^{i=N-1} c(i) \cdot x(n-i)$$

FIGURE 42.54 von Neumann architecture and Harvard/modified Harvard architecture.

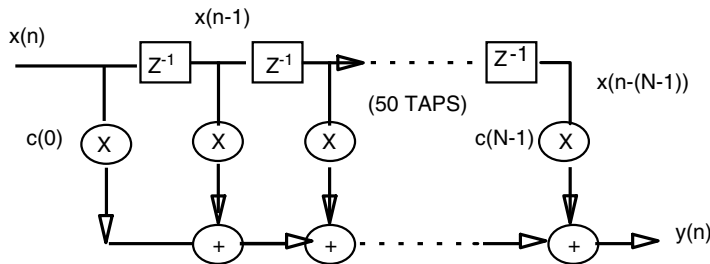

FIGURE 42.55 Finite impulse response filter.

Expansion of this equation results in the following pseudo code statements:

$$\begin{aligned}
 y(0) &= c(0)x(0) + c(1)x(-1) + c(2)x(-2) + \dots + c(N-1)x(1-N); \\
 y(1) &= c(0)x(1) + c(1)x(0) + c(2)x(-1) + \dots + c(N-1)x(2-N); \\
 y(2) &= c(0)x(2) + c(1)x(1) + c(2)x(0) + \dots + c(N-1)x(3-N); \\
 &\dots \\
 y(n) &= c(0)x(n) + c(1)x(n-1) + c(2)x(n-2) + \dots + c(N-1)x(n-(N-1));
 \end{aligned}$$

When this equation is executed in software or assembly code, output samples  $y(n)$  are computed in sequence. To implement this on a von Neumann architecture, the following operations are needed. Assume that the von Neumann has a multiply and accumulate instruction (not necessarily the case). Assume also that pipelining allows to execute the multiply and accumulate in parallel with the read or write operations. Then one tap needs four cycles:

1. Read multiply-accumulate instruction.
2. Read data value from memory.
3. Read coefficient from memory.
4. Write data value to the next location in the delay line (because to start the computation of the next output sample, all values are shifted by one location).

Thus even if the von Neumann architecture includes a single cycle multiply-accumulate unit, it will take four cycles to compute one tap.

Implementing the same FIR filter on a Harvard architecture will reduce the number of cycles to three because it allows the fetch of the instruction in parallel with the fetch of one of the data items. This was

a fundamental property that distinguished the early DSP processors. On the TMS 320C1x, released in the early '80s, it took  $2N$  cycles for a  $N$  tap filter (without the shift of the delay line) [5].

The modified Harvard architecture improves this idea even further. It is combined with a “repeat” instruction and a specialized addressing mode, the circular addressing mode. In this case, one multiply-accumulate instruction is fetched from program memory and kept in the one instruction deep instruction “cache.” Then the data access cycles are performed in parallel: the coefficient is fetched from the program memory in parallel with the data sample being fetched from data memory. This architecture is found in all early DSP processors and is the foundation for all following DSP architectures. The number of memory accesses for one tap are reduced to two and these occur in the same cycle. Thus, one tap can execute in one cycle and the multiply-accumulate unit is kept occupied every cycle.

Newer generation of DSP processors have even more memory banks, accompanying address generation units and control hardware, such as the repeat instruction, to support multiple parallel accesses. The execution of a 32-tap FIR filter on the dual Mac architecture of the Lucent DSP 1621, shown in Fig. 42.56, will take only 19 cycles. The corresponding pseudo code is the following:

```
do 14 { //one instruction !
    a0=a0+p0+p1
    p0=xh*yh p1=xl*y1
    y=*r0++ x=*pt0++
}
```

This code can be executed in 19 clock cycles with only 38 bytes of instruction code. The inner loop takes one cycle to execute and as can be seen from the assembly code, seven operations are executed in parallel: one addition, two multiplications, two memory reads, and two address pointer updates. Note that the second pointer update,  $*pt0++$ , updates a circular address pointer.

Two architectures which speed up the FIR calculation to 0.5 cycle per tap are shown in Fig. 42.56. The first one is the above mentioned Lucent DSP16210. The second one is an architecture presented in [9]. It has a multiply accumulate unit that operates at double the frequency from the memory accesses.

The difficult part in the implementation of this tight loop is the arrangement of the data samples in memory. To supply the parallel Mac data paths, two 32-bit data items are read from memory and stored in the X and Y register, as shown in Fig. 42.56. A similar split in lower and higher halves occurs in the

FIGURE 42.56 DSP architectures for 0.5 cycle per FIR tap.

FIGURE 42.57 Dual Mac architecture with delay register of the Lode DSP core.

Intel/ADI Frio core [10]. Then the data items are split in an upper half and a low half and supplied to the two  $16 \times 16$  multipliers in parallel or the left half and the right half of the TEMP registers in Fig. 42.56(b). It requires a correct alignment of the data samples in memory, which is usually a tedious work done by the programmer, since compilers are not able to handle this efficiently. Note that a similar problem exists when executing SIMD instructions on general purpose micro-processors.

Memory accesses are a major energy drain. By rearranging the operations to compute the filter outputs, the amount of memory accesses can be reduced. Instead of working on one output sample at a time, two or more output samples are computed in parallel. This is illustrated in the pseudo code below:

$$\begin{aligned}
 y(0) &= \mathbf{c(0)x(0)} + c(1)x(-1) + c(2)x(-2) + \dots + c(N-1)x(1-N); \\
 y(1) &= \mathbf{c(0)x(1)} + c(1)\mathbf{x(0)} + c(2)x(-1) + \dots + c(N-1)x(2-N); \\
 y(2) &= c(0)x(2) + c(1)x(1) + c(2)x(0) + \dots + c(N-1)x(3-N); \\
 &\dots \\
 y(n) &= c(0)x(n) + c(1)x(n-1) + c(2)x(n-2) + \dots + c(N-1)x(n-(N-1));
 \end{aligned}$$

In the lode architecture [21] a delay register is introduced between the two Mac units as shown in Fig. 42.57. This halves the amount of memory accesses. Two output samples are calculated in parallel as indicated in the pseudo code of Table 42.3. One data bus will read the coefficients,  $c(i)$ , the other data bus will read the data samples,  $x(N-i)$ , from memory. The first Mac will compute a multiply-accumulate for output sample  $y(n)$ . The second multiply-accumulate will compute in parallel on  $y(n+1)$ . It will use a delayed value of the input sample. In this way, two output samples are computed at the same time.

This concept of inserting a delay register can be generalized. When the datapath has  $P$  Mac units,  $P-1$  delay registers can be inserted and only  $2N/(P+1)$  memory accesses are needed for one output sample. These delay registers are pipeline registers and hence if more delay registers are used, more initialization and termination cycles need to be introduced.

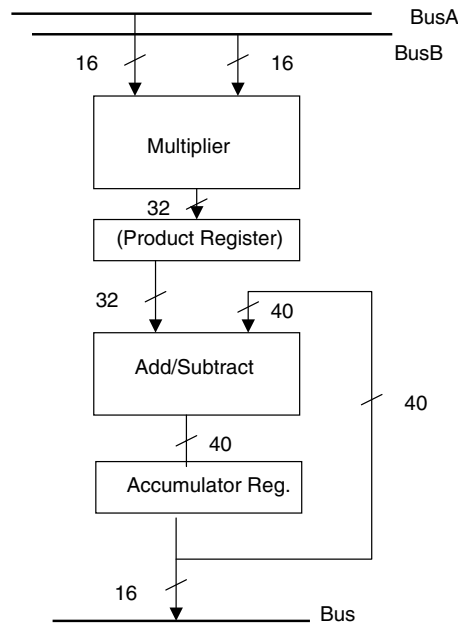

The idea of working on two output samples at one time is also present in the dual Mac processor of TI, the TIC55x. This processor has a dual Mac architecture with three 16-bit data busses. To supply both Macs with coefficient and data samples, the same principle of computing two output samples at the same time is used. One data bus will carry the coefficient and supply this to both Macs, the other two data busses will carry two different data samples and supply this to the two different Macs.

A summary of the different approaches is given in Table 42.2. Note that most energy savings are obtained from reducing the amount of memory accesses and secondly, from reducing the number of instruction cycles. Indeed the energy associated with the Mac operations can be considered as “fundamental” energy without it, no  $N$  tap FIR filter can be implemented.

Modern processors have multiple address busses, multiple data busses and multiple memory banks, including both single and dual port memory. They also include mechanisms to assign parts of the physical memory to either memory space, program, or data. For instance for the C542 processor the on-chip dual

**TABLE 42.2** Data Accesses, Mac Operations, Instruction Cycles, and Instructions for an  $N$  Tap FIR Filter

DSP	Data Memory Accesses	MAC Operations	Instruction Cycles	Instructions
von Neumann	$3N$	$N$	$4N$	$2N$
Harvard	$3N$	$N$	$3N$	$3N$
Modified Harvard with modulo arithmetic	$2N$	$N$	$N$	2 (repeat instruction)
Dual Mac or double frequency Mac	$2N$	$N$	$N/2$	2 (same)
Dual Mac with 3 data busses	$1.5N$	$N$	$N/2$	2
Dual Mac with 1 delay registers	$N$	$N$	$N/2$	2
Dual Mac with $P$ delay registers	$2N/(P+1)$	$N$	$N/(P+1)$	2

**FIGURE 42.58** Multiply accumulate unit.

access RAM can be assigned to the data space or to the data/program space, by setting a specific control bit (the OVLV bit) in a specific control register (the PMST register) [19].

## DSP Data Paths

The focus of the previous section was on the overall architecture of a DSP processor and its fundamental properties to increase the memory bandwidth. This will keep the data paths of the DSP operating every clock cycle. In this section, some essential properties of the DSP data paths will be described.

### Multiply-Accumulate Unit

The unit that is most associated with the DSP is the Mac. It is shown in Fig. 42.58. The most important properties of the Mac unit are summarized below:

- The multiplier takes two 16-bit inputs and produces a 32-bit multiplier output. Internally the multiplication might be implemented as a  $17 \times 17$  bit multiplier. This way the multiplier can implement both two's complement and unsigned numbers.

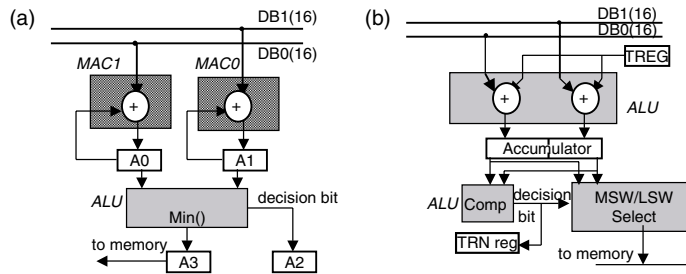

FIGURE 42.59 Two data path variations to implement the add-compare-select operation.

- The product register is a pipelined register to speed up the calculation of the multiply-accumulate operation. As a result the Mac operation executes in most processors in one cycle effectively although the latency can be two cycles.
- The accumulator registers are usually 40 bits long. Eight bits are designated as “guard” bits [11]. This allows the accumulation of  $2^8$  products before there is a need of scaling, truncation, or saturation. These larger word lengths are very effective in implementing DSP functions such as filters. The disadvantage is that special registers such as these accumulators are very hard to handle by a compiler.

### Viterbi Acceleration Unit

Convolutional decoding and more specifically the Viterbi algorithm, has been recognized as one of the main, if not the most, MIPS consuming application in current and next generation standards. The key issue is to reduce the number of memory accesses and secondly the number of operations to implement the algorithm. The kernel of the algorithm is the Viterbi butterfly as shown on Fig. 42.52. The basic equations executed in this butterfly are:

$$d(2i) = \min\{d(i) + a, d(i + s/2) - a\}$$

$$d(2i + 1) = \min\{d(i) - a, d(i + s/2) + a\}$$

These equations are implemented by the “add-compare-select (ACS)” instruction and its associated data path unit. Indeed, one needs to add or subtract the branch metric from states  $i$  and  $i + s/2$ , compare them, and select the minimum. In parallel, state  $2i + 1$  is updated. The butterfly arrangement is chosen because it reduces the amount of memory accesses by half, because the two states that use the same data to update the same two next states are combined.

DSP processors have special hardware and instructions to implement the ACS operation in the most efficient way. The lode architecture [21] uses the two Mac units and the ALU to implement the ACS operation as shown in Fig. 42.59(a). The dual Mac operates as a dual add/subtract unit. The ALU finds the minimum. The shortest distance is saved to memory and the path indicator, i.e., the decision bit is saved in a special shift register A2. This results in four cycles per butterfly.

The Texas Instruments TMS320C54x and the Matsushita processor described in [14,22] use a different approach that also results in four cycles per butterfly. This is illustrated in Fig. 42.59(b). The ALU and the accumulator are split into two halves (much like SIMD instructions), and the two halves operate independently. A special compare, select, and store unit (CSSU) will compare the two halves, will select the chosen one, and write the decision bit into a special register TRN. The processor described in [14] describes two ACS units in parallel. One should note that without these specialized instructions and hardware, one butterfly requires 15 to 25 or more instructions.

**TABLE 42.3** Number of Parallel Address Generation Units for a Few DSP Processors

Processor	Generation Units	
	Data Address	Program Address
C5× [18]	1 (ARAU)	1
C54× [19]	2 (DAGEN has two units: ARAU0, ARAU1)	1
Lode [21]	2 (ACU0, ACU1)	1
Frio [10]	2	1

## DSP Memory and Address Calculation Units

Besides the data paths optimized for signal processing and communication applications, the DSP processors also have specialized address calculation units. As explained in section “DSP Architecture,” the parallel memory maps in the Harvard or modified Harvard architecture are essential for the data processing in DSP processors; however, to avoid overload on the regular data path units, specialized address generation units are included. In general, the number of address generation units will be same as the maximum number of parallel memory accesses that can occur in one cycle. A few examples are shown in Table 42.3. Older processors, such as the C5× with a modified Harvard architecture, have one address generation unit serving the data address bus, and one program address generation unit serving the program address bus. When the number of address busses go up, so will the arithmetic units inside the address calculation unit. For instance the Frio [10] has two address busses served by two ALUs inside the data address generation unit.

The address generation units themselves are optimized to perform address arithmetic in an efficient way. This includes data paths with the correct word lengths. It also includes all the typical address modifications that are common in DSP applications. For instance indirect addressing with a simple increment can easily be done and expressed in the instruction syntax. More advanced addressing modes include circular buffering, which especially suits filter operations, and bit-reversed addressing, especially useful for fast Fourier transforms, and so on. There exist many good instruction manuals that describe the detailed operation of these specialized addressing modes, [11,18,19].

## DSP Pipeline

The pipeline of a DSP processor is different from the pipeline of a general purpose control-oriented micro-processors. The basic slots of the DSP pipeline and the RISC pipeline are shown in Fig. 42.60. In a DSP processor, the memory access stage in parallel with the address generation (usually “post-modification”) occurs before the execute stage. An example is described in [10]. In a RISC processor the memory access stage follows the execute stage [8], because the execute stage is used to calculate the address on the main ALU. The fundamental reason for this difference in pipeline structure is that DSP processors are optimized for memory intensive number-crunching type of applications (e.g., FIRs), while RISC type processors, including micro-controllers and micro-processors, are optimized for complex decision making. This is explained in Figs. 42.61 and 42.62. Typical for real-time compute intensive applications, is the continuous memory accesses followed by operations in the data path units. A typical example is the execution of the FIR filter as shown in the FIR pseudo code above. On a DSP processor, the memory access and the multiply-accumulate operation are specified in one instruction and follow each other in the pipeline stage. The same operation on a RISC machine will need three instruction slots. The first instruction slot will read the value from memory and only in the third instruction slot the actual computation takes place. If these delays are not obeyed, a data hazard will occur [8]. Fixing data hazards will lead to a large instruction and cycle overhead.

Similarly, it can be argued that branches have a larger penalty on DSP processors than on RISC machines. The reason is explained on Fig. 42.62. If a data dependent branch needs to be executed, e.g., “branch if accumulator is zero,” then it takes that this instruction cannot follow immediately after the

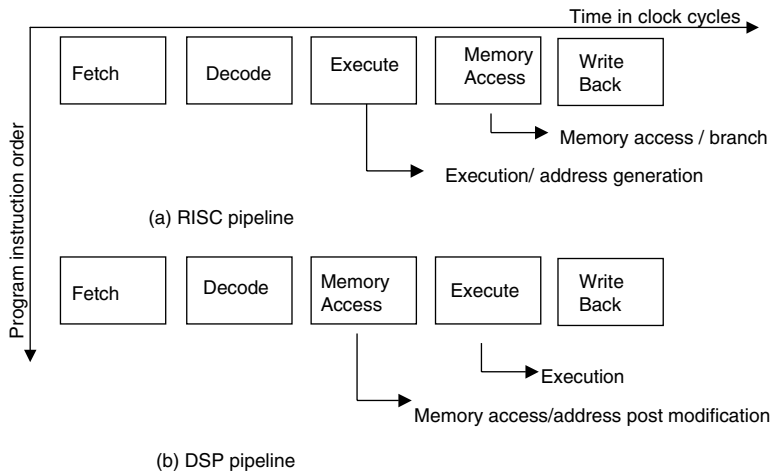

FIGURE 42.60 Basic pipeline architecture for a RISC and a DSP processor.

FIGURE 42.61 Memory-intensive number crunching on a RISC and a DSP.

accumulator is set. In the simple examples of Fig. 42.62, there needs to be two, respectively three instruction cycles between the setting of the accumulator flag and the usage of it in the decode stage, by the RISC and DSP processor, respectively. Therefore, the RISC has an advantage for control dominated applications. In practice these pipeline hazards are either hidden to the programmer by hardware solutions (e.g., forwarding or stalls) or they are visible to the programmer, who can optimize his code around it. A typical example are the branch and the “delayed branch” instruction in DSP processor. Because an instruction is fetched in the cycle before it is decoded, a regular branch instruction will incur an unnecessary fetch of the next instruction in memory following the branch. To optimize the code in DSP processors, the delayed branch instruction is introduced. In this case, the instruction that follows the branch instruction in memory will be executed before the actual branch takes place. Hence, a delayed branch instruction takes effectively one cycle to execute while a regular branch will take two cycles to execute.

FIGURE 42.62 Decision making (branch) on a RISC and a DSP.

The delayed branch is a typical example on how DSP programmers are very sensitive to code size and code execution. Indeed, for embedded applications, minimum code size is a requirement.

## Conclusions and Future Trends

DSP processors are a special type of processors, very different from the general purpose micro controller or micro processor architectures. As argued in this chapter section, this is visible in all components of the processor: the overall architecture, the data paths, the address generation units, and even the pipeline structure.

The applications of the future will keep on driving the next generation of DSP processors. Several trends are visible. Clearly, there is a need to support higher level languages and compilers. Traditional compiler techniques do not produce efficient, optimized code for DSP processors. Compiler technology has only recently started to address the needs of low power embedded applications. But also the architectures will need changes to accommodate the compiler techniques. One drastic approach is the appearance of VLIW architectures, for which efficient compiler techniques are known. This results, however, in code size explosion associated with a large increase in power consumption. A hybrid approach might be a better solution. For example, the processor described in [10] has unified register files. Yet, it also makes an exception for the accumulators.

Another challenge is the increased demand for performance while reducing the power consumption. Next generation wireless portable applications will not only provide voice communication, but also video, text and data, games, and so on. On top of this the applications will change and will need reconfigurations while in use. This will require a power efficient way of runtime reconfiguration [16]. The systems on a chip that implement these wireless communication devices will include a large set of heterogeneous programmable and reconfigurable modules, each optimized to the application running on them. Several of these will be DSP processors and they will be crucial for the overall performance.

## Acknowledgments

The author thanks Mr. Katsuhiko Ueda of Matsushita Electric Co., Japan, for the interesting discussions and for providing several figures in this chapter section.

### 43.1 Introduction

---

Cryptography is the science of data security. This chapter gives a brief survey of cryptographic practice and research. The chapter is organized along the lines of the principal categories of cryptographic primitives: unkeyed, symmetric key, and asymmetric key. For each of these categories, the chapter defines the important primitives, give security models and attack scenarios, discuss constructions that are popular in practice, and describe current research activity in the area. Security is defined in terms of the goals and resources of the attacker.

### 43.2 Unkeyed Cryptographic Primitives

---

The main unkeyed cryptographic primitive is the cryptographic hash function. This is an efficient function from bit strings of any length to bit strings of some fixed length (say 128 or 160 bits). The description of the function is assumed to be publicly available. If  $H$  is a hash function, and if  $y = H(x)$ , then  $y$  is called the “hash” or “hash value” of  $x$ .

One desirable property of a cryptographic hash function is that it should be difficult to invert. This means that given a specific hash value  $y$  it is computationally infeasible to produce any  $x$  such that  $H(x) = y$ . Another desirable property is that it should be difficult to find “collisions.” This means that it is computationally infeasible to produce two inputs  $x$  and  $x'$  such that  $H(x) = H(x')$ . The attacker is assumed to know a complete specification of the hash function.

A cryptographic hash function can be used for establishing data integrity. Suppose that the hash of a large file is stored in a secure location, while the file itself is stored in an insecure location. It is infeasible for an attacker to modify the file without detection, because a re-hash of the modified file will not match the stored hash value (unless the attacker was able to invert the hash function). We will see other applications of cryptographic hash functions when we look at asymmetric cryptographic primitives in Section 43.4.

Popular choices for cryptographic hash functions include MD-5 [1], RIPEMD-160 [2], and SHA-1 [3]. It is also common to construct cryptographic hash functions from symmetric key block ciphers [4].

## Random Oracle Model

One direction of recent research is on the “random oracle model.” This is a design methodology for protocols and primitives that make use of cryptographic hash functions. Pick a specific cryptographic hash function such as MD-5. Its designers may believe that it is difficult to invert MD-5 or to find collisions for it. However, this does not mean that MD-5 is a completely unpredictable function, with no structure or regularity whatsoever. After all, the complete specification of MD-5 is publicly available for inspection and analysis, unlike a truly random function that would be impossible to specify in a compact manner. Nevertheless, the random oracle model asserts that a specific hash function like MD-5 behaves like a purely random function. This is part of a methodology for proving security properties of cryptographic schemes that make use of hash functions.

This assumption was introduced by Fiat and Shamir [5] and later formalized by Bellare and Rogaway [6]. It has been applied to the design and analysis of many schemes (see, e.g., the discussion of optimal asymmetric encryption padding in the subsection on “Chosen Ciphertext Security for Public Key Encryption”).

Recently, a cautionary note was sounded by Canetti, Goldreich, and Halevi [7]. They demonstrate by construction that it is possible for a scheme to be secure in the random oracle model and yet have no secure instantiation whatsoever when any hash function is substituted. This is a remarkable theoretical result; however, the cryptographic community continues to base their designs on the random oracle model, and with good reason. Although it cannot provide complete assurance about the security of a design, a proof in the random oracle model provides confidence about the impossibility of a wide range of attacks. Specifically, it rules out common attacks where the adversary ignores the inner workings of the hash function and treats it as a “black box.” The vast majority of protocol failures are due to this kind of black box attack, and thus the random oracle model remains an invaluable addition to the cryptographer’s tool kit.

## 43.3 Symmetric Key Cryptographic Primitives

---

The main symmetric key cryptographic primitives are discussed including block ciphers, stream ciphers, and message authentication codes.

### Symmetric Key Block Ciphers

A symmetric key block cipher is a parameterized family of functions  $E_K$ , where each  $E_K$  is a permutation on the space of bit strings of some fixed length. The input to  $E_K$  is called the “plaintext” block, the output is called the “ciphertext” block, and  $K$  is called the “key.” The function  $E_K$  is called an “encryption” function. The inverse of  $E_K$  is called a “decryption” function, and is denoted  $D_K$ .

To encrypt a message that is longer than the fixed-length block, it is typical to employ a block cipher in a well-defined “mode of operation.” Popular modes of operation include output feedback mode, cipher feedback mode, and cipher block chaining mode; see [8] for a good overview. In this way, the plaintext and ciphertext can be bit strings of arbitrary (and equal) length. New modes of operations are being solicited in connection with the development of the Advanced Encryption Standard (see subsection “Advanced Encryption Standard (AES)”).

The purpose of symmetric key encryption is to provide data confidentiality. Security can be stated at a number of levels. It is always assumed that the attacker has access to a complete specification of the parameterized family of encryption functions and to a ciphertext of adequate length. Beyond that, the specific level of security depends on the goals and resources of the attacker. An attacker might attempt a “total break” of the cipher, which would correspond to learning the key  $K$ . An attacker might attempt a “partial break” of the cipher, which would correspond to learning some or all of the plaintext for a given ciphertext. An attacker might have no resources beyond a description of the block cipher and a sample ciphertext, in which case he is mounting a “ciphertext-only attack.” An attacker might mount a “known-plaintext attack,” if he is given a number of plaintext-ciphertext pairs to work with (input-output pairs for the encryption function). If the attacker is allowed to choose plaintexts and then see the corresponding ciphertexts, then he is engaged in a “chosen-plaintext attack.”

Symmetric key block ciphers are valuable for data secrecy in a storage scenario (encryption by the data owner for an insecure data repository, and subsequent decryption by the data owner at a later time), or in a transmission scenario (across an insecure channel between a sender and receiver that have agreed on the secret key beforehand).

Perhaps the most popular symmetric key block cipher for the past 25 years has been the Data Encryption Standard (DES) [9], although it may be near the end of its useful life. NIST recently announced the Advanced Encryption Standard (AES) block cipher, which we discuss in section “Advanced Encryption Standard (AES).”

Most modern block ciphers have an “iterated” design, where a “round function” is repeated some fixed number of times (e.g., DES has 16 rounds). Many modern block ciphers have a “Feistel structure” [10], which is an iterated design of a particular type. Let  $(L_{j-1}, R_{j-1})$  denote the output of the  $(j - 1)$ th round, divided into two halves for notational convenience. Then the output of the  $j$ th round is  $(L_j, R_j)$ , where  $L_j = R_{j-1}$ , and  $R_j = L_{j-1} \text{ xor } f(R_{j-1}, K_j)$  for some function  $f$ . Here  $K_j$  is the  $j$ th “round key,” derived from the secret key according to some fixed schedule. Note that a block cipher with a Feistel structure is guaranteed to be a permutation even if the function  $f$  is not invertible.

## Differential Cryptanalysis

Differential cryptanalysis is a powerful statistical attack that can be applied to many symmetric key block ciphers and unkeyed cryptographic hash functions. The first publication on differential cryptanalysis is due to Biham and Shamir [11], but Coppersmith [12] has described how the attack was understood during the design of the DES in the early 1970s.

The central idea of differential cryptanalysis for block ciphers is to sample a large number of pairs of ciphertexts for which the corresponding plaintexts have a known fixed difference  $D$  (under the operation of bitwise exclusive-or). The difference  $D$  leads to a good “characteristic” if the XOR of the ciphertexts (or of an intermediate result during the computation of the ciphertext) can be predicted with a relatively large probability. By calculating the frequency with which every difference of plaintexts and every difference of ciphertexts coincides, it is possible to deduce some of the key bits through a statistical analysis of a sufficiently large sample of these frequencies.

For a differential cryptanalysis of DES, the best attack that Biham and Shamir discovered requires  $2^{47}$  chosen plaintext pairs with a given difference. They note that making even slight changes to the S-boxes (nonlinear substitution transformation at the heart of DES) can lead to a substantial weakening with respect to a differential attack.

## Linear Cryptanalysis

Linear cryptanalysis is another powerful attack that can be applied to many symmetric key block ciphers and unkeyed cryptographic hash functions. Consider the block cipher as being a composition of linear and nonlinear functions. The goal of linear cryptanalysis is to discover linear approximations for the nonlinear components. These approximations can be folded into the specification of the block cipher, and then expanded to find an approximate linear expression for the ciphertext output bits in terms of plaintext input bits and secret key bits. If the approximations were in fact perfect, then enough plaintext-ciphertext pairs would yield a system of linear equations that could be solved for the secret key bits; however, even when the approximations are far from perfect, they enable a successful statistical search for the key, given enough plaintext-ciphertext pairs. This is a known-plaintext attack, unlike differential cryptanalysis, which is chosen-plaintext.

Linear cryptanalysis was introduced by Matsui and Yamagishi [13]. Matsui applied linear cryptanalysis to DES [14]. In his best attack,  $2^{43}$  known plaintexts are required to break DES with an 85% probability. See Langford and Hellman [15] for close connections between differential and linear cryptanalysis.

## Advanced Encryption Standard (AES)

In 1997, NIST began an effort to develop a new symmetric key encryption algorithm as a Federal Information Processing Standard (FIPS). The goal was to replace the DES, which was widely perceived to be

at the end of its usefulness. A new algorithm was sought, with longer key and block sizes, and with increased resistance to newly revealed attacks such as linear cryptanalysis and differential cryptanalysis. The AES was to support 128-bit block sizes, and key sizes of 128 or 192 or 256 bits. By contrast, DES supported 64-bit block sizes, and a key size of 56 bits.

Fifteen algorithms were proposed by designers around the world. This was reduced to five finalists, announced by NIST in 1999: MARS, RC6, Rijndael, Serpent, and TwoFish. In 2000, Rijndael was selected as the Advanced Encryption Standard. Rijndael has a relatively simple structure; however, unlike many earlier block ciphers (such as DES), it does not have a Feistel structure.

The operation of Rijndael proceeds in rounds. Imagine that the block to be encrypted is written as a rectangular array of byte-sized words (four rows and four columns). First, each byte in the array is replaced by a different byte, according to a single fixed lookup table (S-box). Next, each row of the array undergoes a circular shift by a fixed amount. Next, a fixed linear transformation is applied to each column in the array. Last, the entire array is exclusive-or with a “round key.” All of the round keys are calculated by expanding the original secret key bits according to a simple key schedule. Note that the only nonlinear component is the S-box substitution step. Details of Rijndael’s operation can be found at [16].

## Symmetric Key Stream Ciphers

Stream ciphers compute ciphertext one character at a time, where the characters are often individual bits. By contrast, block ciphers compute ciphertext one block at a time, where the block is much larger (64 bits long for DES, 128 bits long for AES). Stream ciphers are often much faster than block ciphers. The typical operation of a stream cipher is to exclusive-or message bits with a “key stream.” If the key stream were truly random, this would describe the operation of a “one-time pad.” The key stream is not truly random, but it is instead derived from the short secret key.

A number of stream ciphers have been optimized for hardware implementation. The use of linear feedback shift registers is especially attractive for hardware implementation, but unfortunately these are not sufficiently secure when used alone. The Berlekamp–Massey algorithm [17] allows a hidden linear feedback shift register to be determined from a very short sequence of output bits. In practice, stream ciphers for hardware often combine linear feedback shift registers with nonlinear components to increase security. One approach is to apply a nonlinear function to the output of several linear feedback shift registers that operate in parallel (“nonlinear combination generator”). Another approach is to apply a nonlinear function to all of the states of a single linear feedback shift register (“nonlinear filter generator”). Still another approach is to have the output of one linear feedback shift register determine when a step should be taken in other linear feedback shift registers (“clock-controlled generator”).

Some stream ciphers have been developed to be especially fast when implemented in software, e.g., RC5 [18]. Certain modes of operation for block ciphers can be viewed as symmetric key stream ciphers (output feedback mode and cipher feedback mode).

## Message Authentication Codes

A message authentication code (MAC) is a keyed cryptographic hash function. It computes a fixed-length output (tag) from an input of any length (message). When both the sender and the receiver know the secret key, a MAC can be used to transmit information with integrity. Without knowing the key, it is very difficult for an attacker to modify the message and/or the tag so that the hash relation is maintained. The MAC in the symmetric key setting is the analog of the digital signature in the asymmetric key setting. The notion of message authentication in the symmetric key setting goes back to Gilbert, MacWilliams, and Sloane [19].

Security for MACs can be described with respect to different attack scenarios. The attacker is assumed to know a complete specification of the hash function, but not the secret key. The attacker might attempt to insert a new message that will fool the receiver, or the attacker might attempt to learn the secret key. The attacker might get to see some number of message-tag pairs, either for random messages or for messages chosen by the attacker.

One popular MAC is the CBC-MAC, which is derived from a block cipher (such as DES) run in cipher block chaining mode. Another approach is to apply an unkeyed cryptographic hash function after the message has been combined with the key according to some pre-packaging transform. Care must be taken with the choice of transform; one popular choice is HMAC [20]. The UMAC construction [21] has been optimized for extremely fast implementation in software, while maintaining provable security. Jutla [22] recently showed especially efficient methods for combining message authentication with encryption, by using simple variations on some popular modes of operation for symmetric key block ciphers.

## 43.4 Asymmetric Key Cryptographic Primitives

---

Two asymmetric key cryptographic primitives are discussed in this section: public key encryption schemes and digital signature schemes.

### Public Key Encryption Schemes

A public key encryption scheme is a method for deriving an encryption function  $E_K$  and a corresponding decryption function  $D_K$  such that it is computationally infeasible to determine  $D_K$  from  $E_K$ . The encryption function  $E_K$  is made public, so that anyone can send encrypted messages to the owner of the key. The decryption function  $D_K$  is kept secret, so that only the owner of the key can read encrypted messages. The functions are inverses of each other, so that  $D_K(E_K(M)) = M$  for every message  $M$ . Unlike the symmetric key setting, there is no need for the sender and receiver to pre-establish a secret key before they can communicate securely.

Security for a public key encryption scheme relates to the resources and goals of the attacker. The attacker is assumed to have a complete description of the scheme, as well as the public encryption key  $E_K$ . Thus, the attacker is certainly able to encrypt arbitrary messages (“chosen-plaintext attack”). The attacker might be able to decrypt arbitrary messages (“chosen-ciphertext attack,” discussed in more detail in subsection on “Chosen Ciphertext Security for Public Key Encryption”). The goal of the attacker might be to deduce the decryption function  $D_K$  (“total break”), or simply to learn all or some information about the plaintext corresponding to a particular ciphertext (“partial break”), or merely to guess which of two plaintexts is encrypted by a given ciphertext (“indistinguishability”).

The idea of public key encryption is due to Diffie and Hellman [23]. Most popular public key encryption schemes base their security on the hardness of some problem from number theory. The first public key encryption proposed remains one of the most popular today—the RSA scheme due to Rivest, Shamir, and Adleman [24]. Other popular public key encryption schemes are based on the “discrete logarithm problem,” including ElGamal [25] and elliptic curve variants [26].

For efficiency purposes, public key encryption is often used in a hybrid manner (called “key transport”). Suppose that a large message  $M$  is to be encrypted using a public encryption key  $E_K$ . The sender chooses a random key  $k$  for a symmetric key block cipher such as AES. The sender then transmits  $E_K(k)$ ,  $AES_k(M)$ . The first component enables the receiver to recover the symmetric key  $k$ , which can be used to decrypt the second component to recover  $M$ . The popular e-mail security protocol PGP uses this method (augmented with an integrity check).

It is also possible to use a “key agreement protocol” to establish a secret key over an insecure public channel, and then to use the secret key in a symmetric key block cipher. The idea is due to Diffie and Hellman [22], and the original Diffie–Hellman key agreement protocol is still widely used in practice.

### Digital Signature Schemes

A digital signature scheme is a method for deriving a signing function  $S_k$  and a corresponding verification function  $V_K$  such that it is computationally infeasible to derive  $S_k$  from  $V_K$ . The verification function  $V_K$  is made public, so that anyone can verify a signature made by the owner of the signing key. The signing function  $S_k$  is kept secret, so that only the owner of the signing key can sign messages. The signing

function and verification function are related as follows: If the signature of a message  $M$  is  $S_K(M)$ , then it should be the case that  $V_K(S_K(M)) = \text{“valid”}$  for all messages  $M$ .

Security for a digital signature scheme depends on the goals and resources of the attacker [27]. The attacker is assumed to know a complete specification of the digital signature scheme, and the verification function  $V_K$ . The attacker might also get to see message–signature pairs for random messages (“known message attack”), or for arbitrary messages chosen by the attacker (“chosen message attack”). The goal of the attacker might be to derive the signature function (“total break”), or to forge a signature on a particular message (“selected message forgery”), or to forge any message–signature pair (“existential message forgery”).

In practice, a signing function is applied not to the message itself, but rather to the hash of the message (i.e., to the output of an unkeyed cryptographic hash function applied to the message). The security of the signature scheme is then related to the security of the hash function. For example, if a collision can be found for the hash function, then an attacker can produce an existential message forgery under a chosen message attack (by finding a collision on the hash function, and then asking for the signature of one of the colliding inputs).

One of the most popular digital signature schemes is RSA (based on the same primitive as RSA public key encryption, where  $S_K = D_K$  and  $V_K = E_K$ ). Other popular digital signature schemes include the digital signature algorithm (DSA) [28] and ElGamal [25].

## Advanced Topics for Public Key Cryptography

### Chosen Ciphertext Security for Public Key Encryption

As discussed earlier, a number of definitions for the security of a public key encryption scheme have been proposed. Chosen ciphertext security is perhaps the strongest natural definition, and it has emerged as the consensus choice among cryptographers as the proper notion of security to try to achieve. This is not to say that chosen ciphertext security is necessary for all applications, but instead of having a single encryption scheme, that is, chosen ciphertext secure will allow it to be used in the widest possible range of applications.

The strongest version of definition of chosen ciphertext security is due to Rackoff and Simon [29], building from a slightly weaker definition of Naor and Yung [30]. It can be described as a game between an adversary and a challenger. The challenger chooses a random public key and corresponding private key  $[E_K, D_K]$ , and tells the public key  $E_K$  to the adversary. The adversary is then allowed to make a series of decryption queries to the challenger, sending arbitrary ciphertexts to the challenger and receiving their decryptions in reply. After this stage, the adversary chooses two messages  $M_0$  and  $M_1$  whose encryptions he thinks will be particularly easy to distinguish between. The adversary sends  $M_0$  and  $M_1$  to the challenger. The challenger chooses one of these messages at random; call it  $M_b$ , where  $b$  is a random bit. The challenger encrypts  $M_b$  and sends the ciphertext  $C$  to the adversary.

Now the adversary attempts to guess whether  $C$  is an encryption of  $M_0$  or  $M_1$ . To help him with his guess, he is allowed to engage in another series of decryption queries with the challenger. The only restriction is that the adversary may never ask the challenger to directly decrypt  $C$ . At some point the adversary makes his guess for  $M_b$ . If the adversary can win this game with any nonnegligible advantage (i.e., with probability  $1/2$  plus  $1/k^c$ , where  $k$  is the length of the private key and  $c$  is any positive constant), then we say that he has mounted a successful chosen ciphertext attack. If no adversary (restricted to the class of probabilistic polynomial time turing machines) can mount a successful chosen ciphertext attack, then we say that the cryptosystem is chosen ciphertext secure.

This might seem like overkill for a definition of security. Unlimited access to a decryption oracle might seem like an unrealistically strong capability for the attacker. Merely distinguishing between two plaintexts might seem like an unrealistically weak goal for the attacker. Nevertheless, this definition has proven to be a good one for several reasons. First, it has been shown to be equivalent to other natural and strong definitions of security [31]. Second, Bleichenbacher [32] showed that a popular standard (RSA PKCS #1) was vulnerable to a chosen ciphertext attack in a practical scenario.

In the random oracle model, chosen ciphertext security can be achieved by combining a basic public key encryption scheme such as RSA with a simple “prepackaging” transform. Such a transform uses random padding and unkeyed cryptographic hash functions to scramble the message prior to encryption. The prepackaging transform is invertible, so that the message can be unscrambled after the ciphertext is decrypted.

The optimal asymmetric encryption padding (OAEP) transform takes an  $m$ -bit message  $M$ , a random bit string  $R$  of length  $s$ , and outputs  $\text{OAEP}(M, R) = ((M \parallel 0^s) \text{ xor } H(R)) \parallel (R \text{ xor } G((M \parallel 0^s) \text{ xor } H(R)))$ . Here  $G$  and  $H$  are unkeyed cryptographic hash functions that are assumed to have no exploitable weaknesses (random oracles). This can be viewed as a two-round Feistel structure (e.g., DES is a 16-round round Feistel structure). Unpackaging the transform is straightforward. The OAEP transform is used extensively in practice, and has been incorporated in several standards. OAEP combined with RSA yields an encryption scheme that is secure against a chosen ciphertext attack [33,34].

Shoup [35] shows that OAEP+, a variation on OAEP, yields chosen ciphertext security when combined with essentially any public key encryption scheme:  $\text{OAEP}^+(M, R) = ((M \parallel W(M, R)) \text{ xor } H(R)) \parallel (R \text{ xor } G(M \parallel W(M, R)) \text{ xor } H(R))$ , where  $G$ ,  $H$ , and  $W$  are unkeyed cryptographic hash functions that behave like random oracles. Boneh [36] shows that even simpler prepackaging transforms (essentially one-round Feistel structure versions of OAEP and OAEP+) yield chosen ciphertext secure encryption schemes when combined with RSA or Rabin public key encryption.

Without the random oracle model, chosen ciphertext security can be achieved using the elegant Cramer–Shoup cryptosystem [37]. This is based on the hardness of the Decision Diffie–Hellman problem (see subsection “New Hardness Assumptions for Asymmetric Key Cryptography”). Generally speaking, constructions in the random oracle model are more efficient than those without it.

## Threshold Public Key Cryptography

In a public key setting, the secret key (for decryption or signing) often needs to be protected from theft for long periods of time against a concerted attack. Physical security is one option for guarding highly sensitive keys, e.g., storing the key in a tamper-resistant device. Threshold public key cryptography is an attractive alternative for safeguarding critical keys.

In a threshold public key cryptosystem, the secret key is never in one place. Instead, the secret key is distributed across many locations. Each location has a different “share” of the key, and each share of the key enables the computation of a “share” of the decryption or signature. Shares of a signature or decryption can then be easily combined to arrive at the complete signature or decryption, assuming that a sufficient number of shareholders contribute to the computation. This “sufficient number” is the threshold that is built into the system as a design parameter. Note that threshold cryptography can be combined with physical security, by having each shareholder use physical means to protect his individual share of the secret key.

Threshold cryptography was independently conceived by Desmedt [38], Boyd [39], and Croft and Harris [40], building on the fundamental notion of secret sharing [41,42]. Satisfactory threshold schemes have been developed for a number of public key encryption and digital signature schemes. These threshold schemes can be designed so as to defeat an extremely strong attacker who is able to travel from shareholder to shareholder, attempting to learn or corrupt all shares of the secret key (“proactive security”). Efficient means are also available for generating shared keys from scratch by the shareholders themselves, so that no trusted dealer is needed to initialize the threshold scheme [43,44]. Shoup [45] recently proposed an especially simple and efficient scheme for threshold RSA.

## New Hardness Assumptions for Asymmetric Key Cryptography

A trend has occurred in recent years toward the exploration of the cryptographic implications of new hardness assumption. Classic assumption include the hardness of factoring a product of two large primes, the hardness of extracting roots modulo a product of two large primes, and the hardness of computing discrete logarithms modulo a large prime (i.e., solving  $g^x = y \text{ mod } p$  for  $x$ ).

One classic assumption is the Diffie–Hellman assumption. Informally stated, this assumption is that it is difficult to compute  $(g^{ab} \text{ mod } p)$  given  $(g^a \text{ mod } p)$  and  $(g^b \text{ mod } p)$ , where  $p$  is a large prime. This assumption

underlies the Diffie–Hellman key agreement protocol. The “Decisional Diffie–Hellman Assumption” has proven to be useful in recent years. Informally stated, this assumption is that it is difficult to distinguish triples of the form  $(g^a \bmod p, g^b \bmod p, g^{ab} \bmod p)$  and triples of the form  $(g^a \bmod p, g^b \bmod p, g^c \bmod p)$  for random  $a, b, c$ . Perhaps most notably, the Cramer–Shoup chosen ciphertext secure encryption scheme is based on this new assumption.

The security of RSA is based on a root extraction problem related to the hardness of factoring: Given message  $M$  and modulus  $N = pq$  of unknown factorization and suitable exponent  $e$ , compute  $M^{1/e} \bmod N$ . Recently, a number of protocols and primitives have been based on a variant of this assumption called the “Strong RSA Assumption:” Given  $M$  and  $N$ , find  $e$  and  $M^{1/e} \bmod N$  for any suitable  $e$ . For example, a provably secure signature scheme can be based on this new assumption without the need for the random oracle assumption [46].

The RSA public key scheme is based on arithmetic modulo  $N$ , where  $N = pq$  is a product of two primes (factors known to the private key holder but not to the public). Recently, Paillier [47] has proposed a novel public key encryption scheme based on arithmetic modulo  $p^2q$ . His scheme has nice “homomorphic” properties, which enable some computations to be performed directly on ciphertexts. For example, it is easy to compute the encryption of the sum of any number of encrypted values, without knowing how to decrypt these ciphertexts. This has many nice applications, such as for secure secret ballot election protocols.

Lastly, the “Phi-Hiding Assumption” was introduced by Cachin, Micali, and Stadler [48]. This is a technical assumption related to prime factors of  $p - 1$  and  $q - 1$  in an RSA modulus  $N = pq$ . This assumption enables the construction of an efficient protocol for querying a database without revealing to the database what queries are being made. (Private Information Retrieval).

### Privacy Preserving Protocols

Using the cryptographic primitives described in earlier sections, it is possible to design protocols for two or more parties to perform useful computational tasks while maintaining some degree of data confidentiality. Theoretical advances were well established with the “completeness theorems” of [49] and others; however, practical solutions have often required special-purpose protocols tailored to the particular problem.

One important example—both historically and practically—is the problem of conducting a secret ballot election [50,51]. This can be viewed as a cryptographic protocol design problem among three types of parties: voters, talliers, and independent observers. All types of parties have different security requirements. Voters want to guarantee that their individual ballots are included in the final tally, and that the contents of the ballots remain secret. Talliers want to produce an accurate final count that includes all valid ballots counted exactly once, and no invalid ballots. Independent observers want to verify that the tally is conducted honestly. One of the best secret ballot election protocol currently known for large-scale elections is probably [52], which is based on threshold public key encryption.

## 43.5 Other Resources

---

An excellent resource for further information is the CRC Handbook of Applied Cryptography [53], particularly the first chapter of that handbook, which has an overview of cryptography that is highly recommended. Ross Anderson’s book on security engineering [54] is a recommended resource, especially for its treatment of pragmatic issues that arise when implementing cryptographic primitives in practice. See also the frequently asked questions list maintained by RSA Labs ([www.rsa.com/rsalabs](http://www.rsa.com/rsalabs)).

## 44.1 Introduction

---

Rapidly evolving submicron technology and design automation has enabled the design of electronic systems with millions of transistors integrated on a single silicon die, capable of delivering gigaflops of computational power. At the same time, increasing complexity and time to market pressures are forcing designers to adopt design methodologies with shorter ASIC design cycles. With the emergence of system-on-chip (SoC) concept, traditional design and test methodologies are hitting the wall of complexity and capacity. Conventional design flows are unable to handle large designs made up of different types of blocks such as customized blocks, predesigned cores, embedded arrays, and random logic as shown in [Fig. 44.1](#). Many of today's test strategies have been developed with a focus on single monolithic block of logic; however, in the context of SoC the test strategy should encompass multiple test approaches and provide a high level of confidence on the quality of the product. Design reuse is one of the key components of these methodologies. Larger designs are now shifting to the use of predesigned cores, creating a myriad of new test challenges. Since the end user of the core has little participation in the core's architectural and functional development, the core appears as a black box with known functionality and I/O. Although enabling designers to quickly build end products, core-based design requires test development strategies for the core itself and the entire IC/ASIC with the embedded cores.

This chapter begins with a discussion of some of the existing test methodologies and the key issues/requirements associated with the testing of SoC. It is followed by a discussion on some of the emerging approaches that will address some of these issues.

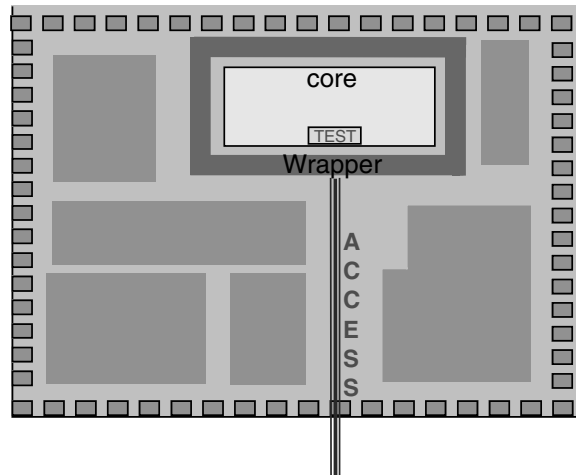

FIGURE 44.1 Core access through wrapper isolation.

## 44.2 Current Test Practices

Current test practices consist primarily of ATE-based external test approaches. They range from manual test development to scan-based test. Most of the manual test development efforts depend on fault simulation to estimate the test coverage. Scan-based designs are becoming very common, although their capacity and capability to perform at-speed test are being increasingly affected by physical limitations.

### Scan-Based Test

Over the past decade, there has been an increased use of the scan DFT methodology across a wide variety of designs. One of the key motivations for the use of scan is the resulting ability to automatically generate test patterns that verify the gate or transistor level structures of the scan-based design. Because test generation is computationally complex for sequential designs, most designs can be reconfigured in test mode as combinational logic with inputs and outputs from and to scannable memory elements (flip-flops) and primary I/O. Different types of scan design approaches include mux-D, clock scan, LSSD, and random access scan [1]. The differences are with respect to the design of the scannable memory elements and their clocking mechanisms.

Two major classes of scan design are full scan and partial scan. In the case of full scan, all of the memory elements are made to be scannable, while in the case of partial scan, only a fraction of the memory elements, based on certain overhead (performance and area) constraints, are mapped into scan elements. Because of its iterative nature, the partial scan technique has an adverse impact on the design cycle. Although full scan design has found wider acceptance and usage, partial scan is seen only in designs that have very stringent timing and die size requirements. A major drawback with scan is the inability to verify device performance at-speed. In general, most of the logic related to scan functionality is designed for lower speed.

### Back-End Scan Insertion

Traditional scan implementation depended on the “over-the-wall” approach, where designers complete the synthesis and hand off the gate netlist to the test engineer for test insertion and automatic test pattern generation (ATPG). Some electronic design automation (EDA) tools today help design and test engineers speed the testability process by automatically adding test structures at the gate level. Although this technique is easier than manual insertion, it still takes place after the design has been simulated and synthesized to strict timing requirements. After the completed design is handed over for test insertion,

many deficiencies in the design may cause iteration back into module implementation, with the attendant risks to timing closure, design schedule, and stability.

These deficiencies may be a violation of full-scan design rules (e.g., improper clock gating or asynchronous signals on sequential elements not handled correctly). In some cases, clock domain characteristics in lower-level modules can cause compatibility problems with top-level scan chain requirements. In addition, back-end scan insertion can cause broken timing constraints or violate vendor-specific design rules that cannot be adequately addressed by reoptimization.

If back-end scan insertion is used on a large design, the reoptimization process to fix timing constraints violated by inserting scan can take days. If timing in some critical path is broken in even a small part of the overall design, and the violated constraint could not be fixed by reoptimization, the entire test process would have to iterate back into synthesis to redesign the offending module. Thus, back-end test, where traditionally only a small amount of time is budgeted compared to the design effort, would take an inordinately long time. Worse, because these unanticipated delays occur at the very end of the design process, the consequences are magnified because all the other activities in the project are converging, and each of these will have some dependency on a valid, stable design database.

### **RT-Level Scan Synthesis**

Clearly, the best place to insert test structures is at the RT-level while timing budgets are being worked out. Because synthesis methodologies for SoCs tend to follow hierarchical design flows, where subfunctions within the overall circuit are implemented earliest and then assembled into higher-level blocks as they are completed, DFT should be implemented hierarchically as well. Unfortunately, traditional full-scan DFT tools and methodologies have worked only from the top level of fully synthesized circuits, and have been very much a back-end processes.

The only way to simultaneously meet all design requirements—function, timing, area, power, and testability—is to account for these during the very earliest phases of the design process, and to ensure that these requirements are addressed at every step along the way. A tool that works with simulation and synthesis to insert test logic at this level will ensure that the design is testable from the start. It also ensures that adequate scan structures are inserted to meet the coverage requirements that most companies demand—usually greater than 95%. Achieving such high coverage is usually difficult once a design has been simulated and synthesized.

Tools that automatically insert test structures at the RT-level have other benefits as well. Provided that they are truly automatic and transparent to the user, a scan synthesis tool makes it easy for the designer to implement test without having to learn the intricacies of test engineering. Inserting scan logic before synthesis also means that designers on different teams, working on different blocks of a complex design, can individually insert test logic and know that the whole device will be testable when the design is assembled. This is especially important for companies who use intellectual property (IP) and have embraced design reuse. If blocks are reused in subsequent designs, testability is ensured because it was built in from the start. A truly automated scan synthesis tool can also be used on third party IP, to ensure that it is testable.

One of the key strengths of scan design is diagnosability. The user is able to set the circuit to any state and observe the new states by scanning in and out of the scan chains. For example, when the component/system fails on a given input vector, the clock can be stopped at the erring vector and a test clock can be used to scan out the error state of the machine. The error state of the machine is then used to isolate the defects in the circuit/system. In other words, the presence of scan enables the designer to get a “snap shot” of the system at any given time, for purposes of system analysis, debug, and maintenance.

## **44.3 SoC Testing Complexity**

---

With the availability of multiple millions of gates per design, more and more designers are opting to use IPs to take advantage of that level of integration. The sheer complexity and size of such devices is forcing them to adopt the concept of IP reuse; however, the existing design methodologies do not support a cohesive or comprehensive approach to support reuse. The result is that many of these designs are created

using ad hoc methodologies that are localized and specific to the design. Test reuse is the ability to provide access to the individual IPs embedded in the SoC so that the test for the IP can be applied and observed at the chip level. This ability to reuse becomes more complex when the IPs come from multiple sources with different test methods. It becomes difficult to achieve plug and play capability in the test domain. Without a standard, the SoC design team is faced with multiple challenges such as a test model for the delivery of cores, the controllability and observability of cores from the chip I/O, and finally testing the entire chip with embedded IPs, user defined logic, and embedded memories.

## **Core Delivery Model**

Core test is an evolving industry-wide issue, so no set standards are available to guide the testing of cores and core-based designs. Cores are often delivered as RTL models, which enable the end-users to optimize the cores for the targeted application; however, the current test practices that exist in the “soft core” based design environment are very ad hoc. To a large extent it depends on whether the “soft core” model is delivered to the end user without any DFT built into the core itself. The core vendors provide only functional vectors that verify the core functionality. Again, these vectors are valid only at the core I/O level and have to be mapped to the chip I/O level in order to verify the core functionality at the chip level. Functional testing has its own merits and demerits, but the use of functional tests as manufacturing tests without fault simulation cannot provide a product with deterministic quality. It can easily be seen that any extensive fault simulation would not only result in increased resources, but also an extended test development time to satisfy a certain quality requirement.

## **Controllability and Observability of Cores**

A key problem in testing cores is the ability to control and observe the core I/O when it is embedded within a larger design. Typically, an ASIC or IC is tested using the parallel I/O or a smaller subset of serial ports if boundary scan is used. In the case of the embedded core, an ideal approach would be to have direct access to its I/O. A typical I/O count for cores would be in the order of 300–400 signals. Using a brute-force approach all 300 signals could be brought out to the chip I/O resulting in a minimum of 300 extra multiplexers. The overhead in such a case is not only multiplexers, but also extra routing area for routing the core I/O to the chip I/O and most of all, the performance degradation of at least one gate delay on the entire core I/O. For most performance driven products, this will be unacceptable. Another approach would be to access the core I/O using functional (parallel) vectors. In order to set each core I/O to a known value, it may be necessary to apply many thousands of clocks at the chip I/O. (This is because, the chip being a sequential state machine, it has to be cycled through hundreds of states before arriving at a known state—the value on the core I/O signal).

## **Test Integration**

Yet another issue is the integration of test with multiple cores potentially from multiple sources. Along with the ability to integrate one or more cores on an ASIC, comes other design challenges such as layout and power constraints and, very importantly, testing the embedded core(s) and the interconnect logic. The test complexity arises from the fact that each core could be designed with different clocking, timing, and power requirement. Test becomes a bottleneck in such an environment where the designer has to develop a test methodology, either for each core or for the entire design. In either case, it is going to impact the overall design cycle. Even if the individual cores are delivered with embedded test, the end user will have to ensure testing of the interconnects between the multiple cores and the user logic. Although functional testing can verify most of these and can be guaranteed by fault simulation, it would be a return to resource-intensive ways of assuring quality.

Because many cores are physically distinct blocks at the layout level, manufacturing test of the cores has to be done independent of other logic in the design. This means that the core must be isolated from the rest of the logic and then tested as an independent entity. Conventional approaches to isolation and test

impact the performance and test overhead. When multiple cores are implemented, testing of the interconnects between the cores and the rest of the logic is necessary because of the isolation-and-test approach.

## Defects and Performance

Considerable design and test challenges are associated with the SoC concept. Test challenges arise both due to the technology and the design methodology. At the technology level, increasing densities has given rise to newer defect types and the dominance of interconnect delays over transistor delays due to shrinking geometry's. Because designers are using predesigned functional blocks, testing involves not only the individual blocks, but also the interconnect between them as well as the user-created logic (glue logic). The ultimate test objective is the ability to manufacture the product at its specified performance (frequency) with the lowest DPM (defective parts per million).

As geometry's shrink and device densities increase, current product quality cannot be sustained through conventional stuck-at fault testing alone [2]. When millions of devices are packed in a single die, newer defect types are created. Many of these cannot be modeled as stuck-at faults, because they do not manifest themselves into stuck-at-like behavior. Most of the deep submicron processes use multiple layers, so one of the predominant defect types is due to shorts between adjacent layers (metal layers), or even between adjacent lines (poly or metal lines). Some of these can be modeled as bridging faults, which behave as the Boolean ANDing or ORing of the adjacent lines depending on the technology. Others do not manifest themselves as logical faults, but behave as delay faults due to the resistive nature of certain shorts. Unlike stuck-at faults, it becomes computationally complex to enumerate the various possible bridging faults since most of them depend on the physical layout. Hence, most of the practical test development is targeted towards stuck-at faults, although there has been considerable research in the analysis and test of bridging faults.

At the deep submicron level interconnect delays dominate gate delays and this affects the ability to test at speed the interconnect (I/O) between various functional blocks in the SoC design environment. Since manufacturing test should be intertwined with performance testing, it is necessary to test the interaction between various functional blocks at-speed. The testing of interconnects involves not only the propagation of signal between various blocks, but also at the specified timing. Current approaches to test do not in general support at-speed test because of a lack of accurate simulation model, limited tester capabilities, and very little vendor support. Traditional testing, which is usually at lower speed, can trigger failures of the device at the system level.

## 44.4 Emerging Trends in SoC Test

---

Two major capabilities are needed to address the major test challenges that were described earlier in this chapter: (1) making the core test-ready and (2) integration of test-ready cores and user logic at the chip level.

### Creation of Test-Ready Cores

Each core is made test-ready by building a wrapper around it as well as inserting appropriate DFT structures (scan, BIST, etc.) to test the core logic itself. The wrapper is generally a scan chain similar to the boundary scan chain [3] that helps the controllability and observability of the core I/O. The wrapper chain enables access to the core logic for providing the core test vectors from the chip boundary (Fig. 44.1). The wrappers also help in isolating the cores from other cores while the core is being tested, independent of the surrounding cores and logic. One of the key motivation for wrapper is test-reuse. When a test-ready core is delivered, the chip designer does not have to recreate the core test vectors but reuses the core test vectors. The wrappers also help in isolating the core electrically from other cores so that signals coming from other cores do not affect the core and vice versa.

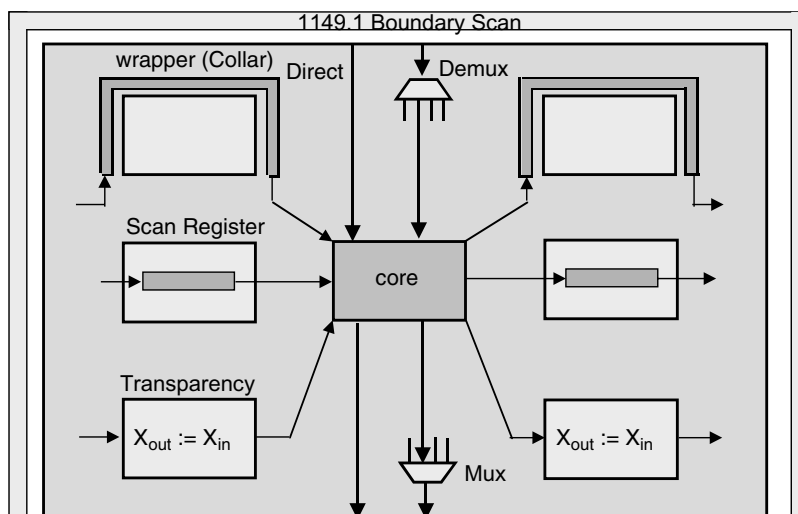

FIGURE 44.2 Core isolation techniques.

FIGURE 44.3 An example for transparency.

### Core Isolation

Many different approaches (Fig. 44.2) can be used to isolate a core from other cores. One common approach is to use multiplexers at each I/O of the core. The multiplexers can be controlled by a test mode so that external vector source can be directly connected to the core I/O during test. This approach is very advantageous where the core doesn't have any internal DFT structure and has only functional vectors which can be applied directly from an external source to the core I/O; however, this approach is disadvantageous when the number of core I/O exceeds that of the chip I/O and also impacts physical routing.

In contrast, other approaches minimize the routing density by providing serial access to the core I/O. The serial access can be through dedicated scan registers at the core I/O or through shared registers, where sharing can happen between multiple cores. The scan register is called a wrapper or a collar. The scan registers isolate the core from all other cores and logic during test mode. The wrapper cell is built with a flip-flop and multiplexer that isolates each pin. It can be seen that the wrapper-based isolation has impact on the overall area of the core. Sharing existing register cells at core I/O helps minimize the area impact. Trade-offs exist with respect to core fault coverage and the core interconnect fault coverage, between shared wrapper and dedicated wrappers.

Access to cores can also be accomplished using the concept of “transparency” through existing logic. In this case, the user leverages existing functionality of a logic block to gain access to the inputs of the core and similarly from the core outputs to the chip I/O through another logic block. Figure 44.3 shows an example of “transparency” in a logic block. Although this approach involves no hardware overhead, detection of transparency is not a simple automation process. In addition, the existence of transparency cannot be predicted a priori.

FIGURE 44.4 An SoC includes multiple cores with memory and user logic.

FIGURE 44.5 A high-level architecture for SoC test integration.

It becomes evident that the isolation approach and the techniques to make a core test-ready depends on various design constraints such as area, timing, power as well as the test coverage needs for the core, and the core interconnect faults.

### Core Test Integration

Testing SoC devices with multiple blocks (Fig. 44.4), each block embedding different test techniques, could become a nightmare without an appropriate test manager that can control the testing of various blocks. Some of these blocks could be user-designed and others predesigned cores. Given the current lack of any test interface standard in the SoC environment, it becomes very complex to control and observe each of the blocks. Two key issues must be addressed: sequencing of the test operations [4] among the various blocks, and optimization of the test interface between the various blocks and the chip I/O. These depend very much on the test architecture, whether test controllers are added to individual blocks or shared among many, and whether the blocks have adopted differing design-for-test (DFT) methodologies. A high-level view of the SoC test architecture is shown in Fig. 44.5, where the embedded test in each of the cores is integrated through a test bus, which is connected to a 1149.1 TAP controller for external access. Many devices are using boundary scan with the IEEE 1149.1 TAP controller not only to manage in-chip test, but also to aid at board and system-level testing. Some of the test issues pertain to the use of a centralized TAP controller or the use of controller in each block with a common test bus to communicate between various test controllers. In other words, it is the question of centralized versus distributed controller architecture. Each of these has implications with respect to the design of test functionality within each block.

Besides testing each core through their individual access mechanism such as the core isolation wrapper, the complete testing of the SoC also requires an integrated test which tests the interconnects between the cores and the user-defined-logic (UDL). The solution requires, first to connect the test facilities

between all the cores and the UDL, and then connect it to a central controller. The chip level controller needs to be connected to either a boundary scan controller or a system interface. When multiple cores with different test methodologies are available, test scheduling becomes necessary to meet chip level test requirements such as test time, power dissipation, and noise level during test.

### 44.5 Emerging SoC Test Standards

One of the main problems in designing test for SoC is the lack of any viable standard that help manage the huge complexity described in this article. A complete manufacturing test of a SoC involves the reuse of the test patterns that come with the cores, and test patterns created for the logic outside the cores. This needs to be done in a predictable manner. The Virtual Socket Interface Alliance (VSIA) [5], an industry consortium of over 150 electronic companies, has formed a working group to develop standards for exchanging test data between core developers and core integrators as well as test access standards for cores. The IEEE Test Technology Committee has also formed a working group called P1500 to define core test access standards. As a part of the IEEE standardization effort, P1500 group [6,7] is defining a wrapper technology that isolates the core from the rest of the chip when manufacturing test is performed. Both the VSIA and IEEE standard are designed to enable core test reuse. The standards will be defining a test access mechanism that would enable access to the cores from the chip level for test application. Besides the access mechanism, the P1500 group is also defining a core test description language called core test language (CTL).

CTL is a language that describes all the necessary information about test aspects of the core such that the test patterns of the core can be reused and the logic outside the core can be tested in the presence of the core. CTL can describe the test information for any arbitrary core, and arbitrary DFT technique used in the core. Furthermore, CTL is independent of the type of tests (stuck-at, Iddq, delay tests) used to test the core. CTL makes this all possible by using protocols as the common denominator to make all the different scenarios look uniform. Regardless of what hardware exists in a design, each core has a configuration that needs to be described and the method to get in and out of the configuration is described by the protocol. The different DFT methods just require different protocols. If tools are built around this central concept namely CTL, then plug-and-play of different cores can be achieved on a SoC for test purposes. To make CTL a reality, it is important that tools are created to help core providers package their core with CTL and tools be developed that work off CTL and integrate the cores for successful manufacturing test of the SoC.

By documenting the test operation of the core in CTL reduces the test complexity and enables automation tools to use a black-box approach when integrating test at the SoC level. Black-boxed designs are delivered with documentation that describe the fault coverage of the test patterns, the patterns itself, the different configurations of the core, and other pertinent test information to the system integrator. The system integrator uses this information (described in CTL) possibly with the help of tools to translate the test patterns described in CTL at the boundary of the core to the chip I/O that is accessible by the tester. Furthermore, the system integrator would use the CTL to provide information on the boundary of the core to create patterns for the user defined logic (UDL) of the SoC outside the core. The methods used for system integration are dependent on the CTL information of the core, and the core's embedded environment. All these tasks can be automated if CTL is used consistently across all black-box cores being incorporated in the design. Figure 44.6 shows the tasks during the integration process.

FIGURE 44.6 Core integration tasks with CTL.

SoC methodologies require synchronization between the core providers, system integrators, and EDA tool developers. CTL brings all of them together in a consistent manner. Looking ahead we can see the industry will create many other tools and methodologies for test around CTL.

## 44.6 Summary

---

Cores are the building blocks for the newly emerging core-based IC/ASIC design methodology and a key component in the SoC concept. It lets designers quickly build customized ICs or ASICs for innovative products in fast moving markets such as multimedia, telecom, and electronic games. Along with design, core-based methodology brings in new test challenges such as, implementation of transparent test methodology, test access to core from chip I/O, ability to test the core at-speed. Emerging standards for core test access by both VSIA and IEEE P1500 will bring much needed guidance to SoC test methodologies. The key to successful implementation of SoC test depends on automation and test transparency. A ready-to-test core (with embedded test and accompanying CTL, which describes the test attributes, test protocol, and the test patterns) provides complete transparency to the SoC designer. Automation enables the SoC designer to integrate the test at the SoC level and generate manufacturing vectors for the chip.

### 45.1 Introduction

---

Automatic test generation for combinational logic based on the FAN algorithm [1,2], relying on the D-algorithm [3] has reached a high level of maturity. FAN has also been modified for test generation in synchronous sequential circuits [4,5]. Because the shortcomings of the static stuck-at fault model in the detection of opens, dynamic faults, and bridging faults [6,7], became evident, interest has focused on refined fault modeling either using switch-level structures or dynamic gate-level fault models.

The authors have shown [8–10] that the potential fault coverage by stuck-at-based test patterns for transistor faults is potentially as high as 80% or above if the circuit consists of simple 2- and 3-input fully complementary static CMOS gate primitives (AND, NAND, OR, NOR) only, but may drop to 60% or below if complex gates and pass-transistor networks are used. The first solution to this problem is switch-level test generation [11], which is inherently slower than gate-level test generation. The need for test generation based on real transistor structures is also demonstrated by industrial work [12], which reported the first mixed-level test generation approach.

Advanced work in this area was reported more recently in [13–15]. The main problem associated with such methods is the adequate fault modeling based on the transistor circuitry for structures other than primitive logic gates. Cox and Rajski [16] have shown that also using a transition fault model in ATPG, transistor faults in fully complementary CMOS complex gates can be covered by gate-level networks.

This method, however, lacks the applicability to general pass-transistor networks and is also inefficient because the resulting networks have a very large number of gates.

Delay fault testing [17–21] based on gate or path delay fault models has recently emerged as the potentially most powerful method for functional testing. In order to achieve a high fault coverage, delay fault testing requires a detailed timing characterization of the circuit elements. Although this is usually satisfied for gate-level ATPG based on logic primitives, it is difficult to compute timing properties in a full-custom design style employing complex gates, transistor networks, and bidirectional switch-level macros. If no explicit timing information is available, a transition fault model [22] is the most convenient choice. Such a model checks for possible high-low and low-high transitions of all internal circuit nodes at gate-level. The system clock then sets the timing limit for transitions.

Recently, the detection of defects beyond functional faults by methods such as built-in overcurrent measurements (Iddq-testing) [23,24] has received considerable attention. Despite their potential coverage of transistor faults and bridging faults, these methods are static by nature and therefore they are a complement to, instead of a replacement for, dynamic testing.

The work introduced here is aimed at the generation of efficient test sets for conventional voltage-based tests as well as for Iddq tests. The method is based on the transition fault model and on available structural information at transistor-level and gate-level. Our software also supports various other fault models. The basic approach relies on relatively few but efficient modifications to the FAN algorithm in combination with adapted local switch-level test generation. The advantage over other approaches is that switch-level structures are only addressed where truly necessary, and fault propagation is essentially handled at gate-level. Test sets are kept short by using robust multipattern sequences where possible.

A sequential test pattern generation approach is presented in the second part of this paper. It is based on the new FOGBUSTER-algorithm. As opposed to the BACK-algorithm [25], which was built on basic theoretical work [26,27], FOGBUSTER uses a forward propagation and backward justification technique, which is in general more efficient than the exclusive reverse time processing BACK uses.

The advantage of all these test pattern generators over simulation-based approaches [28,29], which are generally much faster than these techniques, is that they are complete, i.e., for any given testable fault a test pattern is generated assuming sufficient time.

The overall approach is summarized in Table 45.1. Although MILEF (mixed-level FAN) is able to generate test patterns for combinational circuits using a modified FAN-algorithm, SEMILET can generate test patterns for synchronous sequential circuits using the FOGBUSTER-algorithm.

The rest of this chapter is organized as follows: The first part (Section 45.2) describes the mixed-level ATPG approach for combinational logic. The second part is devoted to sequential ATPG (Section 45.3). Results for the ISCAS '85 (combinational) and the ISCAS '89 (sequential) benchmark circuits are presented and compared to other approaches. The chapter ends with a summary (Section 45.4).

**TABLE 45.1** The Relation between Test Generation Approaches

ATPG Tool	MILEF	SEMILET
Circuit behavior	Combinational circuits or full scan circuits	Synchronous sequential circuits
Algorithm	Modified FAN	FOGBUSTER
Test generator for embedded switch-level macros	CTEST	CTEST
Voltage-based fault models	Stuck-at Stuck-open Transition	Stuck-at
Current-based fault models	Stuck-at Stuck-on	Stuck-at Stuck-on

## 45.2 Mixed-Level Test Generation

The mechanism of mixed-level test generation technique is described as follows. An extraction algorithm is used for dividing the circuit into relatively small parts (1-stage complex gates, for instance) and extraction of primitive gates (NAND, NOR, INVERTER). The original FAN-algorithm can generate test patterns only for circuits that consist of primitive logic gates because FAN makes, exclusively, use of controlling and noncontrolling values. Thus the FAN-algorithm has to be modified to handle circuits, which consist of gates described by their logic behavior. These modifications and inter-level communication between gate- and switch-level are described in the following. Finally, additional heuristics like the robustness check supporting robust stuck-open test generation and the reconvergency analysis decreasing the number of backtracks between the two hierarchies are shown. The performance increase of the heuristics is pointed out by giving experimental results.

The overall MILEF approach is described in Fig. 45.1. If the circuit consists of complex gates or transistor networks, the logic extractor is called. Primitive gates can directly be handled by the FAN-algorithm. For complex gates and transistor networks, CMOS test pattern generator (CTEST) computes local test patterns. These local patterns are globally applied and propagated. Propagation of fault effects over a switch-level macro is done at gate-level.

### Basic Concepts

The MILEF system developed at GMD initially concentrated on the once popular stuck-open test [30]. MILEF has continuously been developed to cover other potentially more significant faults in an efficient way. MILEF is not restricted to a specific fault model. It is designed to also handle dynamic faults with the exception of explicit consideration of timing limits. Only transitions that are either impossible or delayed beyond the duration of a clock period are detected (gross delay faults).

The main objective in MILEF is to handle only the necessary structures at the switch-level and to perform all general path-tracing operations at the gate-level, thus obtaining an acceptable overall performance of the test generation system.

At the switch-level, a path-oriented ATPG approach as required for stuck-open tests is applied. At the gate-level, MILEF uses a transition fault model, which includes the restriction of single input transitions, e.g., the Hamming distance between init and test pattern is 1. Robust pattern pair requirements can be used as an option (see subsection “Robustness Check for Pattern Pairs”). With these extensions, stuck-open faults and stuck-at faults in primitive gates are safely covered. Stuck-on faults and local bridging faults are excited but not safely propagated.

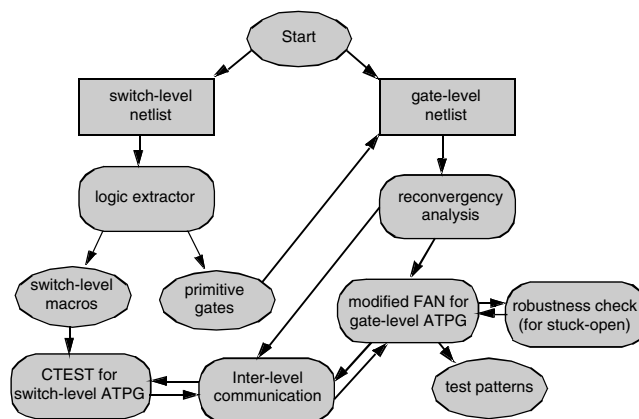

FIGURE 45.1 Functionality of the MILEF ATPG system.

FIGURE 45.2 Logic extraction of switch-level macros.

Input formats of MILEF are ISCAS-benchmarks (for circuits with exclusive primitive gates) and SPICE for circuits including complex gates, transmission gates, and bus-structures.

Transistor-level information is actually reduced to a simplified switch-level structure for the test generation. All transistor-level networks are first analyzed by an advanced logic extraction program, which recognizes structures representing primitive gates such as NANDs, NORs, and inverters [31]. Transistor-level networks that contain only simple gates are shifted to the gate-level before any explicit test generation and are therefore not dealt with at the switch-level. Local test generation is done for nontrivial macros only and can mostly be limited to one-stage complex gates and smaller networks.

The example circuit in Fig. 45.2 consists of a number of primitive gates and one transistor netlist. This transistor netlist is divided into two parts by the extractor. The first part of this transistor netlist can be identified as a 2-input NAND and is therefore shifted to gate-level by the extractor. Test generation for this gate is done exclusively at gate-level. The second part of the transistor netlist representing a ANDNOR function could not be mapped to any primitive gate. Consequently, test generation for this gate is done at the switch-level. Fault propagation over this switch-level macro during the test generation is done at gate-level by using the 0- and 1-cubes of the switch-level macro. The idea of extracting gate-level modules from switch-level circuits was already proposed in [32].

To also handle sequential circuits, the extraction algorithm can also identify several sequential elements such as, for instance, flip-flops and D-latches.

## Switch-Level Test Generation

The local test patterns for the switch-level macros remaining after the extraction are generated by CTEST (CMOS test pattern generator) [30,33]. CTEST generates transition test pattern pairs with a hamming distance 1 between initialization and test. Therefore, the robust stuck-open test condition is satisfied for local test patterns since the switch-level macros extracted do not have internal path reconvergencies. To satisfy this condition also globally in as many cases as possible, MILEF avoids static hazards at the inputs of the switch-level macro with the actual fault whenever possible.

CTEST has a reasonable performance for circuits up to the size of 200 transistors. This is sufficient for the MILEF approach, because the switch-level macros left by the extractor are relatively small, in general, not exceeding 20 transistors [31]. The time spent for switch-level test generation measured in experimental results was less than 5% of the overall test generation time, even when the extraction process

left around 30% of complex gates. The CPU time spent on global path tracing techniques of the FAN-algorithm was immensely larger.

In local mode, CTEST can also handle circuits including bi-directional transistors [34] and small sequential circuits like flip-flops and latches.

## Modified FAN Approach

MILEF is based on extensions of the de-facto standard FAN [1] for the test generation at the gate-level. The original FAN-algorithm is not able to generate test patterns for circuits, including switch-level macros, because FAN is exclusively based on controlling and noncontrolling values of the gates, which in general do not exist for switch-level macros. Consequently, the modified FAN in MILEF also handles Boolean functions of switch-level macros, i.e., multiple cubes [3]. Thus the main FAN functions such as implication, unique sensitization, and multiple backtrace are modified to handle switch-level macros. The modified FAN approach is described as follows (see also Fig. 45.1):

As a preprocess of the test generation process, gate-level netlists are analyzed for path reconvergencies. They have to be identified for the reconvergency analysis described in subsection on “Merging of Test Pattern Pairs.” Most path reconvergencies in practical circuits are of a local nature, so this procedure is quite useful. Results are also transferred to the local switch-level test generator for specific macros in order to obtain globally applicable local test patterns from the beginning (see section “Reconvergency Analysis”). Furthermore, redundancies discovered during this initial step are included in the formal testability analysis. The constraint list is used later in conjunction with global implications in the FAN algorithm.

The second preprocessing step for the gate-level test generation is the formal testability analysis. In particular, the formal controllability and observability analysis guiding the path searching process in FAN was modified in order to also accommodate switch-level macros. Modified testability measures that can optionally be used are, for instance, COP [35], LEVEL [36], SCOAP [37], and EXTEST [8]. We got the best experimental results in MILEF by using COP.

Furthermore, the initial FAN-functions for implication, sensitization, and multibacktrace [1] are modified for handling switch-level macro cells described by multiple cubes [3]. Information for propagation over switch-level macros is described in a 9-valued logic, e.g., multiple cubes are used, and the good and faulty machine are described separately [10].

As MILEF is based on the transition fault model, pattern sequences instead of single vectors are generated. If possible, pattern pairs are merged into longer sequences to minimize initialization efforts and to save on the overall test length.

The path searching performed by MILEF differs from approaches known from gate delay fault test generation in three ways:

- Initialization is excited at a particular gate and test for a particular gate is propagated to primary outputs. The transition may not be observable directly as a transition at one output, which means it can also be observable because of a transition at an output in the faulty case. For example, in Fig. 45.3, the stuck-open fault at the n-transistor with the gate connected to  $A_1$  in  $g_1$  will cause a stable 1 at C and thus a rising transition at D while in the “good case” D has a “0” value.
- Hazard analysis concentrates on static hazards that can invalidate the test by switching other paths or elements to “conducting” (see subsection “Robustness Check for Pattern Pairs”).
- For the generation of only overcurrent-related test vectors in combination with Iddq measurements, the propagation of faults to primary circuit outputs can be omitted. This results in a simplified path-tracing process and fewer patterns.

Three phases of test generation are used in MILEF. In the first phase, test patterns are computed for all easily detectable faults and no backtracking is allowed. No dynamic fault sensitization [2] and no dynamic learning [4] are used in this step. The user may give a backtrack limit for the second phase in which the extensions of SOCRATES [2] are used. For redundancy identification and generating test patterns for hard detectable faults, dynamic learning [4] is used in the third phase of test generation.

FIGURE 45.3 Stuck-open test in gate g1.

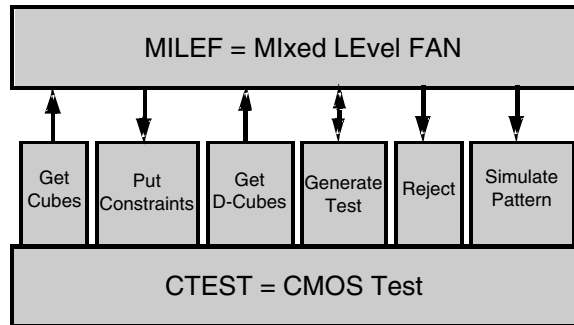

FIGURE 45.4 Communication between MILEF and CTEST.

## Robustness Check for Pattern Pairs

The understanding of “robustness” slightly differs between authors. We follow the robustness definition of Reddy et al., described in [38], avoiding static hazards in the input cone of the fault location.

Since MILEF has no information on timing conditions, a “worst case” analysis for static hazard occurrences is performed. Starting from the fault location backward to the primary inputs of the circuit, every constant signal is checked for a static hazard. If both a rising and a falling transition are found at one gate, the output of the gate is marked hazardous. If for a pattern the static hazard is propagated to the fault location, the corresponding pattern is marked nonrobust. By using a fault simulator that takes into account timing conditions such as FEHSIM [39], these nonrobust patterns possibly can be identified as robust.

## Inter-Level Communications

In the present version, MILEF works on two levels of hierarchy at the gate-level and the switch-level. Communication procedures between the gate-level and the switch-level are performed systematically during several steps of the program execution. The communication functions in Fig. 45.4 are described as follows:

- `get_cubes`: The logic function of a switch-level macro is computed and the corresponding values are prepared to be used at the gate-level.
- `put_constraints`: Constraints are computed on the gate-level for a block (e.g., by the reconvergency analysis described in the following section) and stored for a constraint driven ATPG at the switch-level.
- `get_D_cubes`: Propagation cubes are computed and prepared to be used for the propagation of fault effects over a switch-level macro during the test generation at the gate-level.
- `generate_test`: The previous local io-values of a switch-level macro are used locally as an init-pattern at the switch-level and the computed local test pattern is used at the gate-level for global propagation and application.

- reject: The actual local test pattern is not applicable at gate-level, e.g., the fault is redundant or aborted, an inter-level backtrack is performed. If possible a new local test pattern is generated for the same fault condition.
- simulate\_pattern: A call of the local switch-level fault simulator for local simulation of the actual init/test-pattern pair is performed. A robustness check is included.

## Reconvergency Analysis

The reconvergency analysis is based on a learning technique at reconvergent paths. It is executed as a preprocess of the test generation. The learning technique is similar to SOCRATES [2]. The algorithm is described as follows:

For all switch-level macros  $M$

for all inputs  $S$  of  $M$ , which are part of a reconvergency in  $M$   
 assign all signals of the circuit to value  $X$ ;

(1) assign  $S$  to value 0;

(2) implication;

for all inputs  $I$  of  $M$ , which were set to any value 0 or 1 by the implication

(a) store\_constraint ( $S = 0 \Rightarrow I = \text{value of } I$ );

assign all signals of the circuit to value  $X$ ;

(1) assign  $S$  to value 1;

(2) implication;

for all inputs  $I$  of  $M$ , which were set to any value 0 or 1 by the implication

(a) store\_constraint ( $S = 1 \Rightarrow I = \text{value of } I$ );

Every input of a switch-level macro  $M$ , which is part of a reconvergency in  $M$ , i.e., in one of the reconvergent paths reconverging in  $M$ , is set to both values 0 and 1 (1). By performing the implication of the modified FAN-algorithm (2) every resulting value of this assignment is computed. If any assignment is made at any other input of  $M$ , a local constraint at  $M$  is found. This constraint and its contraposition are stored by the function store\_constraint (a).

Only simple constraints (dependencies between two signals) can be detected by this technique, e.g., if input  $A$  is 1, input  $B$  must be 1. By using these constraints at the switch-level and performing a constraint-based switch-level test generation, a large number of inter-level backtracks can be avoided, and thus the CPU time of switch-level test generation can be reduced. Since the constraints result from a simple FAN implication, no backtrack in test generation is required for computing the constraint behavior. For example, assume a constraint ( $a = 0 \Rightarrow b = 0$ ) is detected by the reconvergency analysis. Thus, a simple implication with starting condition  $a = 0$  will detect that  $b$  has to be assigned to 0. Since the same implication function is also performed during the test generation process whenever  $a$  is set to 0,  $b$  will be set to 0 by the implication. Thus no CPU time could be saved in the test generation at the gate-level. Experimental results showing the efficiency of the reconvergency analysis are illustrated in [Table 45.2](#).

**TABLE 45.2** Inter-Level Backtracks in Test Generation

ISCAS-Benchmark Circuit Extracted from Layout	Inter-Level Backtracks with no Reconvergency Analysis	Inter-Level Backtracks with Reconvergency Analysis	Percentage of Saved Backtracks (%)

FIGURE 45.5 Reconvergency analysis of a simple circuit.

In Fig. 45.5 a simple example is shown. By performing the reconvergency analysis a constraint between the inputs of the macro SLM is detected. If  $B_2$  is set to 0, by performing an implication  $D$  is set to 0. Thus the constraint  $(B_2 = 0 \Rightarrow D = 0)$  is found and stored at SLM by using the function `put_constraints`.

In Table 45.2 the number of inter-level backtracks without using the reconvergency analysis is compared to test generation while using the reconvergency analysis. Depending on the structure of the sequential benchmark circuits, between 39% and 100% of inter-level backtracks could be saved. The average saving in the ISCAS '85 benchmark circuits was about 85%.

These results are also important for hierarchical test generation on higher levels of abstraction (RT-level, behavior-level). The authors believe that using a simple constraint analysis on each abstraction level of the circuit could save a significant time. This requires a constraint-driven test generation technique at lower abstraction levels.

## Merging of Test Pattern Pairs

The test pattern set computed by MILEF is not a minimal set. A test set compaction method is implemented to reduce the number of test patterns as follows. Every generated test pattern is used as an initialization for the next undetected fault whenever possible. Experimental results with ISCAS '85 and ISCAS '89 benchmark circuits have shown that with this method between 30% and 45% of stuck-open patterns could be saved. This method is described in detail in [40].

## Comparative Results

MILEF was used for gate-level benchmark circuits, for mixed gate-level netlists, and for pure transistor netlists. Computations were performed on a Sun SPARC2 with a general limitation of 10 backtracks per fault. The computational effort for fault simulation, which is small in comparison to the test generation effort, is not included in the CPU times of the tables. MILEF was operated in the following modes:

1. Single-input robust transition fault generation including full stuck-open coverage and stuck-on/local bridging fault excitation.
2. Stuck-at test at gate-level including input/output stuck-at tests for switch-level macros.
3. Iddq-test patterns derived from stuck-at patterns, no propagation to outputs.

The fault coverage FC is computed by

$$\text{fault coverage} = \text{detected faults} / \text{total number of faults}$$

Table 45.3 gives results for switch-level circuits containing primitive and complex gates. The layouts of the ISCAS '85 circuits [41] were synthesized by MCNC, Raleigh, NC. For mixed-level netlists containing nontrivial switch-level primitives, no standard benchmarks could be used. The circuits in Table 45.3 contain several types of complex gates. The number of complex gates in these circuits was about 30–40% of the total number of gates in the circuit. This evaluation includes extraction and test generation on two levels with robustness checking.

Table 45.4 shows that MILEF has a reasonable performance for large gate-level circuits. No aborted faults are left within a reasonable amount of time. The results presented in Tables 45.2–45.5 show that the number of redundancies and test patterns based on the different fault models is smallest when using overcurrent-based fault models. The CPU time and the number of test patterns required for overcurrent-based fault models is smaller (about 10% or less depending on the circuit structure) than for test pattern generation for the corresponding voltage-based fault models (exception C6288 where redundancies are

difficult to identify for overcurrent detection). Dynamic fault models require more test patterns than static fault models, but the effort for test pattern generation for dynamic fault models is tolerable. The highest effort in test pattern generation was spent for getting robust single input transition test patterns (Table 45.3) as expected. The time required for mixed-level test pattern generation is almost equal to the functional identical circuits described exclusively on the gate-level.

A further compaction of the test set, in addition to the compaction (described in the subsection on “Merging of Test Pattern Pairs”) leading to a minimal test set, is not performed because long pattern sequences computed for transition fault models are difficult to compress with reordering methods as proposed in [2] for stuck-at pattern sets. With the use of an advanced fault simulator, which includes timing conditions such as FEHSIM [39,42], a further compaction of patterns is possible since MILEF performs a worst-case robustness check as described in the subsection on “Robustness Check for Pattern Pairs.”

## 45.3 The Fobguster Algorithm for Synchronous Circuits

---

To also handle mixed-level sequential circuits without or with a partial scan path, the sequential test generation system SEMILET (sequential mixed-level test generator) was developed as an extension to MILEF. To improve shortcomings of the state-of-the-art test generators such as HITEC [43] and GENTEST [44], the FOGBUSTER (forward propagation backward justification sequential test generator) algorithm was developed.

The only algorithm that uses exclusively forward time processing is the FASTEST approach [45]. The shortcomings of this algorithm are:

- The circuit is copied as often as needed for test generation, so it is very memory consuming.
- The test generation algorithm, in general, needs a large decision tree for fault excitation.

In this section, the FOGBUSTER algorithm for test generation for synchronous sequential circuit and the sequential test generator SEMILET, which makes use of this algorithm are described.

This section is organized as follows: Synchronous circuits that can be handled by our ATPG are characterized in subsection “Circuits.” The main differences of FOGBUSTER and the BACK-algorithm are pointed out in subsection “General Approach in Comparison with Other Algorithms.” The section “Test Generation Technique” describes FOGBUSTER, and subsection “Fault Propagation and Propagation Justification” gives a detailed description of the forward propagation technique. A solution for the over specification problem is presented in next subsection and finally, in next two subsections, the test generator SEMILET using the FOGBUSTER algorithm is described. Experimental results from the ISCAS ’89 benchmark circuits [46] are given in subsection “Experimental Results.”

### Circuits

FOGBUSTER and SEMILET can handle a superset of synchronous sequential circuits that HITEC [43] and GENTEST [44] accept. These circuits have to match the following characteristics:

- All feedback loops include at least one storage element.
- All storage elements have a clock input that is connected to one global clock signal, one data input, and one noninverting data output. It is assumed that the storage elements are master-slave flip-flops, or edge-triggered D-flip-flops.
- Global set and/or reset signals that affect all storage elements are allowed. The test generator can take advantage of them.
- The circuit may consist of primitive (AND, NAND, OR, NOR) and combinational complex gates.

The restriction concerning the types of storage elements seems to be severe at first, but if the design consists of storage elements with a local set and/or reset possibility or with multiple clocking phases,

FIGURE 45.6 Finite state machine model.

FIGURE 45.7 The iterative array model.

they can be substituted by circuits the algorithm can deal with. Basically FOGBUSTER can deal with finite state machines with just one clock depicted in Fig. 45.6.

Each circuit consists of a number of primary inputs and a number of primary outputs. In addition, the circuits have pseudo-inputs—the outputs of the sequential elements, and pseudo-outputs—the inputs of the sequential elements. Each sequential element can be handled as a register. They store the actual state of the circuit. In general, it is not possible to generate a test pattern directly from such a circuit because one special state is needed for the fault injection, and a synchronizing sequence to this state has at least length 1. It is also possible that more than one time frame is needed to propagate the fault effect to the primary outputs of the circuit. For instance, a binary counter may need  $2n$  time frames for the propagation path depending on the fault location, where  $n$  is the number of flip-flops in the counter.

Figure 45.7 shows the iterative array model used in sequential test generation. The combinational logic and the registers are copied as often as needed for the circuit, resulting in a number of copies equal to the test length. The pseudo-outputs of every time frame feed a register storing the state after execution of the time frame via the pseudo-outputs. Each register accesses a time frame feeding it with the state stored in the register. The first time frame is fed with the initial state of the circuit, which is in general the unknown state “xx...x.” Patterns are applied via the inputs of every time frame, and the fault can be observed at the primary outputs of every time frame. For simplicity reasons, the inputs, the outputs, and the registers are left out in the following diagrams in the section on “General Approach in Comparison with Other Algorithms.”

By giving as many time frames to the circuit as needed for the maximal test length, the circuits could be treated by a multi-fault combinational test generator as shown in [25]. This method is impractical because of the memory space required for copying circuit and register. Thus, a window is used, scrolling over the time frames. In most of test generation systems [4,5,44] the window size is one time frame. The only test generator operating also with larger window size is HITEC [43].

## General Approach in Comparison with Other Algorithms

As stated in the introduction, the most common approach in sequential test generation is based on the BACK-algorithm [25]. Starting from a target fault, BACK first selects a primary output, where the fault will be visible a number of time frames later. This selection is supported by a drivability measure, an additional approach to testability analysis [4,5]. After selecting a primary output, the fault propagation path starting from the selected primary output backward to the fault location is computed. Finally, the needed state at the fault location is generated in the backward direction.

In Fig. 45.8 a diagram for the BACK algorithm is shown. In this example, seven time frames are used for the test generation. It is visible that the pattern computing direction is reverse, e.g., the values of the time frame, where the fault effect occurs at a circuit output, are computed first, and the values for the time frame with the initial state are computed last. Thus, the fault propagation path and the fault justification are computed by reverse time processing.

Nearly all test pattern generators at the gate-level for sequential circuits [4,5,14,22,44,47,48] make use of a technique based on the BACK-algorithm. The only approaches that use different techniques are HITEC [43] and FASTEST [45]. FASTEST is a technique, which uses exclusively forward time processing. In HITEC, Niermann and Patel use a forward propagation backward justification technique, which means that the propagation is performed by forward processing and the line justification is done using reverse time processing. This technique is illustrated in Fig. 45.9.

The main advantages of forward propagation backward justification over the BACK algorithm are

- No drivability is needed for the test generation process, i.e., computing time is saved.
- In the BACK algorithm the selection of the output where the fault is finally visible requires a large search space, e.g., the initial decision tree is relatively large. Thus, if it is impossible to propagate the fault effect to this output, a backtrack to a different output has to be performed.
- It is possible to use efficient forward propagation techniques (unique sensitization, dominators), which are well known in combinational test generation; in the reverse time processing of the BACK algorithm these techniques are of no use.

FIGURE 45.8 The BACK-algorithm.

FIGURE 45.9 The forward propagation, backward justification technique.

A characteristic of HITEC is that it selects the best observable signal for the fault propagation leaving all others in a stack for backtracking possibility. The main disadvantage of HITEC is:

- In HITEC a large decision tree is built during the propagation by selecting one fanout branch when arriving at a fanout stem for driving the fault effect to a primary output. Thus, many backtracks requiring large CPU time are needed for redundancy identification.

An advantage of HITEC is that it can handle more than one time frame at the same time during propagation, because value assignment in later time frames can be performed. This should result in reduced CPU time required for the test generation. The main disadvantage of this technique is that much memory space is required for multiple storing of time frames.

To overcome the disadvantages of BACK and HITEC, an efficient test generator using forward propagation backward justification technique (FOGBUSTER) was implemented. FOGBUSTER and the corresponding test generation tool SEMILET are described in the following sections.

## Test Generation Technique

In this subsection, the different phases of FOGBUSTER are described. The algorithm proceeds in three main phases of computation:

1. Forward propagation phase
2. Propagation justification phase
3. Justification phase

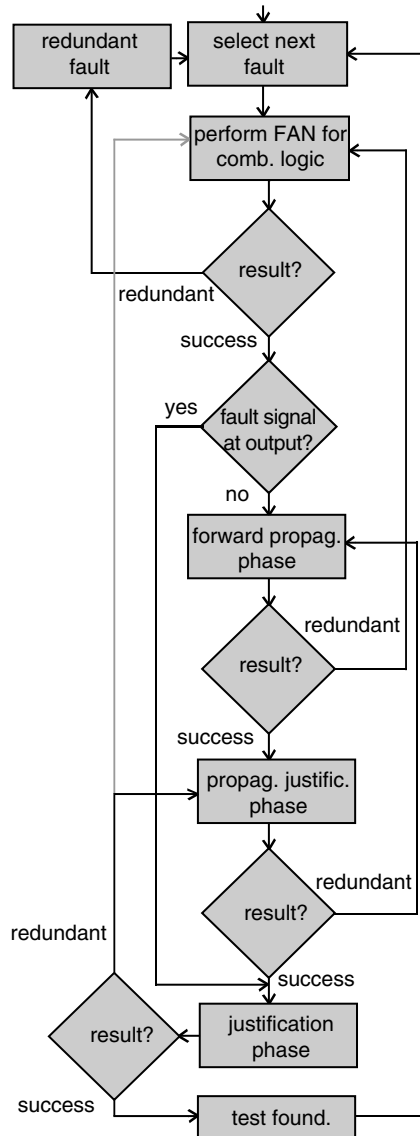

In the first phase the fault is transported to at least one primary output of the circuit. Efficient heuristics for fault propagation are used in this phase, for instance, *unique\_sensitisation* [1] with detection of dynamic dominators. In the second phase, the propagation path is justified, e.g., unjustified signals of the first phase, which are at the pseudo-outputs of the circuit, are justified. In the justification phase the initial state of the time frame of fault occurrence is confirmed, e.g., a synchronizing sequence for this state is computed.

If a fault is hard to detect, the computing time for finding a test pattern for this fault may be too large. To keep the computing time low, the maximal number of backtracks for one fault can be limited by the user. Hard faults are very often detected by a test pattern for a different fault. Therefore, after a test pattern for any fault is found, fault simulation for all remaining faults (which are not detected by any previous test pattern) of the test generation process is performed.

In [Fig. 45.10](#), a simple diagram of the FOGBUSTER algorithm is shown. After selecting a fault and executing fault injection, the combinational FAN is started to compute a combinational test pattern for this fault. In this part of test generation, combinational redundancies can directly be identified. If a combinational test pattern is generated, the fault effect may be visible at least at one primary output. In this case the justification phase is directly started from here on. Otherwise, the fault effect must be visible at least at one pseudo-output, e.g., at one storage element of the circuit, and one or more time frames are needed to propagate this fault effect to a primary output. Then the forward propagation phase has to be entered.

In the forward propagation phase, a pattern sequence is computed to make the fault effect visible at a primary output of the circuit. For each time frame in the fault propagation, the FAN-algorithm for a multi-fault model is called. A multi-fault model is needed in the FAN-algorithm because the good machine and the bad machine are possibly different at least at one pseudo-input and at the fault location. If there is no path for fault propagation to a primary output for the computed combinational pattern, e.g., the combinational pattern is redundant, a backtrack has to be performed to the combinational FAN-algorithm. If a pattern sequence propagating the fault effect to a primary output is found, the propagation phase terminates, and the propagation justification phase is started.

In the propagation justification phase, all remaining unjustified bound lines [1] (at the sequential elements) of the propagation phase are justified. If justification is not possible, a backtrack to the first

**FIGURE 45.10** The FOGBUSTER algorithm.

phase—the propagation phase—is performed. Otherwise, after termination the justification phase is started. In the justification phase a synchronizing sequence to the initial state (the state required after the propagation justification process) with respect to fault location is computed. This means that the good and the bad machine both must justify a required state. On termination of this third phase, a test pattern sequence for the selected fault is found. If there is no synchronizing sequence for the initial state, a backtrack to the propagation justification phase or to the combinational FAN algorithm (if no propagation was required after the combinational FAN execution) is performed.

The justification phase of the FOGBUSTER-algorithm is equal to the BACK-algorithm after reaching the fault location. The main differences in FOGBUSTER are the D-propagation through the time frames and the propagation justification. These functions are described in the following subsection.

FIGURE 45.11 An example circuit.

FIGURE 45.12 An example circuit.

## Fault Propagation and Propagation Justification

The fault propagation phase and the propagation justification phase are used to propagate a fault from the fault location to a primary output. The objective is to find an input-sequence resulting in a difference of at least one output of the good and the faulty machines, especially in the fault propagation phase where completeness of the algorithm can easily get lost. In HITEC completeness is guaranteed by the targeted D-front approach with optional decisions at every fanout of the circuit. In FOGBUSTER, as an alternative to the targeted D-front, the D-front is propagated through all fanout branches leaving a lower number of optional assignments. This method is motivated in Figs. 45.11 and 45.12 later in this subsection.

In each time frame the actual state is set to the pseudo-inputs of the circuit. The nonempty set of signals, which are on the propagation path, are added to the D-front [1], which is at any time built of the “end point signals” of all paths, transporting the fault effect in the multi-fault FAN-algorithm. The objective is to propagate the signals of the D-front until one output is included in the D-front, e.g., until the fault effect is visible at one output. The fault location is marked and added to the D-front, when a different value in the good machine is computed here. The multi-fault FAN terminates:

- If the D-front cannot be propagated through this time frame. A backtrack to the previous time frame has to be performed.
- If the D-front reaches a primary output. The propagation is finished and the propagation justification phase is started.
- If the D-front is completely propagated to pseudo-outputs (also partly dissolving of the D-front is possible). This is done because of two reasons. On one hand, for every pseudo-input, which is not included in the D-front by entering the time frame, the good and the faulty machine are equal. On the other hand, after reaching a pseudo-output of the circuit, a primary output and thus a

shorter test sequence could possibly be reached. If the propagation of the actual time frame would be stopped when reaching a pseudo-output, the completeness would also be lost. This will be illustrated later using Figs. 45.11 and 45.12.

In each time frame, some pseudo-inputs may have initial values X, because values here are not needed for fault propagation in the previous time frame. If these signals have value requirements in the actual time frame, they are marked as unjustified and prepared for justifying in the propagation justification phase. The latter has to be computed using reverse time processing.

In Fig. 45.11, a simple example circuit is shown.  $I_1$  and  $I_2$  are the prime inputs of the circuit and  $O_1$  and  $O_2$  are the prime outputs, respectively. Using the FOGBUSTER algorithm, two time frames are needed to generate a test for the stuck-at-0 fault at signal  $I_1$ . In the first time frame, the primary input  $I_1$  is set to “1” to initialize the fault and thus propagate the fault to the D-flip-flop FF1.

In the second time frame, the values of all pseudo-outputs of the first time frame of the circuit are assigned to the pseudo-inputs, thus the signal A is set to “1/0,” that means “1” in the good circuit and “0” in the faulty circuit. By using a simple implication the D-front consists of three signals, the fanout branches of A. Two of them are pseudo-outputs of the circuit, and the third signal of the D-front is at gate  $A_2$ . As the D-front has to be fully propagated, it is not possible to step to the next time frame in the test generation process. First, an optional assignment has to be performed at signal  $I_2$  to propagate the D-front completely. In our example,  $I_2$  is set to “1,” and by performing an implication the D-front changes. Now  $O_2$  is in the D-front, and thus the fault effect is propagated to a primary output of the circuit and the test pattern is generated.

Note that the assignment of signal  $I_2$  to “1” is an optional assignment. It is also possible that  $I_2$  was assigned to “0” instead. In this case the fault effect is not driven to the output  $O_2$ . Then, a third time frame has to be used with signals B and C in the initial D-front. As the fault effect cannot be propagated, neither to an output nor to a pseudo-output in the third time frame, a backtrack to the second time frame has to be performed. Thus, a backtrack is performed at  $I_2$  setting  $I_2$  to 1 and propagating the fault effect to the output  $O_2$ .

If the D-front was not completely propagated, the completeness of test generation would be lost. A completeness of algorithm means that for every testable fault, the algorithm can find a test pattern.

In Fig. 45.12 the effect of noncomplete D-front propagation is shown using the same example circuit. When the D-front reaches FF<sub>2</sub> and FF<sub>3</sub>, a direct step into time frame 3 is executed, with signals B and C in the D-front. After performing a simple implication, the D-front is empty, and thus a backtrack has to be performed. As there was no optional assignment in the test generation process up to here, there is no backtracking possibility and the fault is marked redundant, although, as seen in Fig. 45.11, it is testable.

## The Over Specification Problem in Sequential Test Generation

A main problem of test generation for sequential circuits is the over specification problem. This problem results from mapping the backtracking technique of combinational test generation to sequential test generation. At worst-case, this problem may result in losing completeness in test generation. Solutions of the problem are the consequent value model described in [5] and the use of a ternary decision tree described in [49], which both rely on increasing the logic used in the test generation. For completeness reason our algorithm uses the method described in [49].

## Detection of State Repetitions in Test Generation

To get a relatively short test sequence, state repetitions in the test sequence have to be avoided.

**Theorem:** *If a test sequence leading the good and the faulty machines to states  $q_1, \dots, q_i, \dots, q_j, \dots, q_r$ ,  $i, j, r \in \mathbb{N}$ ,  $1 < i < j < r$ , with  $q_i = q_j$  is a test for fault  $F$ , the test sequence leading the good and faulty machines to  $q_1, \dots, q_i, q_{j+1}, \dots, q_r$  is also a test for fault  $F$  [50].*

A corollary [50] of this theorem is that a synchronizing sequence leading to a defined state (all storage elements store 0 or 1) of all storage elements is upper bounded by  $3n - 2n$  ( $n$  is the number of storage elements in the circuit) assuming that there is no global reset possibility. The reason is that a 3-valued logic is used starting from the undefined state. With  $n$  storage elements, the number of states in the circuit is upper bounded to  $3n$ . Because no state repetition is allowed and the number of states where all storage elements have a defined state, is  $2n$ , the storage elements have a defined state after applying an input sequence with length at most  $3n - 2n$ . A second result is that all reachable states of the circuit can be reached by a sequence, which has a maximum length of  $3n$ .

Usually, the test generation results into a set of states after each considered time frame with  $2y$  elements,  $y$  is the number of  $x$ -values in the storage elements. For this reason, we use “set of states” instead of “state” as notation here.

To avoid long test sequences with state repetitions, SEMILET checks the propagation and the justification phases whether the actual set of states is a subset of a set of states, which occurred a number of time frames earlier in the test generation. For this purpose, the good and the faulty machines are considered during propagation while only the good machine is considered during justification. If the actual set of states is a subset of an earlier set of states, a backtrack to the previous time frame is performed and test generation is continued without loosing the completeness of the algorithm.

## Use of Global Set and Reset Signals in ATPG

If the circuits consist of global set and reset signals, test generation can take advantage of this. A global set signal effects that every flip-flop in the circuit is set to 1, and a global reset signal effects that every flip-flop is set to value 0. In the justification phase of the algorithm it is possible to make use of global set and reset signals:

- A set can be performed, if in the current state in ATPG there is no 0-requirement.
- A reset can be performed, if in the current state in ATPG there is no 1-requirement.

SEMILET can optionally use these features. The results with ISCAS-benchmark circuits in the subsection on “Experimental Results.” Table 45.8 shows that use of global set- and/or reset-signals results in increased fault coverage and/or decreased CPU time as expected.

## Experimental Results

The authors have developed SEMILET for test generation for synchronous sequential circuits. SEMILET makes use of the FOGBUSTER-algorithm and has mixed level capabilities like MILEF. In the actual state of implementation, SEMILET can handle 3 fault models:

- Stuck-at with overcurrent detection (mode 1)
- Stuck-at with state propagation (mode 2)

SEMILET is programmed in C++ with about 30,000 lines of code. It is prepared for sequential test generation with two levels of hierarchy, the switch-level and the gate-level (see also [9]).

The overcurrent techniques are reported in [23,24]. Generation of test patterns for overcurrent techniques is in general easier in comparison with the test generation, which needs propagation techniques. The authors found that, if a stuck-at test is required, in many cases it makes sense to generate IDDQ patterns and simulate them like “intelligent random patterns” in a first phase of test generation. For all the faults that are not detected by these patterns, a “normal” stuck-at test pattern set is computed. Thus the test generation mode 3 is done in two phases. Table 45.9 shows experimental results of SEMILET with fault model mode 1 in comparison with results of GENTEST [44] for some ISCAS ’89 benchmark [46] circuits. The times of GENEST, HITEC, and SEMILET were measured on a SUN 4/260. The efficiency is computed as follows:

$$\text{efficiency} = (\text{redundant faults} + \text{detected faults}) / \text{total number of faults}$$

\* No results known for this circuit.

\*\* Test generation was not called for, and all redundancies were detected in the preprocess.

\*\*\* Results were computed on a Convex C-200.

Looking at results of [Table 45.6](#), it is visible that SEMILET has almost the same fault coverage and performance in comparison with GENTEST for IDDQ models. For some of the circuits (s344, s349, s838) SEMILET is a bit faster and for other circuits (s400, s713) SEMILET is a bit slower than GENTEST. This result was theoretically expected because only justification is used for computing test patterns for overcurrent related fault models since no fault propagation is required. Fault justification in FOGBUSTER is equal to fault justification in BACK.

[Table 45.7](#) shows the stuck-at performance of SEMILET in comparison with HITEC and GENTEST. It is shown that the fault coverage of all approaches is equal (exception: for s344 the fault coverage of HITEC is a bit worse). In most cases the test generation time required for SEMILET was smaller in comparison with HITEC (except s386). The test generation times for GENTEST were sometimes a bit smaller (s344, s349, s641) but sometimes much larger (s298, s386, s713, s5378) than the SEMILET times.

**TABLE 45.8** Performance of SEMILET with and without Possibilities of Global Setting and Resetting (Stuck-at Patterns) Mode 3, CPU Times Computed on a Sparc10

Circuit	Without Possibility of Setting and Resetting		With Possibility of Setting and Resetting	
	Fault coverage (%)	CPU Time/s	Fault Coverage (%)	CPU Time/s
s208	63.7	3	78.1	17
s298	85.7	142	87.7	106
s344	96.2	257	99.4	56
s349	95.7	251	96.2	114
s386	81.8	32	81.8	21
s420	41.6	112	58.8	237
s510	0	0	100	109
s641	86.5	6	94.4	55
s713	81.9	7	87.6	74
s1196	99.8	13	99.8	9
s1238	94.7	23	94.7	13
s5378	74.0	9042	74.9	6105
s9234	0.3	4	6.3	22652

**TABLE 45.9** Comparison between Test Generation Phases in SEMILET

Circuit	CPU Time/s	Percentage Prop. (%)	Percentage Prop-Just. (%)	Percentage Just. (%)
s208	3	15.8	16.5	67.7
s298	142	16.7	55.2	28.1
s344	257	10.0	19.5	70.5
s349	251	7.4	17.4	75.2
s386	32	5.6	5.6	88.8
s420	112	9.0	29.6	61.4
s641	6	7.1	4.7	88.2
s713	7	10.8	6.7	82.5
s1196	13	11.5	13.8	74.7
s1238	23	21.7	10.0	68.3
s5378	9042	7.6	14.8	77.6
s9234	4	1.5	0	98.5

In many cases, it was measured in the experiments that if one of the test pattern generators HITEC or GENTEST is a bit faster than SEMILET the other test pattern generator is much slower (example: s344, s349, s386...). Thus, SEMILET had much better results than HITEC and GENTEST in the average. In the s510, no test pattern generation and fault simulation was necessary for SEMILET because all untestable faults could be identified in the preprocessing phase of the test generator.

In Table 45.8, “normal” test generation for the circuits is shown in comparison with test generation when using global set and reset signals in the circuit. For circuits that consist of noninitializable storage elements, the fault coverage increases rapidly. For instance, the s510 is completely untestable without use of global initialization, and by applying a global set and reset signal to all flip-flops it is completely testable. The stuck-at fault model was used for test generation here. The use of global set and reset signals results in increased fault coverage at reduced testing time. The fault coverage increased for s510 and s420. The testing time was reduced for s344 and s5378.

Table 45.9 shows the percentage of computation time in the three different phases of the algorithm. Most of the time was spent in the justification phase for almost all experiments (exception s298). This result is consistent with the HITEC analysis in [51].

## 45.4 Summary

---

Automatic test pattern generation yielding high fault coverage for CMOS circuits has received wide attention in industry and academia for a long time. Mixed-level test pattern generation offers advantages, since test generation from gate-level netlists has shortcomings regarding fault coverage in complex CMOS gates. A switch-level approach relying on the transistor structure only is too slow and impractical for larger circuits. The first part of this chapter describes automatic test pattern generation with a mixed switch-level and gate-level approach. It combines acceptable performance for large networks with a high fault coverage also for nontrivial transistor networks. Patterns generated this way are inherently capable to detect stuck-open faults and transition faults as well as various other fault models on different abstraction levels. In combination with local overcurrent detectors, also stuck-on and local bridging faults can be identified. To increase the efficiency of mixed-level test generation, a reconvergence analysis is performed and constraints are stored.

An original approach to test generation for synchronous sequential circuits was presented. Two levels of hierarchy, the switch-level and the gate-level are supported. Inter-level backtracks between these two hierarchies are implemented. The number of inter-level backtracks is minimized using simple heuristics for constraint identification, which is a promising method for hierarchical test generation also on higher levels (RT or behavior level). A new efficient algorithm called FOGBUSTER for the forward propagation backward initialization technique handles synchronous sequential circuits. A 4-valued logic and a two-staged backtracking mechanism are used to handle the over-specification problem and to achieve completeness. Experimental results for the ISCAS '85 and ISCAS '89 benchmark circuits are encouraging. In comparison to the BACK-algorithm and to the HITEC approach, FOGBUSTER on the average has a significantly better performance.

### 46.1 Introduction

---

Given a design under test (DUT), a *test solution* is qualified as *efficient* if it allows the generation of test patterns, which enable the detection of most of possible physical faults that may occur in the design. Researchers talk about 99% of fault coverage and more. To reach such a test efficiency, the cost to pay is related to time which is necessary for test pattern generation and application, the area overhead for the added logic, the added number of pins, etc. These parameters are concerned through scan testing techniques, which are presented in the next section.

Some studies have shown that the testing phase can constitute a serious problem in the overall production time. For typical circuits, testing can take from the one-third to the half of the total time to market (TTM) [1]. In [2], it has been shown that a design-for-testability (DFT) technique such as full scan can reduce by more than a half the total engineering costs. Indeed, scan helps in detecting a fault quickly and in an efficient manner.

As shown in [Fig. 46.1](#) the well-known “rule of ten” is true when scan is considered. Indeed, sooner a fault is detected the lower is the subsequent cost. This is explained by the fact that DFT helps in the generation of efficient test patterns. In other words, given in a short period of time, if a fault appears in a DFT-based design, a high probability exists to detect the fault. Furthermore, a DFT technique such as scan helps in the testing through the whole life cycle of the design including debug, production testing, and maintenance.

### 46.2 Scan Testing

---

Today, given strong time to market constraints on new products, only DFT is capable of ensuring the design of complex system-on-chips with a high testing quality. Scan is widely used in industry. It took almost 20 years to reach such a maturity, even if some designers still think that scan penalizes a design due to the required cost and performance degradation.

Scan testing is applied to sequential testing, i.e., testing of sequential designs. It relates to the ability of shifting data in and out of all sequential states. Regardless to the used scan approach, all flip-flops are interconnected into one or more shift registers that ensures the shifting in and the shifting out functions. The built shift register is fully controlled/observed from primary inputs/outputs as shown in [Fig. 46.2](#) [3].

\$ 0 , 0 1 - \$ 0 , 1	Wafer
\$ 0 , 1 - \$ 1	Integrated circuit
\$ 1 - \$ 1 0	Printed Circuit Board
\$ 1 0 - \$ 1 0 0	System
\$ 1 0 0 - \$ 1 0 0 0	Network

FIGURE 46.1 Rule of ten in testing economics.

FIGURE 46.2 Sequential scan.

Hence, scan testing transforms the testing problem of a sequential design into a testing of a combinational design. The problem of testing combinational circuits problem is easier since classical test generation algorithms are more efficient (better testing results which mean an obtained fault coverage close to 100%). In fact, it is well known that the number of feedback cycles in a circuit can increase the complexity of sequential test generation. It is important to notice that the built shift register need to be tested too.

However, when scan is considered, the price to pay is related to the following parameters: logic overhead, which means more space, degradation of the production yield and the design performance since more logic is added to the original one, design effort, and usually more pins. As shown in Fig. 46.2, the “register” built on the flip-flops or the design memory cells is transformed into a *scannable* shift register (S-register). The complexity of the obtained register is more important since each memory cell might be used in both normal and test modes. This requires at least a *multiplexor* at each cell level and some additional wiring. As shown in the same figure, the normal and the test modes are controlled by the added input “Test.”

One of the drawbacks when scan is used is the necessary time for scan-in (downloading test patterns) and scan-out (getting test results) operations. If the DUT includes thousands of memory cells, which is the case of nowadays integrated circuits (ICs), only one scan chain means shifting all test data serially through the whole “S-register.” This is usually too long even if the frequency of the clock “Clk” is reasonably high. Dividing a scan chain into several scan chains is a good issue. Figures 46.3 and 46.4 illustrate each of the two concepts where one or several *scan paths* (called also *scan chains*) are considered. An example of a PCB (printed circuit board) of six ICs is considered.

To test this PCB, instead of using one scan chain as shown in Fig. 46.3, three scan chains are considered as illustrated in Fig. 46.4. It is noteworthy that more pins are required to allow the parallel use of the scan chains: three for scan-in and three for scan-out operations. In this case, two test pins are necessary for each scan path.

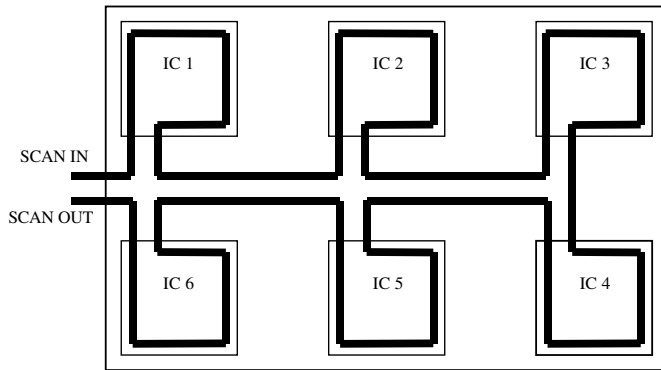

FIGURE 46.3 Scan architecture with a single path.

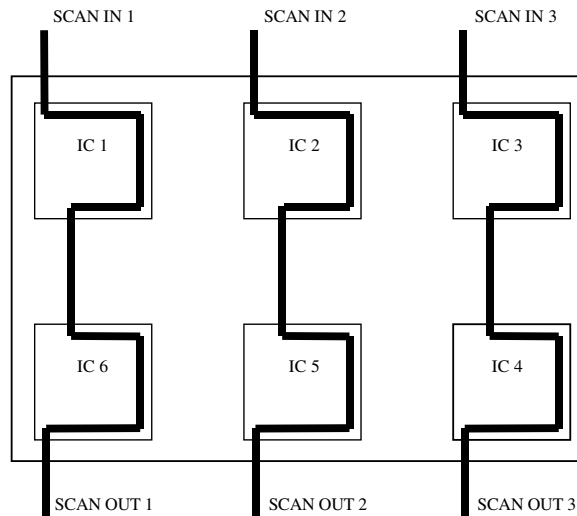

FIGURE 46.4 Scan architecture with several scan chains.

## Boundary Scan

As a widely used scan technique, boundary-scan (BS) provides an access to internal structures (blocks, IC, etc.) knowing that few logic is directly accessible from primary inputs and primary outputs. Probably one of the famous scan approaches is BS through the ANSI/IEEE 1149.1 standard. This standard is also known as JTAG (Join Action Test Group). A decade earlier, a group of test experts from industry and academia worked together in order to propose standardized protocols and architectures that help in the dissemination of the BS technique.

Given a DUT such as a PCB, BS consists of as a first step in making each input and output of a circuit as a memory element. Given all memory elements, the next step consists in linking all memory elements into a register called BS register. The access to this mandatory register is possible from four standard pins. Finally, in order to be conform with the boundary scan standard ANSI/IEEE Std. 1149.1, a controller called TAP (Test Access Port) and a set of registers are implemented within each circuit. This is shown in Fig. 46.5.

The BS register is mandatory in a JTAG compliant architecture. Figure 46.6 gives an example of a BS cell. Such a cell can be used as either an input or as an output cell. Such a cell supports four functional modes: normal mode (when  $Mode\_Control = 0$ ), where the BS cell is transparent during the normal use

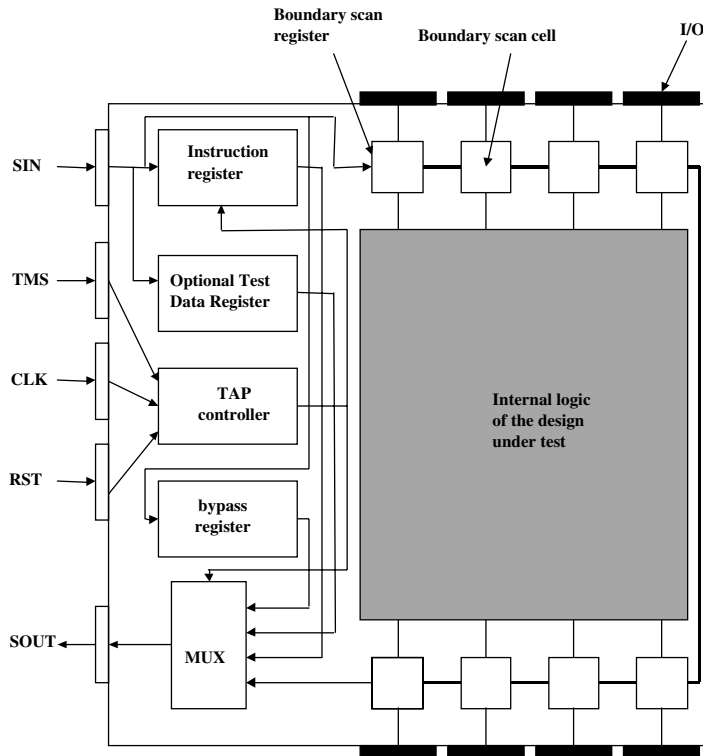

FIGURE 46.5 Overview of the ANSI/IEEE 1149.1 architecture.

FIGURE 46.6 A BS cell.

of the DUT. In the second mode called scan mode, all BS cells are connected into a BS chain. In this mode  $ShiftDR = 1$  and the necessary clock pulses are applied. The third mode is the capture mode where data are loaded through the input IN into the scan path. In this mode,  $ShiftDR = 0$  and one clock pulse  $ClockDR$  is applied. The QA flip-flop serves as a snapshot cell. The final mode is called update mode. In this mode,  $Mode\_Control = 1$  and one pulse of the  $UpdateDR$  is activated.

These four functioning modes allow each of the instructions summarized below to be executed.

The main motivation for this standard is to overcome the problem of physical access to circuits that becomes more and more difficult. JTAG overcomes the need of bed-of-nails fixtures with a very fine resolution, if available.

As shown in Fig. 46.6, the BS architecture includes the following blocks:

- *TAP controller*: This block generates all clocks and signals that are necessary for the architecture.
- *Instruction register*: This register holds the instruction, which is related to the test that needs to be executed.

- *Test data register*: These registers hold test patterns that need to be run on the test logic. A specific register scanned BS register is mandatory; however, other registers can be added if necessary.

Based on the BS architecture, several tests can be executed: test logic, internal logic, and interconnection:

- *Test logic*: Before running the test of the circuit under test, the test logic must be checked through specific states of the TAP controller that can be used for that.
- *Internal logic testing*: This is ensured through the use of the specific instruction called *intest* presented below. Testing the internal test logic of a DUT means that each DUT block can be tested.
- *Interconnection testing*: It is related to the test of interconnection between two blocks. As summarized in the next paragraph, a specific instruction called *extest* is used.

The JTAG standard enables the application of several kinds of tests. This is summarized in the instructions proposed by the standard. These instructions are executed by the TAP controller. As explained in the following list, some of these instructions are mandatory and some are optional.

- *Bypass*: It is mandatory. This instruction allows a specific DUT to be tested by bypassing one or more other designs.
- *Extest*: This mandatory instruction allows the test of interconnection between two DUT. It is especially useful in the case of *integration testing*.
- *Intest*: This instruction is optional. It can be used to test the internal logic, a block, or a circuit.
- *Sample/Preload*: This instruction is mandatory. It helps in taking snapshots of useful data that run during normal operation of the DUT.
- *Icode and Usercode*: These two instructions are optional. They allow the access to a specific register known as the device-identification register.
- *RUNBIST*: This optional instruction allows the running of a BIST (built-in-self test) solution by using the TAP controller. BIST is explained later.

For more details regarding these instructions, please refer to [12].

## Partial Scan

The scan approach presented above is also called full scan because the built scan chain includes all the DUT memory elements; however, this might be costly for complex ICs where the number of memory elements exceeds thousands of cells. By cost, it is meant the area overhead that results from full scan (added multiplexors, wiring, pins, etc.), the performance degradation due to signal slowdown and test time due to very large scan chains. For a better trade-off performance/cost, a scan technique called partial scan is proposed [11]. Only a subset of memory elements are included in the considered scan chain. This decreases both the area overhead and the timing penalty.

The problem of partial scan is still open. No technique proposes how to effectively determine the appropriate subset of flip-flops to be scanned. Indeed, an effective partial scan technique is the one that selects the fewest flip-flops in the scan chain while achieving both a high fault coverage and an optimized physical design.

Knowing that DUT is modeled by a system graph called S-graph, the partial scan problem consists in finding the minimal feedback vertex set (MFSV). This is known as an NP-complete problem [4]. In an S-graph, the vertices are the DUT registers and the edges represent a combinational path from one register to another.

The proposed solutions are some heuristics, which are based on the following techniques: testability analysis, structural analysis, or test pattern generation. A testability analysis-based technique consists in predicting through measures of the problems faced during test pattern generation. The concept through structural analysis is some heuristics that try to break feedback cycles. Finally, when the selected flip-flops are based on test pattern generation (TPG), it generally means that a TPG program is used to

FIGURE 46.7 Example of merging scan and BIST.

generate tests for every fault and then the test patterns, which are selected, are those which necessitate the fewest number of flip-flops that are scanned.

## Scan and Built-in Test Solutions

A scan design can serve as a support for a complete built-in-test solution. Indeed, as assumed earlier (see Fig. 46.2), test patterns are supposed to be generated from outside and applied through the *Sin* pin. Furthermore, it is assumed that test results are scanned out through the *Sout* pin and compared one by one to the test results of a golden circuit. A *golden* circuit is a circuit, which is assumed to be fault-free.

A scan-based design can be used in order to implement both test pattern generation and test result verification functions within the DUT. Built-in-Self-Test (BIST) is a design-for-testability technique in which testing (test generation and test application) is accomplished through built-in hardware features [5–6]. When testing is built as a hardware it is very fast and very efficient.

The example in Fig. 46.7 shows how a basic scan design is considered for a BIST solution. The LFSR (linear feedback shift register) is used as an example of a test pattern generator. Pseudo-random test patterns, which can be very efficient in case of sequential designs, are generated using such a structure. For test results verification, a LFSR is used to compress test results and produce a signature which will represent the obtained test results.

## Tools and Languages for Scan Automation

Today, several CAD vendors include BS in their DFT test tool (Mentor Graphics, Teradyne, Jtag Technologies, Logic Vision, etc.). Tools which are available in the market propose scan testing solutions. The main functions that are proposed by such tools are: scan design rules checking, scan conversion, and the associated test pattern generation.

Through the IEEE standard 1149.1-1990, the BS technology is more and more embraced in electronic systems at several hierarchical levels: ICs, boards, subsystems, and systems. One of the key points that has helped in that is the availability of tools and languages that support such a technology. A subset of VHDL was proposed for this purpose [13]. The language is called BSDL (boundary scan description language). When a new standard is proposed many barriers may slow down its adoption. BSDL was proposed in order to speed up the implementation of the “dot one” standard through BSDL-based tools. This language helps in the description and the checking of the compliance of a design with BS technology. More precisely, BSDL helps in the implementation of testability features, which are related to the “dot one” technology. Hence, necessary simulation and verification of the BS technology can be performed. More precisely, testing if a DUT is compliant with the “dot one” technology means that devices that are mandatory to be implemented are checked. For example, the parameters that related to the TAP controller and the boundary scan register are described and checked out through such a language. Furthermore, BSDL serves as a support for IC vendors to automatically add BS logic through all design process of the design.

More information about BSDL can be found in [13].

# 46.3 Future of Scan: A Brief Forecast

## Scan for Analog and Mixed Designs

Boundary-scan was originally developed for digital circuits and systems. The motivations to use BS for analog designs is also true; however, in contrast to digital circuits and systems, analog components are specified by a continuous range of parameters rather than binary values 0 and 1. A new standard is coming called P1149.4. It consists in the development of a mixed signal test bus. The aim is to standardize to several possible tests in the case of analog DUT: interconnect test, parametric test, and internal test. Such tests should be fully compatible with the IEEE 1149.1 standard and helps in measuring the values of discrete components such as pull-up resistors and capacitors. Consequently, P1149.4 can be seen as an extension of IEEE 1149.1 where the BS cells presented above are replaced by analog boundary modules (ABM) at the level of each analog functional pin. Such pins can be accessed via internal analog test bus. Fig. 46.8 gives the structure of the P1149.4 bus.

As IEEE 1149.1 has proven its efficiency, P1149.4 is most likely a good DFT solution for analog circuits and systems. Furthermore, its compatibility with the IEEE 1149.1 will simplify the test of mixed DUT.

For more details regarding the standard, please refer to [7].

## RTL and Behavioral Scan

Scan techniques that have been presented until now have several drawbacks. First, they are highly related to the used design tools and target libraries. Moreover, in case of highly complex DUT, a high computation time is required because low-level descriptions (gate-level or lower) are considered. Furthermore, the added logic does not take advantage of the global *optimization* of the design, which can be performed by the used synthesis tools.

Recently, several techniques that improve the testability using high level descriptions [8-10], have been proposed. For example in [9], a technique which inserts a partial scan using the B-VHDL (behavioral VHDL) description has been presented. In [10], a technique that allows scan to be inserted at the B-VHDL description of a DUT has been presented. This has many advantages. The scan insertion problem is considered very early in the design process, which means that a fully testable design can be provided at the behavioral level, i.e., before any structural information is known. Compared to approaches that may include scan at the RTL or the logical level, inserting scan at the behavioral level is very promising since it takes fully advantage of design validation and test generation tools that might operate at the

FIGURE 46.8 Structure of the P1149.4 bus.

FIGURE 46.9 Low-level scan.

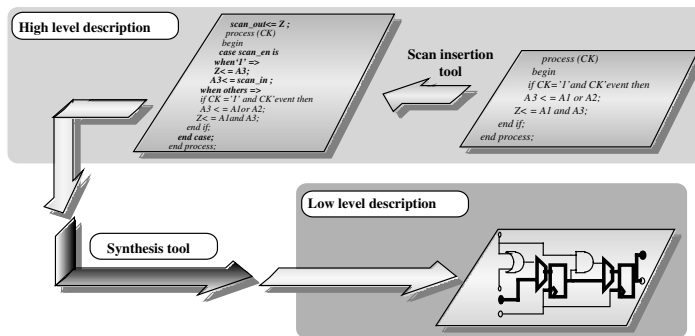

FIGURE 46.10 High-level scan.

behavioral level. Furthermore, the testable description can be synthesized using several libraries and tools. The testable design is consequently more *portable*. Moreover, when a scan chain is inserted at the high level of the DUT, the added logic used for the test is globally compiled and optimized during the synthesis process, which reduces the area overhead.

Fig. 46.9 shows the classical approach of scan insertion. Fig. 46.10 shows how scan can be inserted before the synthesis is performed.

To insert a scan register at a behavioral level (high-level scan), memory elements of the DUT need to be known. In fact, the scan insertion process is made up of two basic steps. First, memory elements are located. Then, the behavioral description of the design is modified in order to describe the behavior of the scan register.

Such a new scan insertion approach necessitates the development of the related tools. *Hiscan* (high-level scan) is a tool that allows scan insertion at the B-VHDL level. Given a synthesizable B-VHDL description, *Hiscan* generates a VIF (VHDL intermediate format) file, which contains necessary information of objects (signals and variables). *Hiscan* uses the VIF file to locate objects that correspond to memory elements once the synthesis is accomplished. Before constructing a B-VHDL scan chain, *Hiscan* considers constraints which can be used in the selection of the detected memory elements. Typically, constraints are related to testability measures at the B-VHDL level or ATPG-based constraints or both. During the last step, *Hiscan* generates a B-VHDL scannable description, which is ready for synthesis.

Given several examples of benchmarks, such a high-level scan insertion approach was shown efficient since the cost of inserting a scan design is significantly reduced when compared to classical scan techniques that operate at a low-level design. Please refer to [10] for more details.

### 47.1 Introduction

---

Yield is one of the cornerstones of a successful integrated circuit (IC) manufacturing technology along with product performance and cost. Many factors contribute to the achievement of high yield but also interact with product performance and cost. A fundamental understanding of yield limitations enables the up-front achievement of this technology goal through circuit and layout design, device design, materials choices, and process optimization. Defect, failure, and yield analyses are critical issues for the improvement of IC yield. Finally, the yield improvement is essential to success.

The coordination of people in many disciplines is needed in order to achieve high IC yield. Therefore, each needs to understand the impact of their choices and methods on this important technology goal. Unfortunately, very little formal university training exists in the area of IC yield. This chapter is intended to bring students, engineers, and scientists up to speed and enable them to function knowledgeably in this area.

Section 47.2 deals with IC yield and critical area models. Section 47.3 is dedicated to a local extraction approach for the extraction of IC critical areas. Finally, Section 47.4 presents an application of previously mentioned models and extraction approach in yield forecast.

### 47.2 Yield Models

---

This section is dedicated to IC yield analysis and modeling. Yield analysis includes the discussion of methods, models, and parameters for detecting which technology and design attributes are really yield relevant. Yield modeling mathematically expresses the dependence of yield on IC process defect characteristics and design attributes. Thus, correct yield models are essential for meaningful yield and cost projections.

Figure 47.1 Defect clustering on semiconductor wafer.

This section describes a macroscopic approach to yield analysis and corresponding functional yield models and yield parameters.

## Classical Yield Models

Functional yield is the probability of zero catastrophic (fatal) defects. Catastrophic defects are defects that result in primitive electrical failures and, consequently, yield loss. Therefore, the yield is derived from Poisson's equation as follow [1]:

$$Y = \exp(-AD) \quad (47.1)$$

where  $A$  is the area sensitive to defects (so-called critical area) [2–7] and  $D$  is the defect density.

However, the simple Poisson yield formula is too pessimistic for IC chips on a wafer, because defects are often not randomly distributed, but rather are clustered in certain regions (Fig. 47.1). Defect clustering can cause large areas of a wafer to have fewer defects than a random distribution, such as the Poisson model, would predict, which in turn results in higher yields in those areas. Therefore, to tackle this nonrandom defect distribution, instead of using a constant defect density, Murphy introduced compound Poisson statistics [8]. The Poisson distribution is compounded with a function  $g(D)$ , which represents the normalized distribution of defect densities:

$$Y = \int_0^{\infty} \exp(-AD)g(D)dD \quad (47.2)$$

The function  $g(D)$  is a weighting function that accounts for the nonrandom distribution of defects.

A number of distribution functions can be used to approximate the defect density distribution and analyze IC yield. Five of these are given below (Fig. 47.2) and corresponding yield models are described.

### Poisson Model

When defects are randomly and uniformly distributed over the wafer, the wafer defect statistics can be characterized by a constant  $\bar{D}$ , which is the average defect density. Therefore,  $g(D)$  is a delta function centered at  $D = \bar{D}$ , resulting in the simple Poisson distribution and the yield given by

$$Y = \exp(-A\bar{D}) \quad (47.3)$$

FIGURE 47.2 Distribution functions for approximation of defect density distribution.

### Murphy's Model

The most preferred distribution function was a Gaussian; however, a Gaussian distribution gets difficult for integration most of the time. In order to carry out the integration in an easier way, Murphy [8] proposed using a symmetrical triangle weighting function for an approximation to a Gaussian distribution. Substituting this into formula (47.2) gives

$$Y = \left[ \frac{1 - \exp(-A\bar{D})}{A\bar{D}} \right]^2 \quad (47.4)$$

Murphy [8] also used a rectangle distribution function to represent the defect density distribution. This distribution function is constant between zero and  $2\bar{D}$ , and zero elsewhere. The meaning of this function, physically, implies that chip defect densities are evenly distributed up to  $2\bar{D}$ , but none have a higher value. Using the rectangle distribution function in Murphy's yield integral, we get

$$Y = \frac{1 - \exp(-2A\bar{D})}{2A\bar{D}} \quad (47.5)$$

### Price's Model

Price [9] applied an exponential distribution function to approximate the defect density distribution. The decaying form of the exponential function implies that higher defect densities are increasingly unlikely. Physically, this means that high defect densities are restricted to small regions of a wafer. The exponential distribution function can be used to represent severe clustering in small regions of a wafer. The resulting yield formula for this distribution function is as follow:

$$Y = \frac{1}{1 + A\bar{D}} \quad (47.6)$$

### Stapper's Model

Stapper [10] used a Gamma distribution, which led to the following yield formula

$$Y = \left[ 1 + \frac{A\sigma^2}{\bar{D}} \right]^{-\bar{D}^2/\sigma^2} \quad (47.7)$$

where  $\sigma^2$  is the variance of Gamma distribution function. The parameter  $\bar{D}^2/\sigma^2$  can be used to account for *defect clustering*. By varying this parameter, the model covers the entire range of yield predictions. The larger variance means more clustering of defects. If the parameter is equal to 1, this yield model reduces to the Price formula (exponential weighting). On the contrary, for  $\sigma^2 = 0$ , it becomes the Poisson formula (no clustering). The value of the clustering parameter must be experimentally determined. The smaller values reflect higher yield and occur with maturity of technology.

## Yield Distribution Model

Much work has been done in the field of yield modeling [11–30] and many results can be applied in yield analysis; however, there is too much indistinctness in a modeling approach and too many disputes about the correct model [16,17,19,23,24]. It appears that the main stumbling block was identification of the yield defined as a probability of failure-free IC chip (the chip yield) with the yield defined as a ratio between the number of failure-free chips  $n$  and the total number of chips  $N$  on a wafer (the wafer yield). There is a major difference between these two quantities: the chip yield is a probability and can be expressed by a number between 0 and 1, while the wafer yield is a stochastic variable and should be expressed by its distribution function.

The final goal of yield modeling must be to predict the wafer yield, so as to enable comparison with the production yield data. The authors have proposed a yield model that does not require any defect density distribution function but is completely based on the test chip yield measurement and can predict the wafer yield as a distribution [31].

## Chip Yield

Using corresponding in-line measurements of the test chip yields  $Y_{ti}$ , defined as a ratio between the number of failure-free test chips and the total number of test chips in a given wafer area, the IC chip yield, associated with the  $i$ th critical process step, can be directly predicted. A typical test chip containing MOS capacitors, diodes, transistors, long conducting lines, and chains of contacts is shown in Fig.47.3. The IC chip yield will differ from the test chip yield due to the difference in the critical area. So, if a ratio between the IC chip and test chip critical areas is given by  $A_{ci}/A_{ti}$  and the wafer area can be divided into  $m$  subareas with approximately uniform distribution of defects, the IC chip yield can be determined by [14,31]

$$Y_{cil} = Y_{til}^{A_{ci}/A_{ti}} \quad (47.8)$$

where  $l$  denotes the corresponding subarea. If a control wafer area has been divided into subareas in the same way for each critical process step, the final IC chip yield is given by

$$Y_{cl} = \prod_{i=1}^k Y_{cil} \quad \text{for } l = 1, 2, \dots, m \quad (47.9)$$

FIGURE 47.3 Test chip containing test structures.

where  $k$  is the total number of critical process steps, i.e., the total number of yield loss mechanisms; however, the chip yield is not enough for complete yield characterization, and the wafer yield  $Y_i$  should be predicted as well.

### Wafer Yield

As far as only  $i$ th critical process step is considered, there is no need to explore the very yield distribution function, but it is enough to determine its parameters: the mean and variance. The parameters of wafer yield distribution function are given by [31]

$$\bar{Y}_i = \sum_{l=1}^m C_{il} Y_{cil} \quad (47.10)$$

$$\sigma_{Y_i}^2 = \frac{1}{N} \sum_{l=1}^m C_{il} Y_{cil} (1 - Y_{cil}) \quad (47.11)$$

where  $C_{il}$  is equal to  $l$ th subarea divided by the total wafer area. At the end, the final wafer yield should be modeled as well. It is obvious that parameters of the final wafer yield distribution can be calculated by [31]

$$\bar{Y} = \sum_{l=1}^m C_l Y_{cl} \quad (47.12)$$

$$\sigma_Y^2 = \frac{1}{N} \sum_{l=1}^m C_l Y_{cl} (1 - Y_{cl}) \quad (47.13)$$

In the most complex case, summations should be done for each IC chip from the wafer separately, with  $C_{il} = 1/N$ ; however, when there is a large number of chips on a wafer, this procedure is too cumbersome and the following approximations can be used:

$$\bar{Y} = \prod_{i=1}^k \bar{Y}_i \quad (47.14)$$

$$\sigma_Y^2 = \prod_{i=1}^k (\sigma_{Y_i}^2 + \bar{Y}_i^2) - \left( \prod_{i=1}^k \bar{Y}_i \right)^2 \quad (47.15)$$

The wafer yield distribution itself can be obtained by Monte Carlo simulation [12], with a simulation cycle consisting of:

- calculation of the final chip yield of each chip (Eq. (47.9)),
- decision of acceptance or rejection for each chip using a uniform pseudo-random number, and
- adding up of the number of failure-free chips on a wafer.

In some specific cases, the distribution of wafer yield can be approximated by known distribution functions. For example, if the total number of chips on a wafer is large ( $N > 30$ ), a Gaussian (normal) distribution function can be used as an approximation:

$$f(Y) = \frac{1}{\sqrt{2\pi}\sigma_Y} \exp\left(-\frac{(Y - \bar{Y})^2}{2\sigma_Y^2}\right) \quad (47.16)$$

FIGURE 47.4 Point and lithographic defects in IC chip.

This distribution function cannot be used when the chip size increase is not accompanied by corresponding increase of the wafer size, and the total number of chips on a wafer is small. Then we can apply for approximation a binomial distribution function given by

$$f\left(Y = \frac{n}{N}\right) = \binom{N}{n} Y_c^n (1 - Y_c)^{N-n} \quad (47.17)$$

where  $Y_c$  is the value of final chip yield calculated by expression (47.9). Because of the small number of chips on a wafer, the clustering of defects cannot be recognized and the values of final chip yields  $Y_d$  are very close to each other.

## Critical Area Models

Yield models generally require the estimation of IC critical area associated with each type of catastrophic defects, i.e., each type of primitive failures. Examples of the defects include point defects (pinholes in insulator layers, dislocations, etc.) and lithographic defects (spots on IC chip). Some of these defects are shown in Fig. 47.4.

### Critical Area for Point Defects

Two most significant types of primitive failures in ICs related to their layer structure are a vertical short of two horizontal conducting layers through oxide (caused by a pinhole) and a leakage current increase (due to defects of silicon crystal lattice in the depletion region of p-n junction). The critical area for both of them can be defined as an overlap area of layout patterns from different IC conducting layers (silicon, polysilicon, or metal), i.e., IC mask layers [32]. Consider a domain shown in Fig. 47.5, where two layout patterns from two different mask layers are overlapping. If  $(x_1, y_1)$  and  $(x_2, y_2)$  denote canonical coordinates of overlap area, an overlap area  $A_l$  is given by

$$A_l = (x_2 - x_1)(y_2 - y_1) \quad (47.18)$$

In the case of defects in the depletion region of p-n junction, it is needed to calculate a vertical part of overlap area  $A_v$  as well. The following expression is used for this calculation:

$$A_v = 2z[(x_2 - x_1) + (y_2 - y_1)] \quad (47.19)$$

where  $z$  is the depth of p-n junction. The total critical area for point defects  $A_p$  is equal to a sum of the lateral part  $A_l$  and the vertical part  $A_v$ .

FIGURE 47.5 Definition of IC critical area for point defects.

 \end{aligned}$$

$$\begin{aligned}
 AB &= x - w; \quad GA = GC = \sin\alpha \cdot x/2; \quad GE = \cos\alpha \cdot x/2 \\
 CD &= CE = x/2; \quad DF = w/2; \quad |CF|^2 = x^2/4 - w^2/4 \\
 |2GA|^2 &= |AC|^2 = \frac{(x-w)^2}{4} + \frac{x^2}{4} - \frac{w^2}{4} = \frac{x(x-w)}{2}
 \end{aligned}$$

FIGURE 47.6 Definition of IC critical area for lithographic defects.

### Critical Area for Lithographic Defects

Lithographic defects are extra and missing material spots on IC caused by particles and mask defects. The sizes of these defects are comparable to critical dimensions of IC layout patterns and, therefore, they can result in short and open circuits. The critical area for both of them can be defined as an area in which the center of a defect must fall to cause one of these failures. If the assumption of circular defects is valid, the critical area is a function of the defect diameter  $x$ . Consider the examples shown in Fig. 47.6. An example in Fig. 47.6(a) shows two geometrical objects of a circuit layout from the same mask layer

and the equivalent critical area for shortening them. Moreover, an example in Fig. 47.6(b) shows a geometrical object of a circuit layout and the equivalent critical area for opening it. We have proposed the following expression [33]:

$$A_s^o(x) = \frac{x-s}{8} \sqrt{x^2-s^2} + \frac{x^2}{4} \left( \arcsin \sqrt{\frac{x-s}{2x}} - \sqrt{\frac{x-s}{2x}} \cos \arcsin \sqrt{\frac{x-s}{2x}} \right) \quad (47.20)$$

for the definition of the circular part of the critical area for shortening two geometrical objects, and the expression [33]:

$$A_o^o(x) = \frac{x-w}{8} \sqrt{x^2-w^2} + \frac{x^2}{4} \left( \arcsin \sqrt{\frac{x-w}{2x}} - \sqrt{\frac{x-w}{2x}} \cos \arcsin \sqrt{\frac{x-w}{2x}} \right) \quad (47.21)$$

for the definition of the circular part of the critical area for opening a geometrical object, where  $x$  is the defect diameter,  $s$  is the spacing between objects,  $w$  is the width of an object, and  $x \geq s, w$ . The total critical areas can be calculated by

$$A_s(x) = L(x-s) + \frac{x-s}{2} \sqrt{x^2-s^2} + x^2 \left( \arcsin \sqrt{\frac{x-s}{2x}} - \sqrt{\frac{x-s}{2x}} \cos \arcsin \sqrt{\frac{x-s}{2x}} \right) \quad (47.22)$$

$$A_o(x) = L(x-w) + \frac{x-w}{2} \sqrt{x^2-w^2} + x^2 \left( \arcsin \sqrt{\frac{x-w}{2x}} - \sqrt{\frac{x-w}{2x}} \cos \arcsin \sqrt{\frac{x-w}{2x}} \right) \quad (47.23)$$

where  $L$  is the length of objects.

The estimation of the critical area associated with lithographic defects requires averaging with respect to the defect size distribution as follows [3]:

$$A = \int_0^{\infty} A(x)h(x) dx \quad (47.24)$$

where  $A(x)$  ( $A_s(x)$  or  $A_o(x)$ ) is the critical area associated with defects of a given size, and  $h(x)$  is the defect size distribution. A Gamma distribution function (Fig. 47.7) is used to describe the defect size

**FIGURE 47.7** Empirical defect size distribution (histogram) and defect size distribution approximated by Gamma distribution function (dashed line).

distribution [34,35]:

$$h(x) = \frac{x^{\alpha-1} \exp(-x/\beta)}{\Gamma(\alpha)\beta^\alpha} \quad (47.25)$$

Parameters  $\alpha$  and  $\beta$  are the fitting parameters that can be determined from the measured data from the following expressions:

$$M(X) = \alpha\beta = \sum_{j=1}^k x_j f_j \quad (47.26)$$

$$D(x) = \alpha\beta^2 = \sum_{j=1}^k x_j^2 f_j - \left( \sum_{j=1}^k x_j f_j \right)^2 \quad (47.27)$$

where  $M(x)$  and  $D(x)$  are the mean and variance of the measured defect size distribution,  $x_j$  is the middle of  $j$ th interval, and  $f_j$  is the normalized number of defects with the size fallen into  $j$ th interval.

## 47.3 Critical Area Extraction

To facilitate failure simulations and IC yield predictions, the layout information such as minimum spacing and widths, and the critical areas for conducting layers must be extracted. An extractor to obtain the above layout information automatically is needed. Typical layout extraction approaches [36,37] extract the desired information for the entire circuit at once in a global way; however, due to the methodology requirements of the local failure simulators [38–56] as well as a visual inspection of the critical areas [45,47,55], it is convenient to have an extractor where performance is optimized for local layout extraction. To achieve this goal, the described critical area models and internal data structures are used for storing the geometrical objects (rectangles) of a circuit layout and these critical areas.

In this section, a local critical area extraction approach is described. Moreover, an extraction algorithm and implementation details for both the front-end and back-end of the extraction system are presented.

### Local Extraction Approach

The canonical coordinates of the critical area for point defects, i.e., overlap area of layout patterns from two IC conducting layers  $A_l$  (Fig. 47.5) have already been defined. These coordinates can be simply extracted from the canonical coordinates of overlapping layout patterns (rectangles) as follow:

$$x_1 = \max(X_{1_1}, X_{1_2}) \quad (47.28)$$

$$x_2 = \min(X_{2_1}, X_{2_2}) \quad (47.29)$$

$$y_1 = \max(Y_{1_1}, Y_{1_2}) \quad (47.30)$$

$$y_2 = \min(Y_{2_1}, Y_{2_2}) \quad (47.31)$$

Canonical coordinates  $(x_1, y_1)$  and  $(x_2, y_2)$  are defined for a geometrical representation of the equivalent critical areas for lithographic defects by considering examples shown in Fig. 47.8. Consequently, canonical coordinates of the equivalent critical area for shortening two geometrical objects, in the case

FIGURE 47.8 Definition of canonical coordinates of the equivalent critical area for shorts (a) and opens (b).

of  $s = \max(Y_1, Y_2) - \min(Y_2, Y_2)$ , can be obtained by making use of the following expressions [33]:

$$x_1 = \max(X_1, X_{1_2}) - \frac{2A_s^0(x)}{x - s} \quad (47.32)$$

$$x_2 = \min(X_2, X_{2_2}) + \frac{2A_s^0(x)}{x - s} \quad (47.33)$$

$$y_1 = \min(Y_2, Y_{2_2}) - (x/2 - s) \quad (47.34)$$

$$y_2 = \max(Y_1, Y_{1_2}) + (x/2 - s) \quad (47.35)$$

but, in the case of  $s = \max(X_1, X_{1_2}) - \min(X_2, X_{2_2})$ , by making use of the expressions [33]:

$$x_1 = \min(X_2, X_{2_2}) - (x/2 - s) \quad (47.36)$$

$$x_2 = \max(X_1, X_{1_2}) + (x/2 - s) \quad (47.37)$$

$$y_1 = \max(Y_1, Y_{1_2}) - \frac{2A_o^0(x)}{x - s} \quad (47.38)$$

$$y_2 = \min(Y_2, Y_{2_2}) + \frac{2A_o^0(x)}{x - s} \quad (47.39)$$

Canonical coordinates of the equivalent critical area for opening a geometrical object, in the case of  $w = Y_2 - Y_1$ , are given by the expressions [33]:

$$x_1 = X_1 - \frac{2A_o^0(x)}{x - w} \quad (47.40)$$

$$x_2 = X_2 + \frac{2A_o^0(x)}{x - w} \quad (47.41)$$

$$y_1 = Y_1 - (x/2 - w) \quad (47.42)$$

$$y_2 = Y_2 + (x/2 - w) \quad (47.43)$$

and, in the case of  $w = X_2 - X_1$ , by the expressions [33]:

$$x_1 = X_1 - (x/2 - w) \quad (47.44)$$

$$x_2 = X_2 + (x/2 - w) \quad (47.45)$$

$$y_1 = Y_1 - \frac{2A_o^0(x)}{x - w} \quad (47.46)$$

$$y_2 = Y_2 + \frac{2A_o^0(x)}{x - w} \quad (47.47)$$

The simplest way to extract the critical area for shortening and opening geometrical objects is the comparison of a geometrical object to all the other geometrical objects. This is computationally prohibitive in the case of modern ICs that can contain millions of transistors due to its  $O(n^2)$  performance, where  $n$  is the total number of objects. Therefore, algorithms that enable efficient processing of geometrical objects and minimization of the number of comparisons between object pairs must be used. These algorithms are more complex than  $O(n)$  and their complexity determines the CPU time and memory consumption.

Two main types of methods are used to scan objects in an IC layout: raster-scan based algorithm [57] and edge-based scan-line algorithm [58]. In raster-scan algorithms, the chip is examined in a raster-scan order (left to right, top to bottom) looking through an I-shaped window containing three raster elements. The main advantage is simplicity, but a lot of time is wasted scanning over grid squares where no information is to be gained. It further requires that all geometry be aligned with the grid. Edge-based scan-line algorithms divide the chip into a number of horizontal strips where the state within the strip does not change in the vertical direction. Change in state occurs only at the interface between two strips. At the interface, the algorithm steps through the list of objects touching the scan-line and makes the necessary updates to state. One of the main advantages of these algorithms over the raster-scan algorithms is that empty space and large device structures are extracted easily. Because scan-line algorithms are superior to raster-scan algorithms, a typical scan-line algorithm is used with a list for storing the incoming objects where the top edges coincide with the scan-line. Then every object in this list is sorted and inserted into another list called active list [32]. In the meantime, layout extractions are carried out by comparison of the object being inserted to other objects in the active list. An object then exits the active list when the scan-line is at or below its bottom edge.

## Data Structures

The choice of a data structure for efficient geometrical object representation plays an important role. The local extraction methodology is chosen, so a good candidate for the data structure requires a fast region query operation and reasonable memory consumption. Many data structures are suggested for the local extraction purposes. Among them, singly linked list, bin, k-d tree, and quad tree have been used most often [59–61]. A singly linked list is the most memory efficient but has the slowest region query performance. Conversely, a bin structure has the fast region query but consumes the most memory space. Both k-d tree and quad tree reside in the middle and have a trade-off between speed and memory space.

**FIGURE 47.9** Data structure for a geometrical object representation in the active list (a) and data structure for critical area representation (b).

The layout information can be obtained by manipulating any efficient local extraction algorithm on the geometrical objects stored in internal data structure.

Two kinds of data structures are needed for the critical area extraction. The first one is used for efficient object representation in the active list. To minimize the number of comparisons between object pairs, a suitable structure should be developed so that extraction can be performed as locally as possible. A singly linked list is chosen for the active list not only for its simplicity, but also for its speed and memory efficiency [32,62]. The chosen singly linked list and corresponding data structure are described in Fig. 47.9(a). It contains fields  $X_1$ ,  $X_2$ ,  $Y_1$ , and  $Y_2$ , which represent the coordinates of the left, right, bottom, and top edges of a rectangle, respectively, and three additional fields called *layer*, *rect*, and *mk* used to indicate the layer number, the rectangle number, and the rectangles of the same pattern. The comparisons between active rectangles stored in the active list can be carried out as locally as possible by examining the sorted coordinates of rectangles. The second data structure is used for a list of coordinates of the critical areas (Fig. 47.9(b)). It contains fields  $x_1$ ,  $x_2$ ,  $y_1$ , and  $y_2$ , which represent the coordinates of the left, right, bottom, and top edges of the critical area, respectively, and a field  $A_p, A_s, \text{ or } A_o$ , which represents the value of critical area itself. This data structure also includes four additional fields called *layer 1*, *layer 2*, *rect 1* and *rect 2* used to indicate the layer and rectangle numbers.

## Extraction Algorithm

The main tasks of described approach are to find out all pairs of overlapping rectangles from two IC mask layers, to determine canonical coordinates of their overlap areas  $(x_1, y_1)$  and  $(x_2, y_2)$ , and to compute the critical areas by making use of Eqs. (47.18) and (47.19) or, in the case of extraction of the critical areas for lithographic defects, to find out all objects narrower than the largest defect with the diameter  $x_{\max}$ , all pairs of objects with a spacing between them shorter than the largest defect diameter  $x_{\max}$ , to determine canonical coordinates of the critical areas  $(x_1, y_1)$  and  $(x_2, y_2)$  for the largest defect diameter  $x_{\max}$ , and to compute the critical areas by making use of the expression (47.24). Therefore, an algorithm has been developed for local critical area extraction based upon the scan-line method for scanning the sorted geometrical objects and the singly linked list for representation of the active list of geometrical objects. The main steps of the algorithm are as follows [32,62].

## Algorithm

- *Input*: a singly linked list of rectilinearly oriented rectangles sorted according to the top edges from top to bottom from two different IC mask layers (i.e., from the same IC mask layer in the case of extraction of the critical areas for lithographic defects).
  - *Output*: overlap areas between rectangles from two different IC mask layers (i.e., the critical areas for opens and shorts between rectangles from the same IC mask layer).
1. Set the scan-line to the top of the first rectangle from input list.
  2. WHILE (the scan-line  $\geq$  the top of the last rectangle from input list)
    1. Update an active list called SOR;
    2. Fetch rectangles from input list whose the top coincides with the scan-line and store them in a singly linked list called TR;
    3. Update the scan-line;
    4. FOR each new rectangle in TR
      1. *Seek/Left* sorts the new rectangle and inserts it into SOR, computes  $A_l$  and  $A_v$  (i.e.,  $A_s^o, A_s, A_o^o$  and  $A_o$ ) for the new rectangle and rectangles from SOR left to it, and computes and stores the coordinates of overlap areas in a singly linked list (i.e., the coordinates of critical areas for short and open circuits in two singly linked lists);
      2. *Seek/Right* computes  $A_l$  and  $A_v$  (i.e.,  $A_s^o, A_s, A_o^o$  and  $A_o$ ) for the last inserted rectangle into SOR and rectangles from SOR right to it, and computes and stores the coordinates of overlap areas in a singly linked list (i.e., the coordinates of critical areas for short and open circuits in two singly linked lists);
  3. Write the critical areas into output files.

The scanning process starts with setting the scan-line to the top edge of the first rectangle from input list. The second step is a loop for updating the active list and moving the scan-line. To update rectangles in SOR, substep 2.1 of the above algorithm performs comparison between the current scan-line and the bottom edges of rectangles in SOR. If the bottom edge of a rectangle is above the current scan-line for a threshold value (in the case of critical areas for lithographic defects, the largest defect diameter  $x_{\max}$ ) or more, a rectangle will be deleted from SOR. This guarantees that the critical areas for short circuit between any two rectangles in the  $y$ -direction can be detected. Substep 2.2 makes a singly linked list TR contained rectangles with the same  $y$ -coordinates of the top edges. This step enables to sort rectangles according to the  $x$ -coordinate of the left edge. The  $y$ -coordinate of the next scan-line (substep 2.3) is equal to the top edge of the next rectangle in input list. Substep 2.4 sorts and inserts each new rectangle from TR into the SOR active list, and computes and stores the critical areas in output lists. The last step of the algorithm writes the content of output lists, i.e., coordinates of the critical areas  $(x_1, y_1)$  and  $(x_2, y_2)$ , as well as values of the critical areas  $A_p, A_s$  or  $A_o$  in output files.

Procedure *Seek/Left* takes the new rectangle from TR and the SOR active list as inputs and reports the critical areas as output. Rectangles are sorted by the comparison of their left edge coordinates  $X1$ s. The sorted rectangles are stored in the active list SOR. Procedure *Seek/Right* takes the last inserted rectangle into SOR and SOR itself as input and reports the critical areas as output. In a loop of this procedure, the place of the last inserted rectangle in SOR is checked first by the comparison of its right edge coordinate  $X2$  with the left edge coordinate  $X1$  of the current SOR rectangle. It enables to end this loop earlier.

Note that geometrical objects (rectangles) from two IC mask layers have to be stored in the active list during extraction of the overlap areas. In the contrary, geometrical objects from only one IC mask layer have to be stored in this list during extraction of the critical areas for lithographic defects. A simple example illustrating the proposed algorithm is described in Fig. 47.10. The figure presents rectangles in the active list with scan-lines shown in sequence. When the scan-line reaches the position S1, the newest rectangle in SOR is the rectangle 6. In the meantime, the critical area for opening this rectangle and the critical areas for shortening it with the rectangles 3 and 4 are computed. As the scan-line moves down,

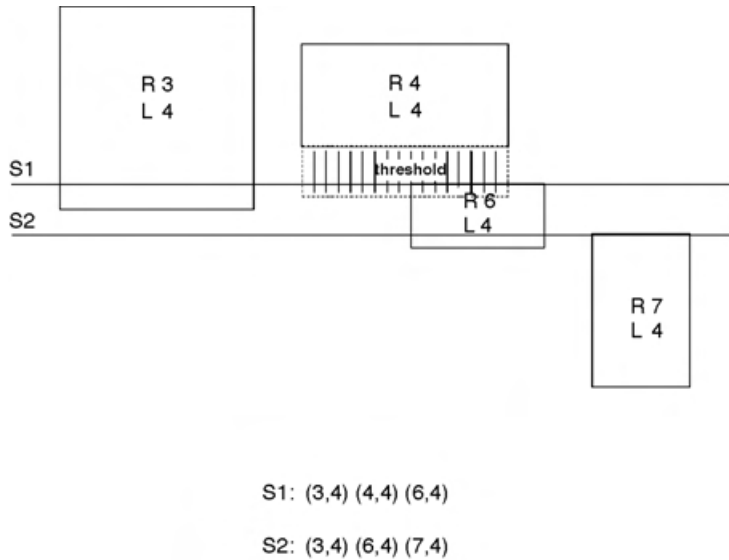

FIGURE 47.10 Scan-lines with rectangles in the active list.

FIGURE 47.11 Software system for extraction of IC critical areas.

its next stopping position is S2. Now the newest rectangle in the active list is the rectangle 7. In the same time, the rectangle 4 exits the active list because the spacing between its bottom edge and the current scan-line is greater than a threshold value ( $x_{max}$ ). By making use of the described algorithm, the critical areas related to point and lithographic defects for any IC can be extracted.

## Implementation and Performance

The layout extraction starts from the layout description in CIF format and ends by reporting the critical areas for point or lithographic defects. In our case, this procedure is done through software system, which consists of three tools. The previous algorithm is only dedicated to the back-end of the entire system and is implemented in a program called EXACCA (EXtrActor of Chip Critical Area). The structure of this system is shown in Fig. 47.11.

### Transformer of CIF (TRACIF)

The front-end of system is a technology-independent processor for transforming IC layout description from the unrestricted to a restricted format TRACIF [63]. The unrestricted format can contain overlapping rectangles, as well as rectangles making bigger rectangles from the same IC mask layer; however, an internal restricted geometric representation should contain a set of nonoverlapping rectangles that about only along horizontal edges. Two important properties are part of the restricted format:

- Coverage—Each point in the  $x$ - $y$  plane is contained in exactly one rectangle. In general, a plane may contain many different types of rectangles.
- Strip—Patterns of the same IC mask layer are represented with horizontal rectangles (strips) that are as wide as possible, then as tall as possible. The strip structure provides a canonical form for the database and prevents it from fracturing into a large number of small rectangles.

**TABLE 47.1** Processing Time and Number of Objects Before and After Transformation of CIF File by TRACIF

TRACIF takes a CIF file as input and generates files containing geometrical objects (rectangles) defined by the canonical coordinates of each IC cell and mask layer as outputs. Thus, the outputs of TRACIF are lists of sorted rectangles according to the top edges from top to bottom. TRACIF can handle Manhattan shaped objects and consists of about 800 lines of C code. Therefore, TRACIF is capable to perform the layout description transformation hierarchically. Namely, TRACIF transforms a CIF file to the restricted format in a hierarchical way and makes different files for different cells and layers. This feature is desirable because most of the modern IC designs exploit the technique of design hierarchy. Within this design methodology, the layout extraction is only required once for each layout cell. Here, the results of transforming CIF file of IC *chip* that was designed using double metal CMOS process will be presented. The total number of rectangles before and after processing, as well as the CPU time needed for transforming this CIF file by TRACIF on Silicon Graphics Indy workstation are shown in [Table 47.1](#).

### **EXtrActor of Chip Critical Area (EXACCA)**

EXACCA takes the sorted rectangles and starts the critical area extraction by using the proposed algorithm. EXACCA can handle Manhattan-type objects and consists of about 2000 lines of C code. The outputs of EXACCA are lists of the critical areas for point or lithographic defects. Software tool GRAPH performs the visual presentation of the critical areas. Pictorial examples of the layouts and snapshots of the corresponding critical areas are shown in [Figs. 47.12.](#) and [47.13.](#) Precision of a visual presentation

FIGURE 47.12 Layout of two metal layers of operational amplifier and corresponding critical (overlap) areas.

FIGURE 47.13 Layout of metal 1 of input pad and corresponding critical areas for shorts (a) and opens (b).

of the critical areas is limited by the error made in approximation of the circular parts by rectangular subareas.

To analyze the performance of the algorithm, an idealized model is used. If there are  $n$  uniformly distributed rectangles in a region of interest, there will be around  $\sqrt{n}$  rectangles, on an average, in each scan-line. Based upon this model, the time complexity of the algorithm is analyzed. Step 1 in the algorithm

**TABLE 47.2** Critical Area Extraction Time (in seconds) on Silicon Graphics Indy Workstation for Five Values of  $x_{\max}$

Integrated Circuit	Number of Rectangles	10 $\mu\text{m}$	12 $\mu\text{m}$	14 $\mu\text{m}$	16 $\mu\text{m}$	18 $\mu\text{m}$
chip	4125	65.1	83.7	89.4	97.8	112.0
counter4	11637	342.4	379.5	406.7	459.9	503.1

counter8	24677	897.6	954.2	1083.6	1217.8	1399.8
counter10	30198	1116.0	1338.1	1542.2	1689.5	1880.3

is trivial and takes a constant time. Step 2 is a loop with, on an average,  $\sqrt{n}$  elements under which are four substeps are required. Substeps 2.1 and 2.2 take  $O(\sqrt{n})$  expected time due to the  $\sqrt{n}$  length of elements in SOR and TR. Substep 2.3 takes a constant time. Substep 4 has  $\sqrt{n}$  elements in a loop, under which sub-substeps 2.4.1 and 2.4.2 take  $O(\sqrt{n})$ . Hence, substep 4 takes  $O(n)$  time. As a result, step 2 takes  $O(n\sqrt{n})$  time. Note that the critical areas  $A_s$  and  $A_o$  are calculated using Simpson's method for numerical integration with the  $x$ -resolution 0.1  $\mu\text{m}$ . Finally, step 3 takes a constant time. From the previous idealized analysis, the complexity of this algorithm is  $CO(n\sqrt{n})$ , where  $C$  is a constant. The approaches used in [41,42,44] promise  $O(n \log n)$  performance, even though authors note that the actual consumption of CPU time is a very intensive.

Because today's VLSI circuits can contain up to 10 million transistors, the limitation of memory resources places an important role on extraction efficiency. To avoid running out of memory, special-coding techniques have to be employed. These techniques decrease the extraction efficiency, particularly for very big circuits. In general, this memory limitation problem affects the algorithms regardless of which data structure is used for the node representation of the active list. However, a singly linked list suffers the least due to its memory efficiency. Thus, a list structure is preferred as far as memory space is concerned. The memory consumption of EXACCA is proportional to  $\sqrt{n}$ .

Here, the simulated results of five examples, which were designed using double metal CMOS process, will be presented. The number of rectangles, as well as the CPU time of EXACCA on Silicon Graphics Indy workstation for these five IC layouts called *chip*, *counter4*, *counter6*, *counter8*, and *counter10* are shown in Table 47.2. The extraction speed is illustrated by the analysis of CPU times needed for the computation of critical areas for short and open circuits for five values of the largest defect diameter  $x_{\max}$ . The extraction results show that a CPU time increases as the diameter of largest defect increases. Namely, the increase of the largest defect diameter means a greater threshold for updating the active list and, consequently, a greater number of rectangles in the active list. The increase of the number of comparisons between rectangle pairs causes a corresponding increase of the critical area extraction time. As can be seen from Table 47.2, one of the most important advantages of the proposed extraction algorithm and corresponding data structures is the ability to process large layouts in a relatively short CPU time.

## Applications

EXACCA ensures the microscopic layout information needed for more detailed analysis. Thus, the output of EXACCA may be used for any IC yield simulation system and design rule checking system. Also, our software system is useful for the classical yield models that require knowing the critical area of an IC chip. Caution should be taken in this case as the total critical area of a chip must be computed by finding the union of (not by adding) the critical areas. Regardless of the fact that this section has focused only on the extraction of critical areas, EXACCA can also be easily modified for the extraction of parasitic effects. Although the critical areas are required for the simulation of functional failures, the extraction of parasitic effects can be used for the simulation of performance failures.

This software system is capable to perform the critical area extraction hierarchically. Namely, TRACIF is capable to transform a CIF file to sorted lists in a hierarchical way. This feature is desirable since most of the modern IC designs exploit the technique of design hierarchy. Within this design methodology, the critical area extraction is only required once for each layout cell. Therefore, CPU time can be reduced

significantly for extracting the critical areas of an IC with many duplicates of single cells. Following the design hierarchy, it can be used to predict and characterize yields of future products in order to decide about improvements in the corresponding layout cells that enable the desired yield.

## 47.4 Yield Forecast

By making use of the yield distribution model (see subsection “Yield Distribution Model”) and the software system TRACIF/EXACCA/GRAPH (see subsection “Implementation and Performance”), yields associated with each defect type can be calculated and a sophisticated selection of IC types can be undertaken.

### Yield Calculations

An example of the characterization of IC production process is given in Table 47.3 (for point defects) and Table 47.4 (for lithographic defects). The critical processes listed in these tables were assumed to be responsible for the yield loss in double metal CMOS production process and were accompanied by in-line yield measurements made on the corresponding test structures, and the consequent yield analysis. The critical areas of test structures are in mm<sup>2</sup>.

TRACIF/EXACCA/GRAPH system ensures, for the yield model, the critical area of IC (for given defect type) as a union of all local critical areas. Here, the simulated results for the IC *chip*, which was designed using double metal CMOS process, will be presented. The critical areas for five cells of this IC called *inpad*, *ota*, *buffer*, *selector*, and *exor* are shown in Tables 47.5 and 47.6. The numbers in parentheses denote how many times the corresponding cell appears in the circuit layout. As can be seen from Table 47.5, the critical areas for point defects (in mm<sup>2</sup>) are defined as overlap areas of the corresponding mask layers. The first three are for defects of silicon crystal lattice in the depletion region of p-n junction and the second three are for pinholes in thin and CVD oxides.

Also, the critical areas for lithographic defects in [Table 47.6](#) (in  $\mu\text{m}^2$ ) can be divided into two groups. The first one consists of the critical areas for shorts and the second one contains the critical areas for opens.

The wafer yield predictions are shown in [Table 47.7](#) (for point defects) and [Table 47.8](#) (for lithographic defects). The total number of chips in a wafer was  $N = 870$  and  $C_{il} = C_l = 1/2$ . The critical areas are calculated as a sum of the corresponding critical areas of all cells. Calculations needed for getting the mean and variance of the wafer yield related to each critical process step, as well as the mean and variance of the final wafer yield are carried out by means of Eqs. (47.8)–(47.15). The values of these parameters can now be used to decide about a possible corrective action.

## IC Type Selection

A usual approach to the IC production control needs estimating the defect density and does not give the opportunity for selection of IC types; however, the authors' approach uses both yield parameters, the mean and variance of the wafer yield distribution function, and enables sophisticated selection of IC types.

\*after investment in p<sup>+</sup>-diffusion process

**FIGURE 47.14** Example of IC type selection.

An example of the selection of CMOS IC types is given in Table 14.9 and Fig. 47.14. Six critical processes were assumed to be responsible for the yield loss, and were accompanied by in-line yield measurements and the consequent yield analysis. It can be seen from Table 14.9 that in this particular example, the yield associated with p<sup>+</sup>-diffusion was much smaller than the yields of the other process steps and, therefore, was the main cause of the wafer yield loss. It is obvious that in this example an investment in the process of p<sup>+</sup>-diffusion would be extremely beneficial. An investment made to improve the process of p<sup>+</sup>-diffusion

(enhancement of the process cleanliness, etc.) resulted in the final wafer yield increase of over 10%. Such a yield improvement could not be achieved by any investment in any other critical process step.

The usual approach to the IC production control is based on the defect or fault density measurements, and does not take into account the dependence on the complexity of a given IC type. Therefore, the lot of wafers may be stopped regardless of the IC type. Namely, a given defect density level can enable a decent yield (and price) of simpler IC chips, but it may not be sufficient to achieve the desired yield and price of more complex IC chips. The approach considered in this paper does not suffer of described disadvantage. Moreover, it can be used to forecast and characterize yields of future products in order to decide about investments that enable the desired final IC production yield.

In the considered example of production of IC *Chip1*, it is estimated that the mean and variance of the wafer yield associated with  $p^+$ -diffusion should be higher than 0.92 and lower than  $3.5 \times 10^{-5}$ , respectively, in order to ensure the acceptable value of the final wafer yield. It can be seen from Fig. 47.14 that the currently established  $p^+$ -diffusion process fulfills the imposed requirements; however, in the case of production of IC *Chip2*, the same defect density associated with the  $p^+$ -diffusion process has resulted in the mean of the wafer yield 0.792 and its variance  $2.23 \times 10^{-4}$ , both of them being out of estimated limits presented in Fig. 47.14. Therefore, in order to achieve the competitive price with a possible production of more complex IC *Chip2*, a further investment in  $p^+$ -diffusion process should be made.

## 47.5 Summary

---

Basic IC yield models (Murphy's approach) and yield parameters (test structure yield, chip yield, and wafer yield) are presented. Both defect density and defect size distributions are described. Using corresponding in-line measurements of the test structure yields, the chip yield, associated with the  $i$ th critical process step, is directly calculated; however, the chip yield is not sufficient for complete yield characterization, and the wafer yield, defined as a ratio between the number of failure-free chips and the total number of chips on a wafer, is predicted as well. We define the wafer yield as a distribution with two statistical parameters: the mean and variance.

A local layout extraction approach for hierarchical extraction of the IC critical areas for point and lithographic defects is described. The authors propose new expressions for definition of the circular parts of critical areas for shorts and opens between IC patterns. Also, the Gamma distribution is proposed as an approximation of the measured lithographic defect size distribution for estimating of the average critical area. It is shown that the Gamma distribution provides good agreement with the measured data, thus leading to a precise estimation of the critical area. Canonical coordinates  $(x_1, y_1)$  and  $(x_2, y_2)$  have been defined for a geometrical representation of the equivalent critical areas for shortening two geometrical objects and opening a geometrical object. Two kinds of data structures are used for the critical area extraction. The first one is used for efficient object representation in the active list. A singly linked list is chosen for the active list not only for its simplicity, but also for its speed and memory efficiency. The second data structure is used for a list of coordinates of the critical areas. The extraction of critical areas is carried out by an algorithm that solves this problem time proportional to  $n\sqrt{n}$ , on average, where  $n$  is the total number of the analyzed geometrical objects (rectangles). This algorithm is a typical scan-line algorithm with singly linked lists for storing and sorting the incoming objects. The performance of the authors' algorithm is illustrated on five layout examples by the analysis of CPU time consumed for computing the critical areas applying a software tool system TRACIF/EXACCA/GRAPH.

The chip and wafer yields associated with each critical process step (i.e., each defect type) are determined by making use of the above-described approach. The final wafer yield predictions are made as well. An example of such a characterization of IC production process is described. It is shown that the proposed approach can be used for modeling yield loss mechanisms and forecasting effects of investments that are required in order to ensure a competitive yield of ICs. Our approach uses both wafer yield parameters, the mean and variance, and enables sophisticated selection of IC types.
